Normal Heart

Gerald J. Berry

Margaret E. Billingham

Introduction

With the introduction of the cardiopulmonary bypass technique into clinical practice a half-century ago, pathologists found themselves dealing more frequently with cardiac specimens in the surgical pathology laboratory. For many years this consisted of explanted valves, pericardiectomy specimens, ventricular aneurysectomy excisions, and interventricular myomectomy specimens. It was not until cardiac transplantation began in 1968 that the surgical pathologist began handling entire heart specimens. Currently, more than 73,000 heart and combined heart-lung transplant procedures have been recorded in the registry of the International Society of Heart and Lung Transplantation (1). Thoracic transplantation in the pediatric age group ranging from neonates to adolescents is now commonly performed (2). The explanted hearts from infants and children often have complicated congenital heart lesions that have undergone one or more corrective surgical interventions. Surgical pathologists need to have some expertise in the

morphologic evaluation of end-stage heart disease of all types. Since

the early 1970s, endomyocardial biopsies for the assessment of allograft rejection, infiltrative lesions, and inflammatory disorders are performed routinely. Today many institutions have initiated ventricular assist device (VAD) programs, and ventricular apical specimens are routinely submitted. Like other biopsy specimens, these fall under the auspices of the surgical pathologist. Further, the introduction of complex electrophysiologic mapping techniques and imaging modalities such as transesophageal echocardiography, intravascular ultrasound, cardiac gated spiral-computed tomography (CT) angiography, and magnetic resonance imaging (MRI) have renewed interest in structural-functional correlations. Pathologists have assumed a central role in the clinical evaluation and application of these technologies.

The purpose of this chapter is to review normal cardiac anatomy and histology. The histology of the great vessels is described elsewhere in this book. For the most part, adult histology is described; but, where important differences exist, the histology in infants and children is also addressed. Furthermore, the purpose is not to be encyclopedic. Rather, we will highlight those areas that are of practical importance to the surgical pathologist to enable the distinction between normal and subtle cardiac pathology. As each of the major anatomic divisions of the heart is described, relevant aspects of aging, gender changes, and/or applied anatomy are mentioned. We have also included recommendations for handling endomyocardial biopsy specimens and common artifactual alterations in this discussion.

Heart Weights

The weight of the normal adult heart is generally achieved by the end of the second decade of life. Heart weight in infants and children is related to age and body size, and tables are readily available in published works (3,4). A variety of approaches to estimating the weight of the adult heart have been used in clinical practice. These

differ in complexity and accuracy; for example, the practical guidelines for unfixed adult heart weights published by Hudson in 1965 (5) indicate the male heart weighs 0.45% of the body weight (325 Â± 75 g; average 300 g) and the female heart weighs 0.40% of the body weight (275 Â± 75g; average 250 g). Heart weight varies with age, sex, and body height and weight. Using this type of approach, the heart weight in young athletic adults may approach or exceed the upper limits of normal by up to 25%, whereas in the elderly it may approach or be slightly below the lower limits of normal.

Kitzman and colleagues from the Mayo Clinic (6) proposed a more comprehensive approach that predicts the normal heart weight of a formalin-fixed specimen based on body weight. In their study, body height as a predictor proved less accurate than body weight. The impact of formalin fixation on the weight of the heart has been addressed with conflicting findings. In one study, the overall finding was that heart weight increased by 5% after fixation, although considerable individual variationâ€”ranging from weight loss to weight gainâ€”was reported (7). Descriptive tables of normal ventricular wall thickness, chamber size, and valvular orifice measurements are available in textbooks and postmortem dissection manuals (4,8,9,10).

Prenatal Fetal Circulation

It is beyond the scope of this chapter to discuss cardiac embryology. Developmental molecular biology has provided many new insights in cardiogenesis, some of which have radically altered previously held tenets (11,12,13,14). Currently it is thought that the human heart begins to beat around day 17. Well-oxygenated blood leaves the placenta via the umbilical vein, a portion of which passes through the hepatic sinusoids, and the remainder bypasses the liver by way of the ductus venosus to enter the inferior vena cava (IVC). Caval blood enters the right atrium together with an admixture of deoxygenated

blood from the lower body. Approximately one-third of this blood is diverted through the interatrial septum (ostium secundum) into the left atrium, where it mixes with the small amount of deoxygenated blood returning from the lungs. The blood then passes into the left ventricle and exits into the ascending aorta to supply the coronary arteries, brain, and upper limbs. Approximately 50% of the blood is returned to the placenta for reoxygenation via the umbilical arteries. The remainder of the blood supplies the lower half of the body. Blood returning to the heart from the upper body reaches the right atrium through the superior vena cava (SCV). It mixes with the residual two-thirds of the blood from the IVC and enters the right ventricle. A small portion is distributed to the lungs, but the majority is diverted across the ductus arteriosus to the descending aorta. Blood is returned to the placenta with only a small amount reaching the lower body of the fetus.

Postnatal Circulation

At birth, a series of anatomic and physiologic changes occur, beginning with the infant's first respiratory efforts. The circulation of fetal blood through the placenta ceases, and the infant's lungs expand. As alveoli become aerated, the pulmonary vascular bed dilates, causing increases in pulmonary blood flow and abrupt decline in pulmonary vascular resistance. Additionally, active remodeling of the pulmonary vasculature begins and continues over a period

of a few weeks. This consists primarily in the reduction of the muscular medial layer of arterioles and small arteries. Increased blood return to the left atrium by way of the pulmonary veins results in slightly higher left atrial pressures compared to the right atrium. This causes the flap covering the foramen ovale to seal, leaving the indentation called the fossa ovale. By the end of the first month after birth, the significant differences in ventricular hemodynamic load result in thickening of the left ventricular wall and thinning of the right ventricular wall. The ductus arteriosus, located between the left

pulmonary artery and aortic arch, functionally closes within 15 hours after birth, and the umbilical veins begin to constrict.

Pericardium

The pericardium surrounds the heart and consists of a fibrous and a serous sac. The fibrous, or parietal, pericardium envelops the heart and is reflected off the ascending aorta, the pulmonary trunk, and the terminal 2 to 4 cm of the SVC, the distal segment of the IVC, and the pulmonary veins. In the normal state, the fibrous pericardium surrounding the heart remains unattached to the serous (visceral) pericardium except at the pericardial reflections. The parietal pericardium is composed of collagenous fibrous tissue (Figure 20.1). Its inelastic tendencies account for the development of cardiac tamponade when it is acutely stretched with more than 250 ml of fluid. It may contain variable amounts of adipose tissue, particularly toward the apex of the heart. A thin layer of mesothelial cells on its inner surface lines the parietal pericardium. It is normally less than 1 mm in thickness. Heterotopic tissues within this layer include thyroid and thymic elements. Neoplastic and hyperplastic alterations have been described, including intracardiac thyroid in the right ventricular outflow tract (15).

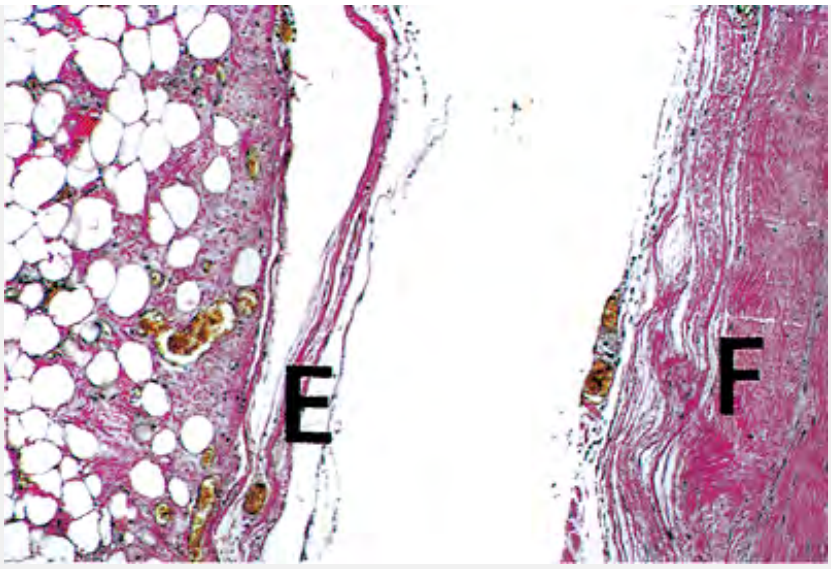

Figure 20.1 Section showing fibrous pericardium (*F*) separated from the thinner epicardium (*E*) (elastic van Giesen).

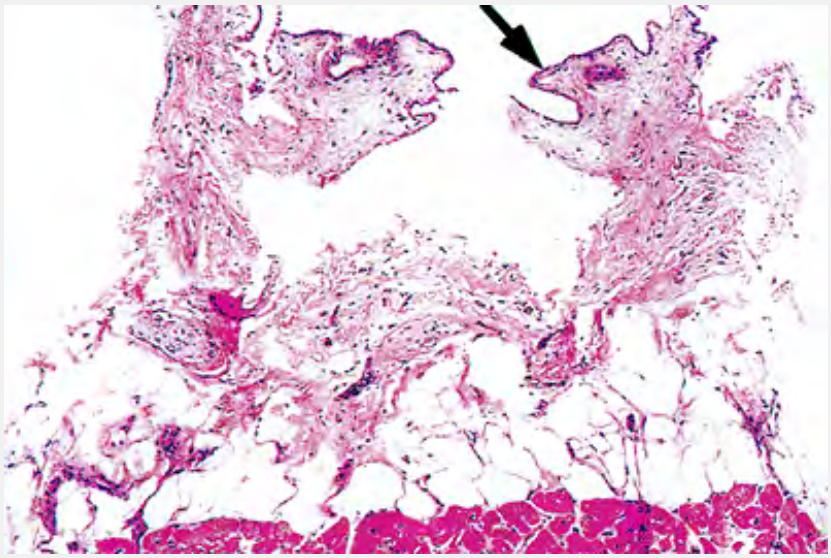

Figure 20.2 Section showing the epicardium lined by mesothelial cells (*arrow*) and covering the subepicardial adipose tissue and myocardium (H&E).

The serous, or visceral, pericardium is also called the epicardium of the heart. It is a single layer of mesothelium that envelops the heart and is in continuity with the fibrous pericardium at the pericardial reflections at the great vessels (Figure 20.2). This delicate membrane covering the heart contains variable amounts of adipose tissue within which are embedded the coronary arteries and veins, lymphatic vessels, nerves, fibroblasts, and macrophages (Figure 20.3). The normal epicardium often has small aggregates of lymphocytes that are present from birth.

Between the two mesothelial layers of the parietal and visceral pericardium is a potential space containing up to 50 mL of straw-colored fluid that allows the surfaces to glide over one another in the normal state. The histologic composition of the two layers of the pericardium does not alter with age and is similar in infants, children, and adults.

Figure 20.3 Section of the epicardium showing the relationship of coronary vessels (*arrows*) and nerves (*N*) to the epicardium (H&E).

Applied Anatomy

Surgical pathologists may receive pericardiectomy specimens in cases of constrictive pericarditis or recurrent tamponade. Nonspecific fibrosis and chronic inflammation are observed, but granulomatous infection and neoplastic infiltrates should be excluded. In explanted hearts, the pericardial surfaces are often thickened by previous disease states or surgical interventions, in which case the epicardium and parietal pericardium are adherent. Occasionally nodular collections of epicardial fat may be misinterpreted grossly as metastases. Congenital cysts of the pericardium are rare. Heterotopic thyroid and thymic tissue should be distinguished from cardiac involvement by contiguous spread or metastasis. In obese subjects, there may be excessive epicardial deposits of adipose tissue, and the measurement of ventricular thickness should be carefully evaluated. In conditions of cachexia, epicardial fat may undergo serous atrophy, resulting in small gelatinous tissue tags (10).

Cardiac Skeleton

The cardiac skeleton at the base of the heart is the central supporting structure to which most of the fibers of the myocardium are attached and to which the atrioventricular and aortic valves are anchored. A separate mass of fibrous tissue (the conus ligament) joins the pulmonary ring to the aortic ring. It also serves to separate the atrial and ventricular chambers. It is composed of the right and left fibrous trigones, membranous septum of the interventricular septum, and the fibrous annuli of the atrioventricular foramina (16). The fibrous skeleton is composed of layers of dense collagenous connective tissue admixed with small numbers of elastic fibers and, on occasion, small aggregates of adipose tissue. The fibrous tissue of the mitral and aortic valve rings is more substantial than the right-

sided valves, and the right and left trigone create the direct mitral-aortic continuity (17). The right trigone and membranous septum form the central fibrous body within which the atrioventricular bundle is embedded. Bone or cartilage is not normally found in the fibrous skeleton of human hearts, although they have been described in some animal species.

Applied Anatomy

Portions of the cardiac skeleton may be seen in explanted valves. The close proximity of the fibrous skeleton to the conduction system and valvular leaflets is an important consideration for surgeons. Alterations can significantly affect the functional outcomes of all these components.

Internal Structure of the Heart Wall

The wall of the heart in all chambers consists of three main layers: (a) the endocardium, (b) the intermediate muscular portion of the myocardium, and (c) the external portion, or epicardium. Most investigators believe that the endocardium is homologous with the tunica intima of blood vessels, the myocardium with the smooth muscle media, and the external epicardium with the adventitial layer. The endocardium consists of a single layer of endothelial cells (Figures 20.4,20.5) with a subendothelial portion containing a loose elastic framework and collagen bundles, as well as nerves and delicate blood vessels (Figure 20.6).

While the chambers of the heart are composed of these three layers, there can be variation in the thickness of one or more components. A rudimentary layer of smooth muscle is often found in the endocardium of both atria and the

ventricles (Figure 20.7). The endocardium of the atria is thicker than the ventricles. Small bundles of smooth muscle are often found but

are of questionable functional significance. The myocardium is composed of bundles of myocytes separated by fibrous bands (Figure 20.8). The individual myocytes form a syncytium with end-to-end junctions (called intercalated disks) and sometimes side-to-side junctions. Individual myocytes contain a central ovoid nucleus with a clear zone at the poles (Figure 20.9). The normal cardiac myocyte contains small amounts of lipofuscin granules (lysosomes), which increase in quantity with age. The myocytes are filled with contractile myofibrils (actin and myosin). In addition, atrial myocytes contain atrial dense-core bodies that are demonstrable by electron microscopy (Figure 20.10). The epicardial portion of the chambers was described earlier.

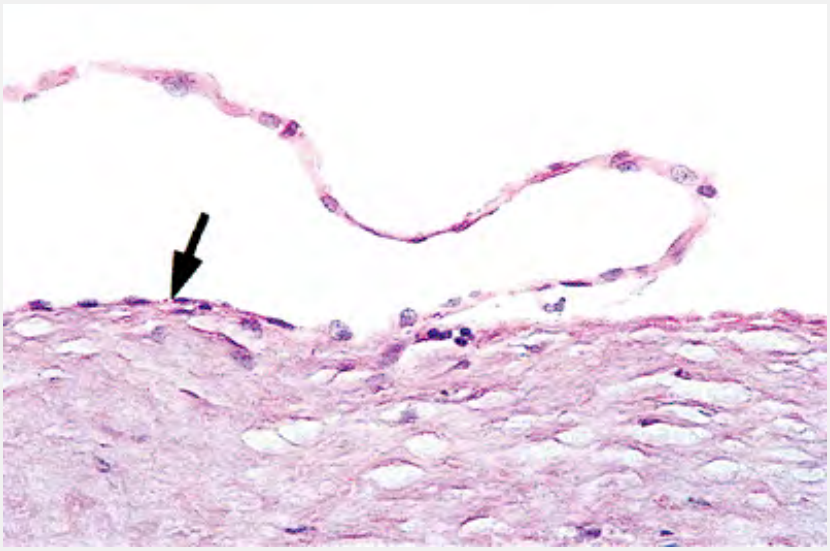

Figure 20.4 Section showing a single layer of endothelial cells covering the myocardium (*arrow*) (H&E).

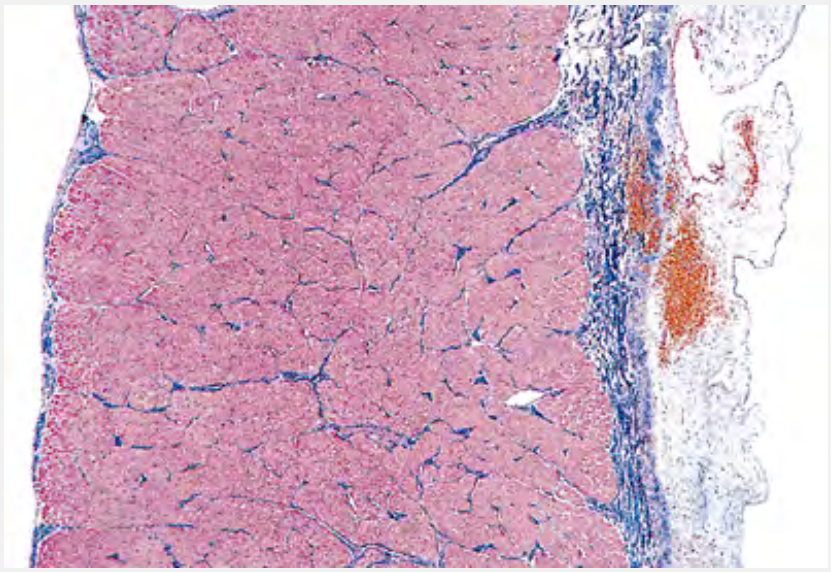

Figure 20.8 Section through the right ventricular wall showing the distribution of collagen from the endocardium (left) through the myocardium and to the epicardium (right) in the normal heart (Masson's trichrome).

Interatrial Septum

The interatrial septum separates the right and left atrial chambers. In the normal state this separation is complete, although the foramen ovale may retain a small communication at its floor where the septum has not fused (the so-called patent foramen ovale). This is reported in up to 30% of adults and is usually without clinical complications (18). The foramen ovale is closed by the septum to form the circular, dime-sized oval fossa. This represents the true interatrial septum, with the remainder of the anatomic structure being comprised of caval or pulmonary venous infoldings and the muscular and membranous components of the atrioventricular region (17). The membrane covering the oval fossa is a paper-thin, translucent layer early in life that becomes fibrotic and thickened with age, measuring up to

2 mm in thickness. The histology of the septum displays variable amounts of atrial muscle, fibrous tissue, mature adipose tissue, and, on occasion, brown fat (Figure 20.11). The thickness of the atrial septum varies considerably.

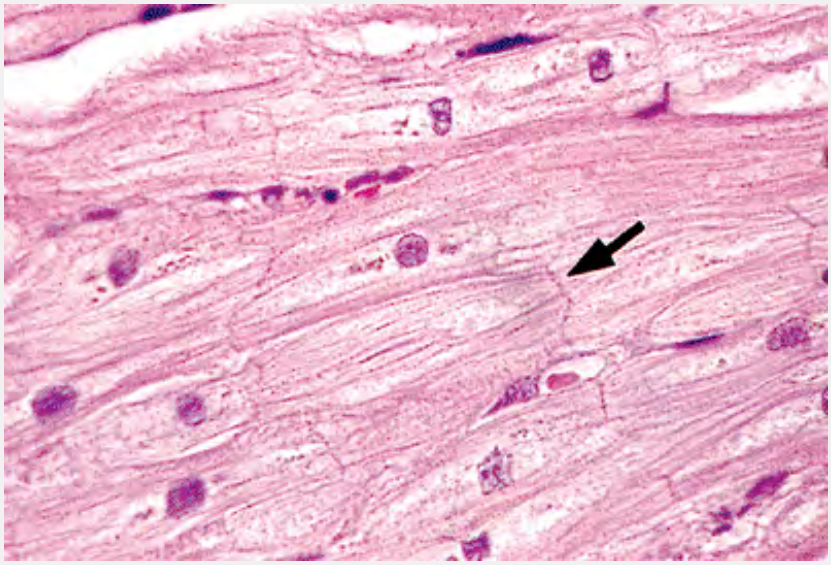

Figure 20.9 Section of myocardium showing ovoid nuclei and intercalated disks (*arrow*) (H&E).

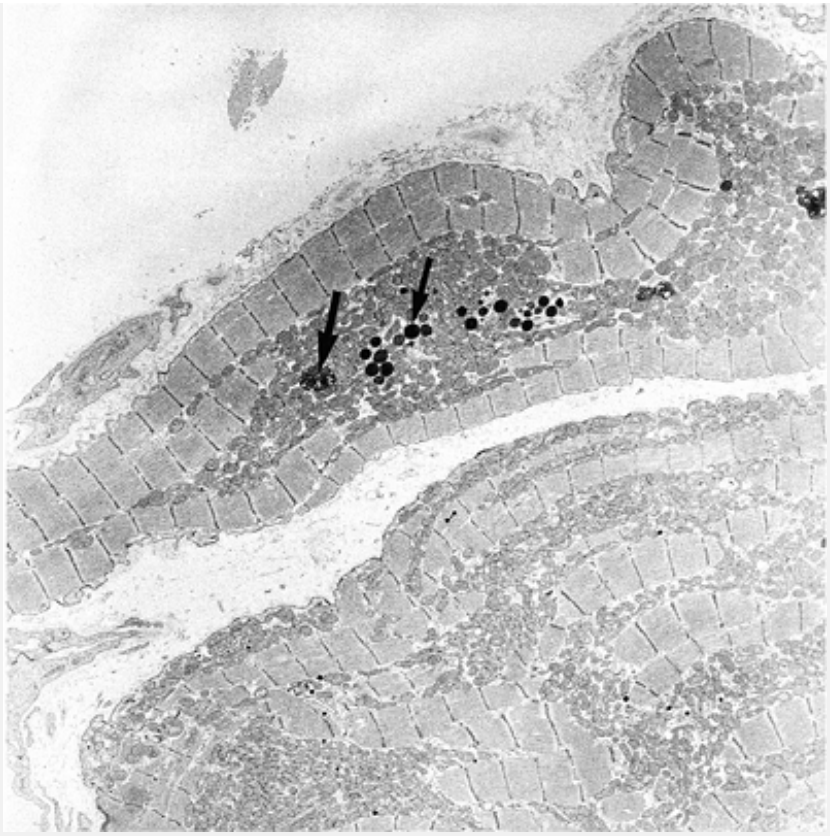

Figure 20.10 Electron micrograph of atrial dense-core granules (*small arrow*) that can be differentiated from the lipofuscin granules (*large arrow*).

Applied Anatomy

Lipomatous hypertrophy of the interatrial septum is characterized by accumulations of adipose tissue within the U-shaped lip, or limbus, of the oval fossa and may produce bulging of the interatrial septum. In some patients, the patent foramen ovale can be the site of interatrial shunting or paradoxical embolism.

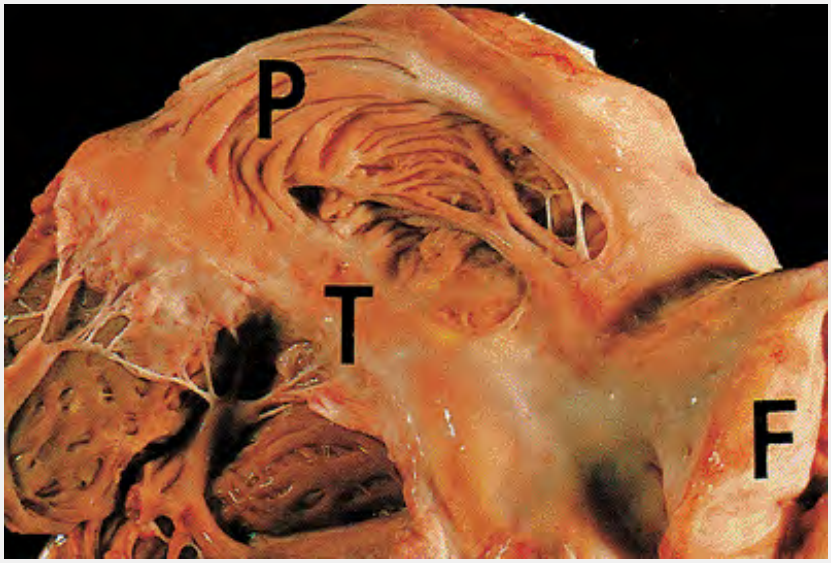

Figure 20.11 The right atrium showing the pectinate muscles (*P*), the crista terminalis (*T*), and the interatrial septal fat (*F*).

Right Atrium

Venous return to the heart occurs via the IVC and SCV into the right atrium. The right atrium forms the right lateral cardiac border and is located anterior to the left atrium and to the right of it. Anteromedially, the right atrial appendage protrudes from the right atrium and overlaps the aortic root (17). The atrium is composed of an auricular appendage, a smooth-walled venous sinus that contains the openings of the cavae and coronary sinus, a septal component, and a portion near the opening of the tricuspid valve (19). Extending between the right sides of the openings of both cavae is a prominent muscular ridge called the terminal crest, which underlies the sulcus terminalis. The wide-based triangular appendage defines the anatomic right atrium. The interior surface of this appendage is trabeculated by muscular bands called pectinate muscles. The portion of the right atrium lateral to the terminal crest is smooth-walled and

is derived embryologically from the sinus venosus (Figure 20.11). The right atrial wall measures 2 mm in thickness.

The orifice of the SVC is valveless. The opening of the IVC has an inconstant, rudimentary valve called the eustachean valve. It forms a crescentic fold over the orifice and directed blood toward the foramen ovale and into the left atrium during fetal life. The opening of the coronary sinus has a rudimentary flap of tissue called the thebesian valve; these valves vary greatly in size and may be fenestrated or absent. A Chiari's network, usually appearing as a lacelike veil of tissue, represents the remnant of the right sinus venosus valve and is occasionally found in normal hearts (Figure 20.12). The right atrial chamber is covered by endocardium. In the subendocardium, elastic fibers pass into a typical fenestrated elastic membrane that contains blood vessels, nerves, and branches of the conducting system. In the spaces between the muscle bundles of the atria, the wall is so thin that the connective tissue of the endocardium blends with the epicardium. The epicardial surface of the atrium is rich in nerves and ganglia (Figure 20.13).

Left Atrium

Like the right atrium, this chamber consists of an appendage, a venous component containing the ostia of the four pulmonary veins, a septal component, and a region near the mitral valve orifice. On average, the wall of the left atrium is 3 mm in thickness. The septal surface is smooth. The four pulmonary veins open into the left atrium in the posterior wall. The atrial appendage has a narrow, angulated tubular shape resembling a hockey stick and is lined by pectinate muscles. At its interface with the venous portion of the atrium, it lacks a terminal crest. The endocardial layer is thicker and more opaque than on the right side, due in part to the higher pressures of the pulmonary veins emptying into the atrium. Sometimes a patch of thickened rough

endocardium is seen on the posterior wall above the mitral valve as a result of mitral regurgitation. This is called MacCallum's patch but is not usually seen in the normal heart. The two left pulmonary veins enter on the posterolateral surface, and the right veins enter on the posteromedial side; there are no true valves at the venous-atrial junction. Small collections of atrial muscle can be found within the walls of the pulmonary veins at this junction and may act as physiologic valves. On occasion, this is the source of isolated or left-sided atrial fibrillation and is treated by ablation techniques.

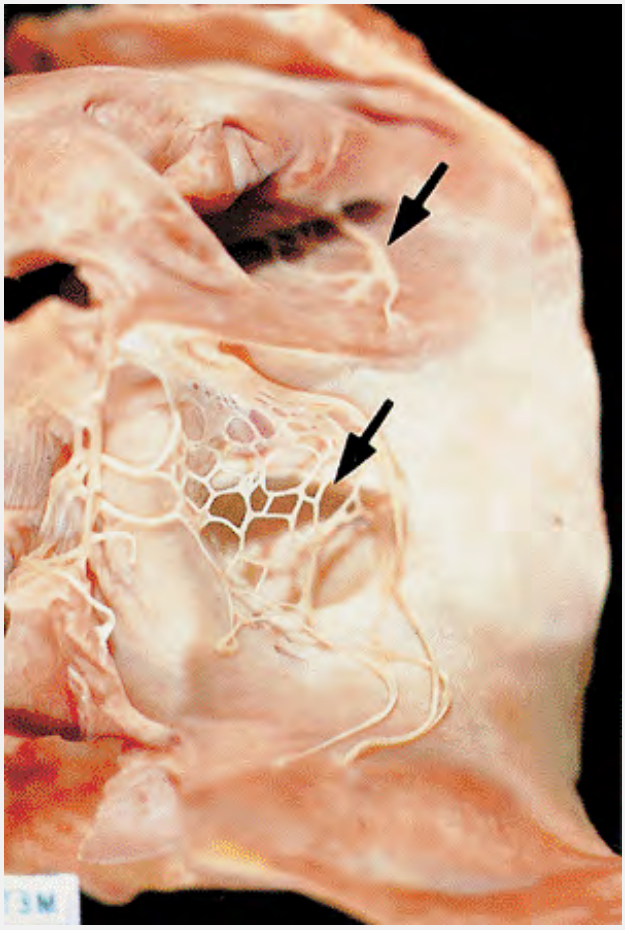

Figure 20.12 Picture of the Chiari's network (arrows), or lacelike pattern of the remnants of the thebesian valve, in the inferior vena cava opening into the right atrium.

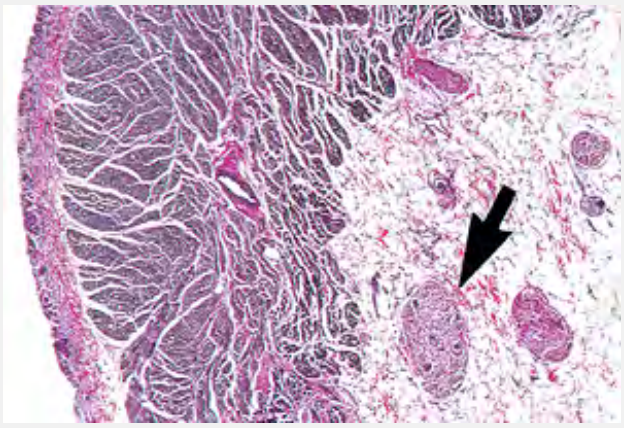

Figure 20.13 Section through the right atrium showing the nerves and ganglion cells (*arrow*) in the overlying subepicardial adipose tissue (elastic van Giesen).

The atrial septum is smooth on the left side but has a central shallow depression corresponding to the oval fossa. The endocardium of the left atrium is thicker as a result of increased collagen layers, particularly near the openings of the pulmonary veins. Otherwise the histology is similar to the right atrium.

Right Ventricle

The morphologic right ventricle lies anterior to the other heart chambers. It has an inflow portion (sinus), an apical trabecular component, and an outflow portion (infundibulum conus) (20). The outflow tract is separated anatomically from the inflow tract by a muscular arch called the crista superventricularis. The endocardial surface is coarsely trabeculated, particularly in the apica region.

On sectioning, the trabeculations form the inner two-thirds of the ventricular wall. The septal surface is deeply trabeculated with

coarse trabeculae carneae and a thick muscular column called the moderator band (Figure 20.14). This moderator band is found in most hearts and connects the distal portion of the septum to the free wall. It terminates in the region of the anterior papillary muscle. Myocyte disarray is a common finding within trabecular muscles and should not be confused with hypertrophic cardiomyopathy. The right bundle branch travels through the muscular ventricular septum and courses down to end in the moderator muscle. The papillary muscles of the right ventricle are relatively constant, with an anterior papillary muscle located on the anterior wall near its junction with the septum and a small posterior papillary muscle arising under the crista superventricularis at the inferior border of the right ventricular outflow tract. In addition, there is an

inconstant group of posterior papillary muscles that can arise from the diaphragmatic wall of the right ventricle.

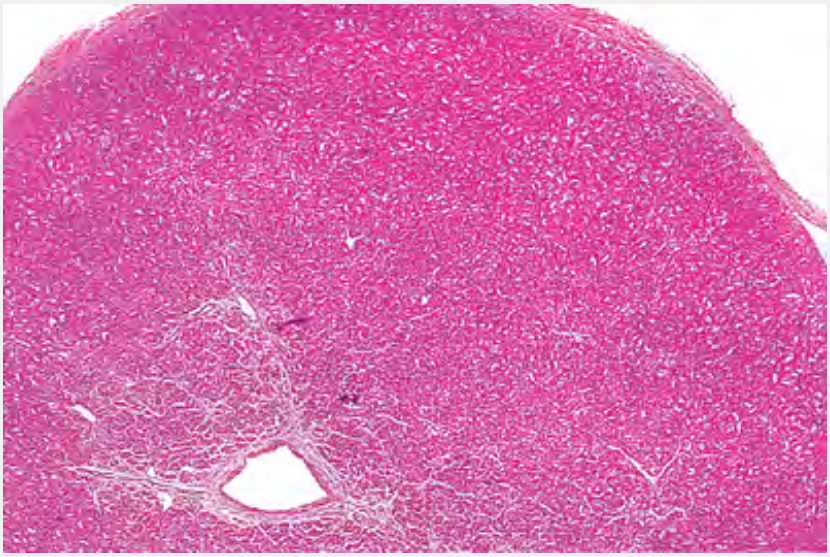

Figure 20.14 A section of trabeculae carneae from the normal right ventricle.

The histology of the right ventricle consists of a thin endocardial layer. The thickness of myocardial wall in normal human adults is about one-third that of the left ventricle and measures up to 5 mm. The endocardium is similar to the other chambers except it has more variability from region to region, with the thickest area found in the septum. The subendocardial space includes a fenestrated elastic membrane and, on occasion, bundles of smooth muscle, particularly in the interventricular septum (Figure 20.7). The interventricular septum also contains blood vessels, nerves, and the left bundle branch of the conduction system. The ventricular free wall has numerous vascular channels consisting of intertrabecular channels that lead into myocardial sinusoids and thebesian veins. Myocardial sinusoids are also found within the trabeculae. Arterioluminal vessels, leading directly from the systemic coronary circulation into the capillary beds, empty into the myocardial sinusoids. The myocardium is richly supplied with small vascular channels that form an intramural circulation (21). There is an extensive web of capillaries that course among the cardiac muscle fibers, are fed by branches of the coronary arteries, and are drained, in part, by the coronary veins. They are also directed to the intramyocardial sinusoids and thence into the lumen of the heart. Deep within the myocardial musculature is found, in addition to the capillary bed, a richly anastomosing network of irregular channels that have been called myocardial sinusoids. These sinusoids receive vessels from the coronary arteries and the capillaries and communicate with coronary veins. The connections between the coronary arteries and the cardiac chambers are called arterioluminal vessels (Figure 20.15). Within the myocardium, variable amounts of adipose tissue can be found, particularly in the free wall portions. When extensive, it is called fatty infiltration of the right ventricle and represents a metaplastic change. It should not be confused with arrhythmogenic right ventricular dysplasia/cardiomyopathy.

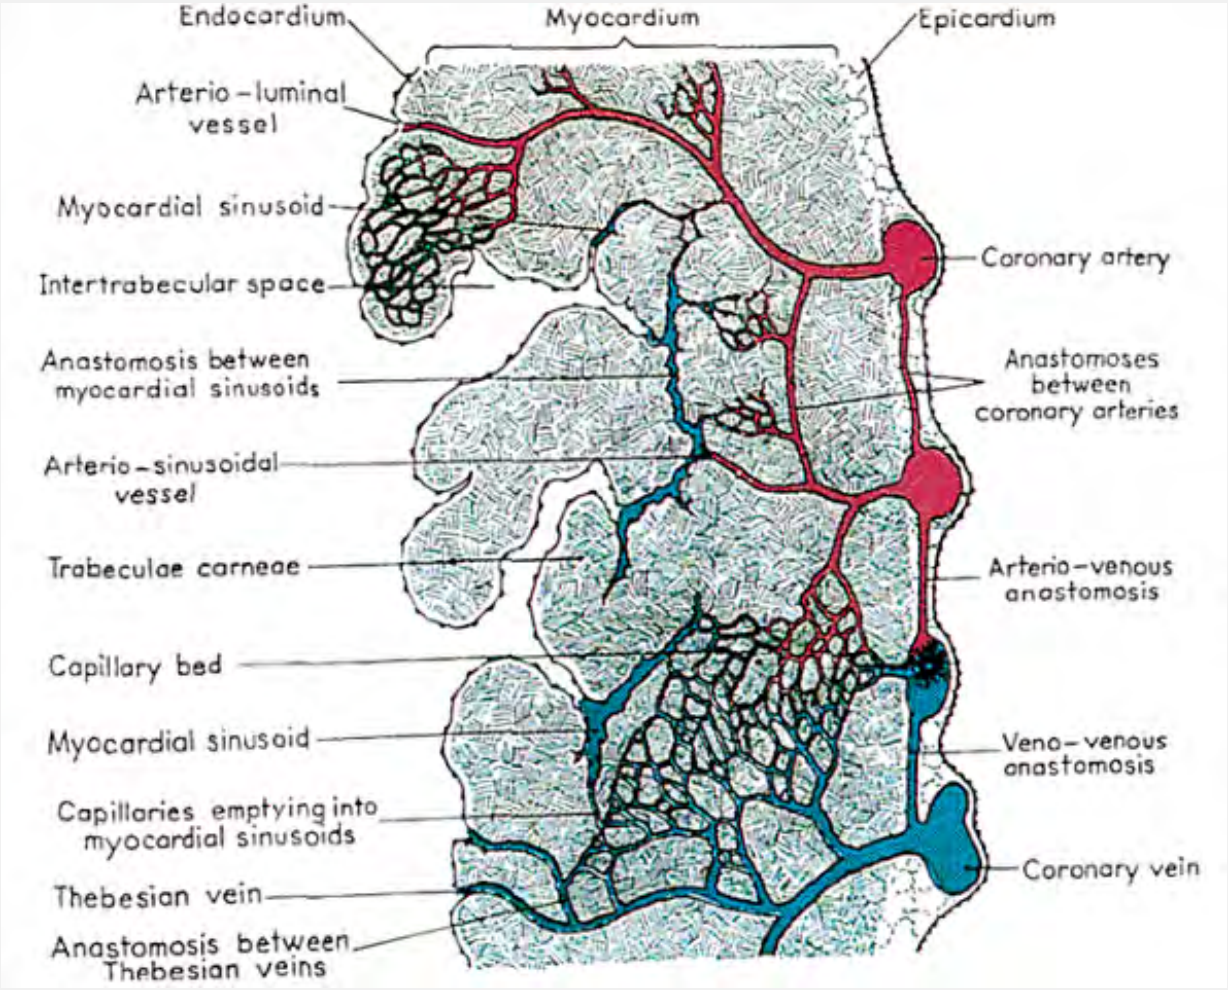

Figure 20.15 Diagrammatic representation of the various intramural vascular channels. Reprinted with permission from: Gittenberger-de Groot AC, Bartelings MM, Deruiter MC, Poelmann RE. Basics of cardiac development for the understanding of congenital heart malformations. *Pediatr Res* 2005;57:169â€“176.

Applied Anatomy

The importance of recognizing the presence of myocyte disarray and adipose tissue as common findings within the trabeculated musculature of the right ventricle of the normal adult heart has been

discussed. The apical trabecular region is also the site of pacemaker wire placement and endomyocardial biopsy sampling.

Left Ventricle

The left ventricle receives blood from the left atrium during ventricular diastole and ejects blood into the systemic arterial circulation across the aortic valve during ventricular systole. The left ventricle is somewhat bullet-shaped, with the blunt tip directed anteriorly and inferiorly and to the left (22). Like the right ventricle, it is composed of inflow, septal, and outflow components. It lacks the moderator band and septomarginal trabeculations of the right ventricle (19). The left ventricular chamber is surrounded by a thick muscular wall measuring up to 15 mm in thickness (note: the papillary muscles are not included in the measurement). The medial wall of the left ventricle is the interventricular septum, which is shared with the right ventricle. The septum is roughly triangular in shape, with the base of the triangle at the level of the aortic cusps; it is entirely muscular, except for the small membranous septum located just below the right coronary and posterior cusps. The upper third of the septum, or outflow tract, is lined by smooth endocardium. The inferior two-thirds of the septum and the remaining ventricular walls are composed of the trabeculae carneae, which are thinner and less prominent than in the right ventricle. The free wall of the left ventricle is that portion that is exclusive of the septum.

The histology of the left ventricle is similar to that of the right side, although the endocardium is slightly thicker as a result of higher hemodynamic pressures. The small arterioles subadjacent to the endocardium have slightly thicker walls than those of the right ventricle, most likely due to the higher pressure in the left ventricle. The myocardium of the left ventricle is arranged in such a way that it appears to spiral inward from the superficial layers. The superficial layers run at right angles to the layers deeper within the wall. These

layers are intimately interdigitated to prevent dissection into lamina structures. The attachment of the muscular layers is from the fibrous skeleton at the base of the heart. The deeper muscle layers of the interventricular septum are composed of the deep bulbospiral muscle in the center of the septum originating from the septal portion

of the atrioventricular annulus. The fascicles of the deep bulbospiral and sinospiral muscles interdigitate within the muscular interventricular septum. The spiral muscle pulls the base of the ventricle toward the apex during systolic contraction. The blood supply is similar to that of the right ventricle.

Applied Anatomy

Portions of the left ventricular subaortic outflow tract may be submitted as myomectomy specimens in patients with asymmetric hypertrophic cardiomyopathy. Portions of the left ventricular free wall may be removed as aneurysectomy specimens or during VAD placement. The intermediate bulbospiral muscle of the interventricular septum is primarily involved in idiopathic hypertrophic subaortic stenosis (IHSS). Because it lies deep within the septum, the disarray associated with IHSS may not always be seen in the superficial myomectomy specimen.

Cardiac Valves

Semilunar Valves

The semilunar valves consist of the pulmonic and aortic valves. The normal valve circumference for the aortic valve is 5.7 to 7.9 cm for women and 6.0 to 8.5 cm for men (23). The normal pulmonic valve circumference is 5.7 to 7.4 cm for women and 9.2 to 9.9 cm for men (23). Interestingly, when adjusted for body surface area, the valves in women are slightly larger than in men (6). Each semilunar valve consists of three semicircular cusps (24), each of which is attached

by its semicircular border, or annulus, to the aortic or pulmonic ring. The three points of lateral attachment of adjacent cusps are the commissures (Figure 20.16). The lines of cusp apposition are not at the free margin but are angulated lines extending from well below the point of attachment in the commissure to just below the midpoint of the free edge. In the aortic valve, these lines (the linea alba) and the central nodules (the noduli arenti) can be seen (24). In the pulmonic valve, these landmarks are less obvious because of the lower right-sided pressures. The lunulae are thin, delicate areas of cusp between the linear alba and the free edge.

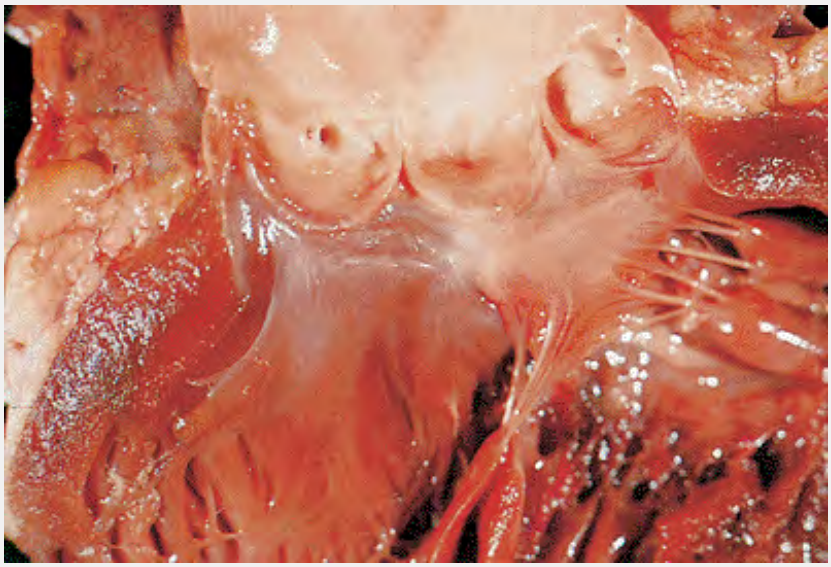

Figure 20.16 Aortic valve from normal heart showing the cusps and the coronary ostia.

The semilunar aortic and pulmonic valves are similar in configuration, except that the aortic cusps are slightly thicker and contain coronary ostia. They are situated at the summit at the outflow tract of their corresponding ventricle, the pulmonic valve being anterior, superior, and slightly to the left of the aortic valve in the normal heart. The cusps, which are often slightly unequal in width, circle the inside of

the respective vessel root (e.g., pulmonary artery trunk or aortic root). Behind each cusp, the vessel wall bulges outward, creating a pouchlike dilatation known as the sinus of Valsalva. The portion of the cusp adjacent to the rim is thin and may contain small perforations in the normal situation. The noduli arenti meet in the center and contribute to the support of the leaflets. Because the plane of the aortic valve is oblique with the right posterior side lower than the left anterior side, the origin of the left coronary artery is slightly superior to that of the right coronary artery. The ostia of coronary arteries are located in the upper third of their respective sinuses. The right coronary artery passes anteriorly and to the left. In some hearts, there is a separate ostium in the right coronary sinus for the conus artery, sometimes called the third coronary artery (22).

The histology of the semilunar valves is that of a well-defined multilayered structure. Three distinct layers are recognizable: the fibrosa, the spongiosa, and the ventricularis. The fibrosa is a layer of dense collagen that constitutes the major structural component of the cusp and extends to its free edge (25). The densely packed collagen bundles blend into the collagen of the valvular ring in the region of the commissures. Some fibroblasts are present in this layer, as are some very fine elastic fibers. The spongiosa is subadjacent to the fibrosa and occupies a central position in the thickness of the cusp (Figure 20.17). It is best developed in the basal third of the cusp. It does not extend to the free edge, which is composed only of fibrosa and ventricularis layers. The spongiosa is composed of large amounts of proteoglycans, such as glycoaminoglycans, loosely arranged collagen fibrils, scattered fibroblasts, and mesenchymal cells (25). The ventricularis is subadjacent to the spongiosa and is in direct contact with the endothelial layer of the inflow surface of the cusp (i.e., closest to the ventricular surface). It is distinguished from the fibrosa by its abundance of elastic fibers. This feature is often helpful in orienting and identifying the layers of excised aortic valvular cusps. The

surface lining of the cusps consists of a single layer of endothelial cells. The surface topography of the aortic cusp varies according to its state of stress. The bundles are wavy and the inflow surface is smoother in the stressed state and rougher in the relaxed state (25).

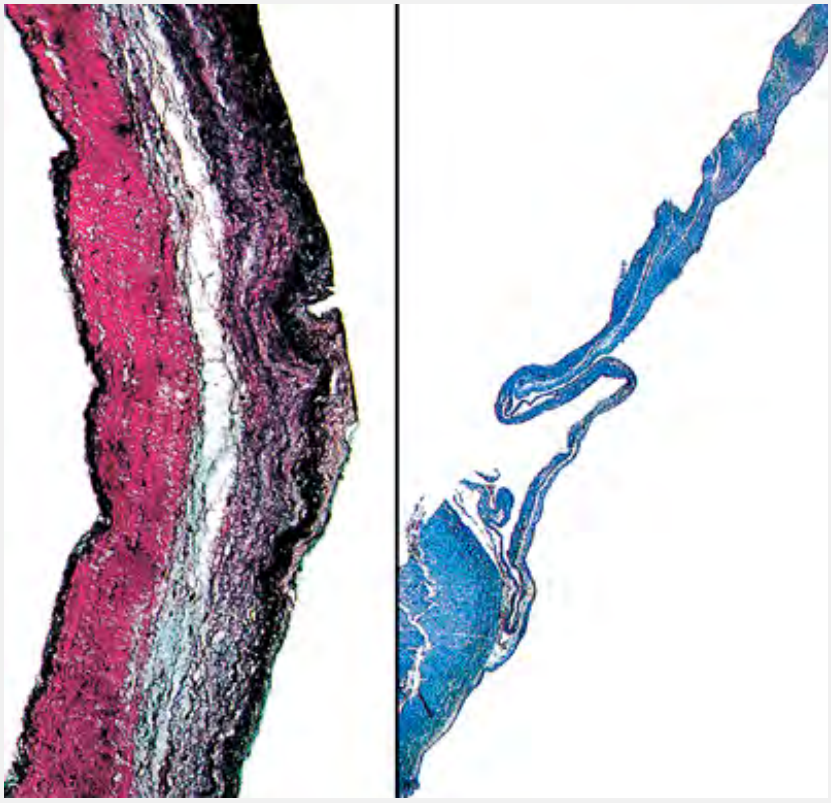

Figure 20.17 High- (A) and low-power (B) views of a section of the aortic cusp showing the three distinct layers as described in the text.

Atrioventricular Valves

The atrioventricular valves consist of the mitral valve and the tricuspid valve. The normal circumference of the tricuspid valve is 10 to 11.1 cm in women and 11.2 to 11.8 cm in men (23). The normal

circumference of the mitral valve is 8.2 to 9.1 cm in women and 9.2 to 9.9 cm in men (23). The valvular apparatus is made up of the annulus, commissures, leaflets, chordae tendineae, and papillary muscles. The annulus is composed of a ring of circumferentially oriented collagen and elastic fibers with extensions into the ventricle and atrium.

The atrioventricular valves have four histologic layers (Figure 20.18). The collagen bundles of the annulus spread down into the cusp of the mitral valve and are known as the fibrosa. They continue into the chordae tendineae and finally spread out into a network that covers the tip of the papillary muscles (Figure 20.19). Adjacent to the fibrosa layer on the ventricular side of the valve is the ventricularis. The ventricularis contains many elastic fibers and is covered by endothelium. Some of the elastic fibers extend into the chordae tendineae; but, in general, this layer is incomplete, as it does not extend to the free edge of the leaflet. The spongiosa is situated on the atrial side of the fibrosa layer. Like the semilunar valves, it has a rich abundance of glycosaminoglycans and a few elastic fibers, collagen fibrils, and connective tissue cells (25). This layer, along with the fibrosa layer, extends through the entire length of the leaflet. The spongiosa in the anterior and posterior mitral leaflets may contain cardiac myocytes that are a direct extension of the left atrial myocardium (Figure 20.18). In the anterior mitral leaflet, this layer extends into the middle third, whereas in the posterior leaflet it only extends into its proximal third. Neural elements and lymphatics can be found in the leaflets. The atrial aspect of the spongiosa (i.e., layer closest to the atrium) is covered by the auricularis,

which in turn has an endothelial lining. The auricularis contains collagen and elastic fibers and smooth muscle cells. It is prominent near the annulus but thins out in the distal third of the leaflet such that the most distal aspect of the valves is composed only of spongiosa and fibrosa. The endothelial cells on the atrial aspect of the atrioventricular valves are plump and have irregular nuclei

compared to the flatter endothelial cells on the ventricular aspect.

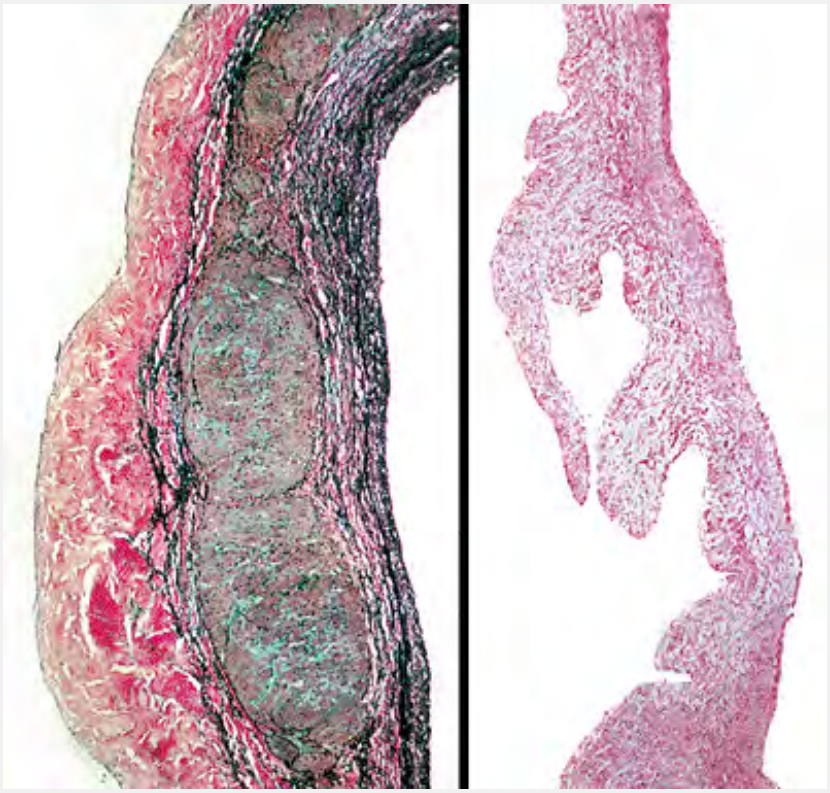

Figure 20.18 High- (A) and low-power (B) views of a section of the mitral leaflet showing the three distinct layers with muscle in the central portion near the base of the valve.

Figure 20.19 A normal mitral valve with chordae tendineae inserting into the papillary muscles.

The architecture of the tricuspid valve apparatus and the layered arrangements of its leaflets are similar to those in the mitral valve; however, the individual layers are thinner in the tricuspid valve. Cardiac muscle bundles insert fairly low into the base of the tricuspid leaflets but do not extend into the leaflet substance. In the posterior and septal leaflets, the auricularis is thicker and contains more abundant smooth muscle cells.

Chordae Tendineae

The chordae tendineae in the normal state are thin fibrous cords that emanate in a fanlike manner from the broad leaflets of the atrioventricular valves and insert into the papillary muscles (Figure 20.19). The central cores of the chordae are composed of longitudinally oriented collagen fibrils. The core is surrounded more peripherally by loosely arranged collagen fibrils and elastic fibers and is embedded in proteoglycan-rich matrix (25) (Figure 20.20). Some

chordae contain a small central core of muscle known as chordae muscularis (Figure 20.21), although others contain blood vessels and collagen in variable amounts and appear fleshier in color (Figure 20.22). The endothelial cells on the chordae resemble the flattened ovoid nuclei of the ventricular surface of the leaflets.

Figure 20.20 Longitudinal section of chordae tendineae showing the relationships of elastic fibers on the surface and collagen in the center (elastic van Giesen).

Figure 20.21 Transverse section of chordae tendineae showing central core of muscle (H&E).

Applied Anatomy of Intracardiac Valves

Semilunar and atrioventricular valves are frequently encountered in the surgical pathology laboratory. Indications for valvular replacement or repair include a variety of congenital, infectious, inflammatory, degenerative, and paraneoplastic causes. In many cases, the chordae and portions of papillary muscle may be attached. In the

setting of myocardial infarction, infection, or valvular prolapse, ruptured papillary muscles may become surgical specimens. Lambl's excrescences and fibrous nodules are papillary projections along the lines of closure or free edge of the valve, respectively.

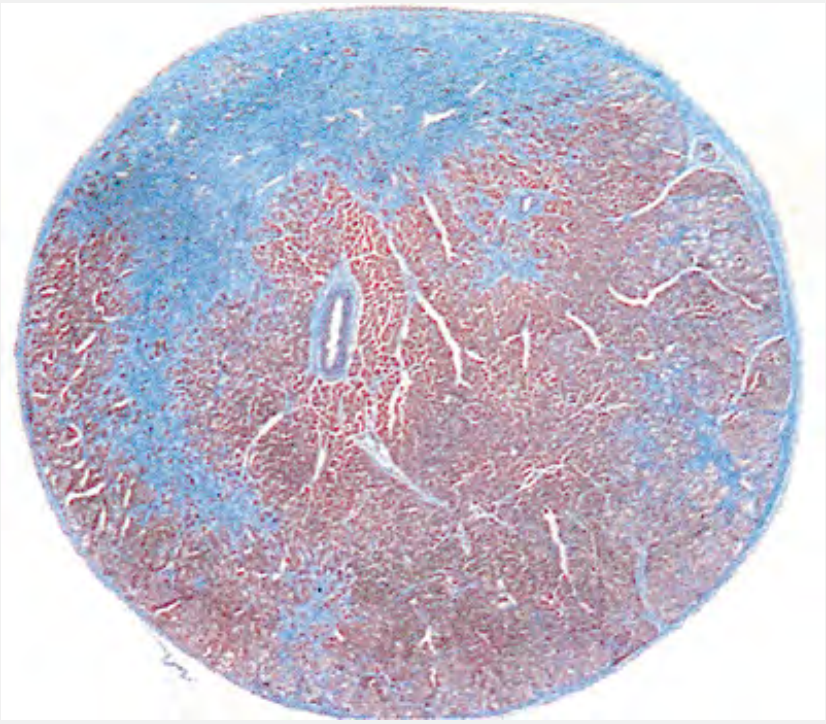

Figure 20.22 Transverse section of a muscular chorda showing fibrous tissue, muscle, and small vessel within the chorda (Masson's trichrome).

Aging Changes of Intracardiac Valves

With age, all the cardiac valves become thicker, more opaque, and less pliable. The increase in collagen content may account for the loss of plasticity, and calcifications may occur. The posterior leaflet of the mitral valve often shows yellow atheromatous alteration. The mitral valve annulus may become calcified with age. The valvular circumferences increase with age (6).

Papillary Muscles

The two papillary muscles of the right ventricle (anterior and conal) are relatively constant. There is also a group of inconstant posterior papillary muscles on the inferior wall. In the left ventricle there are two constant papillary muscles: the anterior and posterior. The papillary muscles receive the chordae. They are variable in shape and width and on occasion may have multiple heads (Figure 20.19).

The histology of the papillary muscles includes the fibrous cap, into which the chordae insert (Figure 20.23). The small arteries and arterioles in the papillary muscle are notable for their wall thickness and irregularity in comparison to other intracardiac small vessels (Figure 20.24). The myocardium and the endocardial covering are similar to their counterparts described elsewhere. In marked ventricular dilatation, the papillary muscles may become thinned and flattened.

Conduction System

Myocardial fibers are delineated along two functional pathways in humans: (a) contractile fibers and (b) myocardial fibers specialized for the initiation and propagation of an impulse for contraction. The conduction system is recognized to be myogenic in origin, with nerves playing only a subsidiary controlling function.

For most pathologists, examining the conduction system is often regarded as a daunting exercise. This is due in large part to the fact that the number of cases requiring detailed morphologic analysis is infrequent and is often limited to specific requests from clinicians. In addition to detailing the microscopic features of the sinoatrial and atrioventricular nodes, we will present our practical approach to the dissection of these structures. We recommend careful attention to key anatomic landmarks to ensure successful retrieval of these structures.

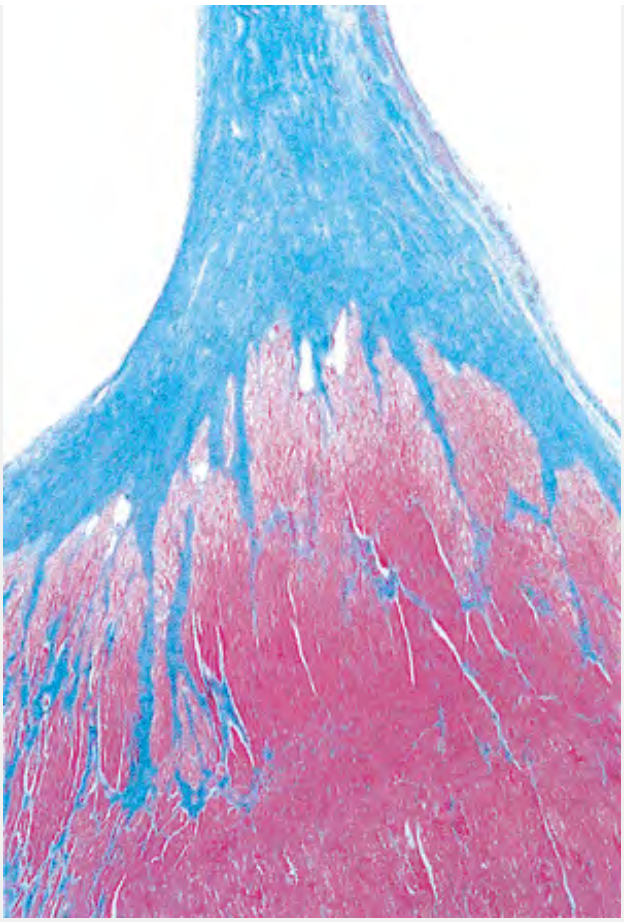

Figure 20.23 Longitudinal section of papillary muscle showing the fibrous cap of the insertion of the chordae tendineae (Masson's trichrome).

Sinoatrial Node

The sinoatrial (SA) node has the highest intrinsic rate and is recognized as the primary pacemaker of the heart. This node

is situated within the terminal groove at the junction of the SVC and the lateral border of the right atrium (Figure 20.25). Its position is constant and is marked by the apex of the crest of the atrial appendage. It is ovoid or cigar-shaped in most hearts, but rare cases

of horseshoe-shaped SA nodes are reported. Removal of a rectangular block of tissue that includes the distal SVC and atrium on either side of the terminal groove is recommended. Serial sectioning in a longitudinal plane parallel to the terminal groove at 2 mm intervals is recommended, and all the tissue slices can be accommodated in 2 tissue cassettes. Grossly identifying the SA nodal artery is also helpful in procuring the node (Figure 20.25). This is a branch of the right coronary artery that is found in slightly more than half of the general population. Microscopically, the node is arranged around a central artery adjacent to epicardial adipose tissue. The node is composed of dense connective tissue within which the small muscle fibers are embedded. The muscle fibers contain sparse myofibrils, the striations are not prominent, and the whole mass has a pseudosyncytial appearance. Connective tissue stains such as Masson's trichrome and elastic van Gieson stains highlight the abundant collagen and elastic fibers, respectively (Figure 20.25). Abundant nerve fibers run into the node. The exact pathway(s) carrying the electrical impulse from the SA node to the atrioventricular node remains controversial. Some investigators think that several specialized bundles of conducting system cells (e.g., anterior, middle and posterior internodal tracts) conduct the impulse around the atrium. Others argue that the arrangement of myocardial fibers within the atrium and interatrial septum serves to propagate the impulse (16).

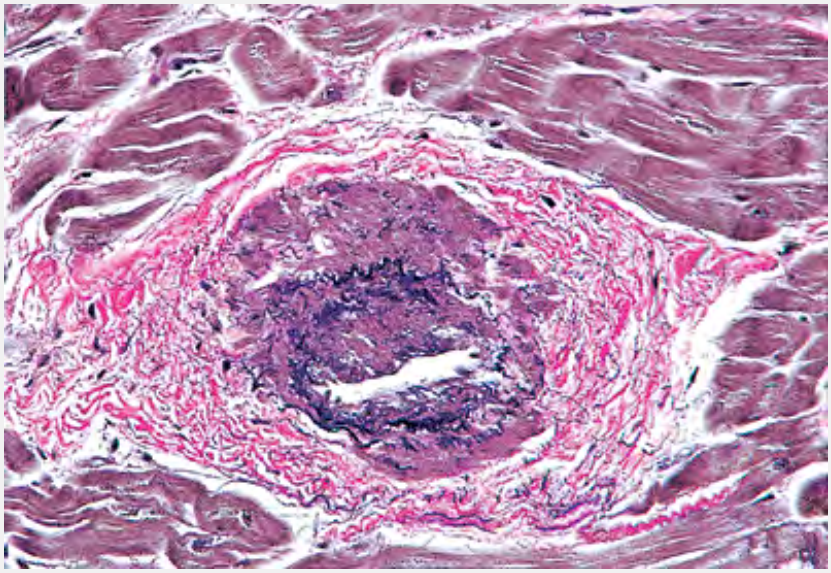

Figure 20.24 Section of abnormally thickened arteriole within a papillary muscle (elastic van Giesen).

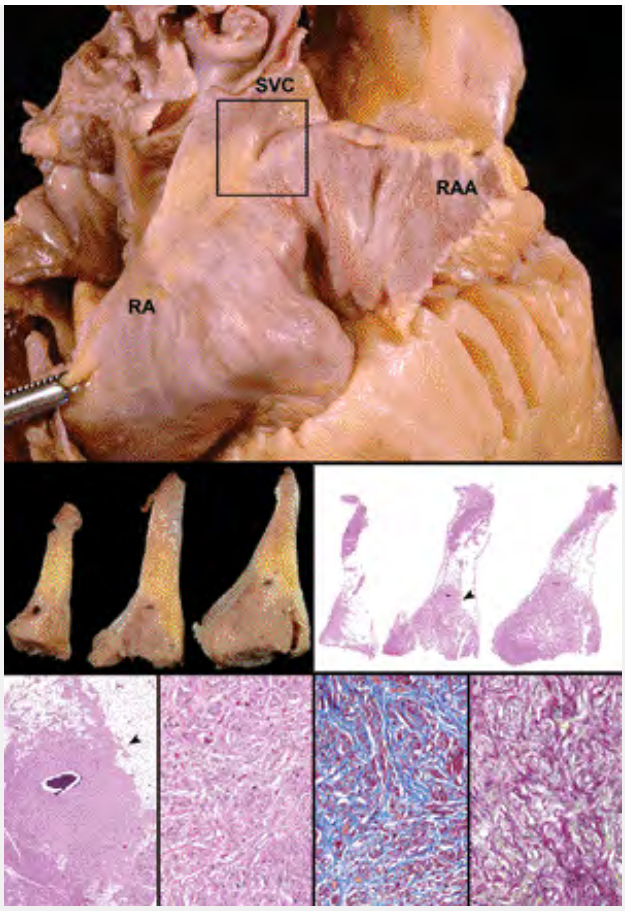

Figure 20.25 The sinoatrial node. A. The location of the sinoatrial node within the terminal groove at the junction of the superior vena cava (SVC) and crest of the atrial appendage (*box*). B. Macroscopic and low-power magnification of serial sections of nodal tissue. Note the nodal artery that is adjacent to the sinoctrial node. C. High-power magnification of the sinoatrial node showing the specialized fibers embedded within collagen and elastic tissue (H&E, trichrome, and elastic van Giesen stains).

Atrioventricular Node

In our experience a heart opened along the lines of flow provides the

optimum exposure for dissecting the atrioventricular (AV) node. From a right-sided approach the interventricular septum is oriented with the tip of the apex pointing downward. The important landmarks include the oval fossa, ostium of the coronary sinus, and tricuspid valve annulus and leaflets. The AV node lies within the subendocardial tissues on the right side of the interatrial septum just anterior to the opening of the coronary sinus, posterior to the membranous interventricular septum, and above the tricuspid valve annulus within the triangle of Koch (26) (Figure 20.26). A rectangular block of tissue, beginning with a vertical incision adjacent to the ostium of the coronary sinus and extending 1 to 2 cm below the annulus, is removed. After careful trimming of valvular structures, the block will contain components of the tricuspid valve (septal leaflet) and mitral and aortic valves (Figure 20.26). Serial sectioning at 2 to 3 mm intervals and sequential placement in tissue cassettes yields a total of 8 to 10 cassettes.

In histologic sections, the AV node is flattened against the central fibrous body and is composed of a network of muscle fibers, with the superficial zone having fibers arranged in a parallel manner. These specialized fibers retain their intercalated disks and striations but are characterized by their pale eosinophilic appearance (Figure 20.26). A small AV nodal artery is often identified adjacent to the AV node. At the anterior end of the AV node, the muscle fibers become arranged in parallel lines to form the main bundle of His or penetrating AV bundle. To reach the ventricle, the AV bundle pierces the central fibrous body and runs forward on the upper margin of the muscular ventricular septum. This penetrating portion of the main bundle is surrounded by dense connective tissue and anatomically is closely related to the aortic and mitral valve rings (Figure 20.26). Connective tissue stains can aid in the localization of the nodal tissue. The

fibers of the main bundle are arranged in parallel. The penetrating AV bundle terminates as the left and right bundle branches. The left

fascicle runs downward over the endocardial surface of the interventricular septum to the base of the anterior papillary muscle, and the right fascicle ends in the moderator band of the right ventricle. Direct connection of both bundle branches to a complex ramifying system of subendocardial conduction fibers can be demonstrated in mammalian hearts. Light microscopy shows the fibers in the bundle of His and the conduction bundles to be small and contain few myofibrils (Figure 20.27).

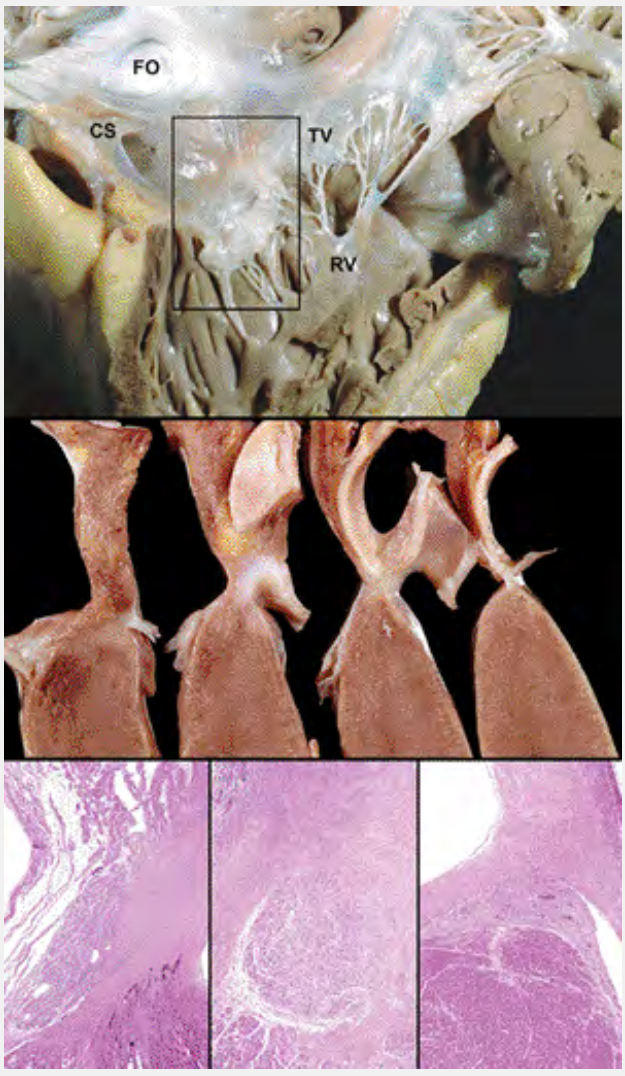

Figure 20.26 The atrioventricular nodal apparatus. A. The

location of the AV node (*box*) viewed from the right ventricle. Important landmarks include the coronary sinus (*CS*), tricuspid valve annulus and leaflet (*TV*), and fossa ovale (*FO*). B. Serial sections of the rectangular block of tissue show the relationship of the nodal tissue to the tricuspid valve, mitral valve, atrioventricular valve, and fibrous skeleton of the heart. C. The atrioventricular (AV) node (*left*), AV penetrating bundle (*middle*) and AV bundle with fascicle (*right*) are shown.

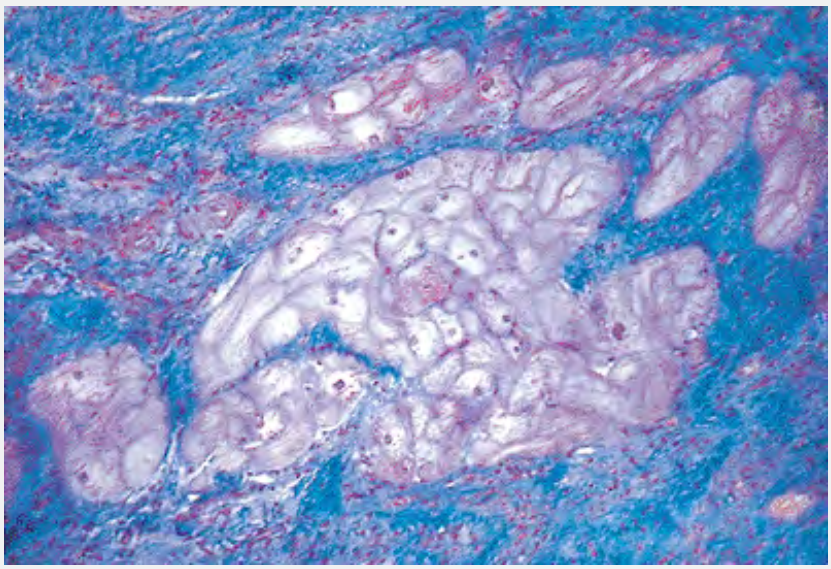

Figure 20.27 Section showing the pale cells of the mammalian conducting system. These cells contain glycogen and only sparse myofibrils (Masson's trichrome).

Aging Changes in the Human Conduction System

With advancing age, the SA node displays progressive increase in

fibrous tissue while the AV node remains relatively unchanged. Similarly, fibrous tissue increases in the upper portion of the interventricular septum. These changes are associated with a loss of conduction fibers in the region of the left bundle branch. Up to 50% of the left bundle origin may be lost in people over 60 years of age (27).

Cardiac Innervation

The nerve supply of the heart is autonomic, including both the sympathetic and parasympathetic supply via both the efferent and afferent fibers. Histologically, large nerves can be seen in the epicardium and adjacent to the coronary blood vessels. Small nerves within the myocardium are hard to identify unless special stains are used. Myocardial nerves are best viewed using electron microscopic examination, by which the autonomic nerves can be distinguished. Cardiac ganglia (parasympathetic) can be found over the surface of the atria and in the AV groove (Figure 20.13).

Autonomic Nerves

Axonal varicosities occur at irregular intervals along autonomic fibers, and their morphology is considered useful in determining whether the nerve is adrenergic or cholinergic (25). In cholinergic nerves, the varicosities contain accumulations of agranular vesicles and a few mitochondria. In adrenergic nerves, the varicosities contain vesicles rich in electron-dense cores. Each of these cores is separated from the limiting membrane of the vesicle by an electron-lucent zone (Figure 20.28). Presumptive sensory nerve terminals

have large diameters and contain numerous mitochondria. They are located in perivascular regions and are surrounded by Schwann cells. A given Schwann cell may enclose adrenergic and cholinergic axons together with sensory axons (25). Autonomic ganglia are found in the subepicardial tissue of the atria and atria appendages and at the root

of the great vessels, along the interatrial and AV grooves in the atrial septum and in the vicinity of the SA and AV nodes. Large nerves can be seen in the subepicardial layer adjacent to the epicardial coronary arteries.

Figure 20.29 Electron micrograph showing an intramyocardial lymphatic with thin walls and no basement membrane (original magnification Ã—20,000).

Lymphatics

There are two networks of lymphatics in the heart: (a) in the endocardium and (b) in the epicardium. The route of drainage of the endocardial network is through channels in the myocardium into the epicardial lymphatics. The epicardial meshwork of channels, containing many valves, drains toward the AV sulcus by means of several longitudinal channels that run for the most part parallel to the coronary veins in the anterior and posterior longitudinal sulci of the ventricles (25). Lymphatics leave the pericardial cavity to empty into one of the pulmonary hilar lymph nodes and join the lymphatic drainage system of the mediastinum or into the thoracic duct. Lymphatics are also found in the myocardial valves and lie within the grooves of the coronary blood vessels.

The lymph capillaries and larger lymphatic vessels accompany blood vessels in the myocardial interstitium. The walls of the myocardial lymphatics consist of extremely thin endothelial cells, the nuclei of which bulge into the lumen (Figure 20.29). In contrast to endothelial cells of blood capillaries, those of the lymphatic capillaries do not have a well-defined external basal lamina. The endothelial cells of lymphatic capillaries may have Weibel-Palade bodies and transplant vesicles (25). The larger lymphatics are confined to the outer third of the myocardial wall and occasionally contain valves. These flaplike structures contain a core of collagen embedded in microfibrils and are covered by endothelium.

Small Intramural Coronary Arteries

The structure of the intramural coronary arteries and the larger coronary arteries is similar and consists of the endothelium, smooth muscle, and adventitia (Figure 20.30).

These smallest muscular arteries contain three or four layers of smooth muscle. Arterioles have flat, elongated endothelial cells that do not protrude into the lumen. Their internal elastic lamina is discontinuous. Metarterioles are also known as precapillary sphincters. The endothelial cells in metarterioles have numerous surface projections that bulge into the lumen (25). Although the medial smooth muscles form a single discontinuous layer, it gradually disappears as capillaries begin. Capillaries are distinguished by the fact that their walls are composed of only a single layer of endothelial cells. They do not have smooth muscle cells but may have closely associated pericytes (25). Capillary endothelial cells may have microvilli and cytoplasmic processes (filopodia). The myocardium has a rich network of capillaries. These branches undergo anastomosis and eventually become thin-walled venules measuring up to 100 Âµm in diameter.

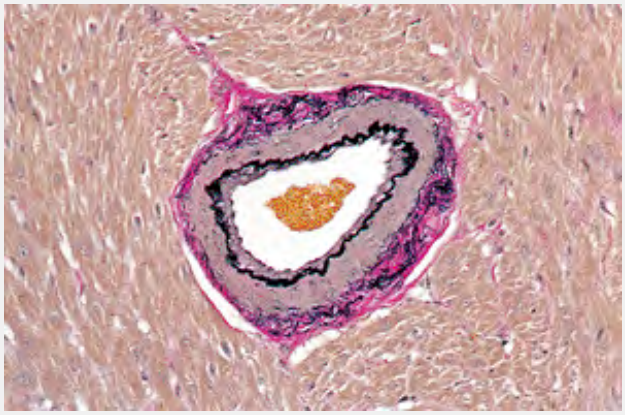

Figure 20.30 Transverse section of intramyocardial arteriole (elastic van Giesen).

Veins and Venules

Venules have thin, flat endothelial cells and characteristically contain a large amount of connective tissue in the vicinity of their external surface; they contain collagen fibrils that approach the endothelial layer and are anchored on its outer surface (25). Venules gradually increase in size to become veins. Veins have larger lumens but thinner walls than their arterial counterparts.

Veins have three layers: the intima, media, and adventitia. The intima is thin, lacks smooth muscle cells and has a poorly defined internal elastic lamina. The media is also thin and contains few smooth muscle cells and elastic fibers. The adventitia is thick with abundant collagen and elastic fibers. Cardiac veins drain blood into either the coronary sinus or directly into the chambers (thebesian veins).

The Endomyocardial Biopsy

The transvenous endomyocardial biopsy is currently utilized for the

diagnosis of allograft rejection and a variety of inflammatory, metabolic, and neoplastic conditions that affect the heart. Originally introduced in the early 1960s, the bioptome and the technique have undergone modifications that now permit clinicians the opportunity to obtain cardiac tissue in a safe outpatient setting (28). The right internal jugular vein or femoral vein approaches are commonly used. Complications are uncommon and include local problems (such as hematomas and nerve injury) and cardiac problems (such as arrhythmias, tricuspid valve apparatus damage, and ventricular perforation).

Tissue Handling and Processing

Proper tissue procurement and handling are essential for optimal diagnostic evaluation (29). Biopsy specimens should be gently extracted from the bioptome with a needle tip to limit crush artifactual distortion. The clinical indications for the biopsy determine, in large part, the method of tissue handling. For example, for standard light microscopy, the tissue should immediately be placed in a standard fixative such as 10% neutral buffered formalin. To demonstrate the type of amyloid fibril in cardiac amyloidosis by immunofluorescence (e.g., AL, AA, or transthyretin), one or two pieces should be received in saline or Zeus medium and then snap frozen in a plastic Beem capsule containing an embedding medium. The diagnosis of chronic anthracycline cardiotoxicity requires that *all* the biopsy pieces (minimum of 3â€“5 pieces) be submitted in fixative for transmission electron microscopy (e.g., 2.5% glutaraldehyde with 2% paraformaldehyde in 0.1M sodium cacodylate buffer, pH 7.2).

For routine diagnostic evaluation, overnight processing and paraffin embedding are sufficient. For emergent cases, a 90-minute rapid (â€œultraâ€•) processing cycle is available, and microscopic slides can be prepared within three to four hours. All the biopsy pieces should be embedded in the same block. We recommend that a minimum of three slides are prepared, with each sectioned at 4 to 5

Âµm thickness from various depths within the paraffin block. Multiple fragments, or â€œribbons,â€• are placed on each slide.

We routinely stain with hematoxylin and eosin (H&E) and use stains such as Masson's trichrome to confirm the presence of myocyte damage or fibrosis, Congo red stain for amyloid fibrils, and the Prussian blue stain for iron deposition. Immunohistochemical, immunofluorescent, and molecular studies are utilized for specific indications. Paraffin section immunohistochemistry is used to evaluate for the presence of infectious myocarditis (e.g., cytomegalovirus (CMV) or toxoplasmic myocarditis), posttransplant lymphoproliferative disorders (PTLD) [B-cell clonality, Epstein-Barr virus (EBV) latent membrane proteins, anomalous coexpression of B-cell and T-cell antigens] or acute antibody mediated rejection (intravascular collections of CD68+ histiocytes and deposition of C4d on the microvasculature). In situ hybridization is helpful to demonstrate the presence of EBV or other viral genome or light chain restriction in PTLD.

Biopsy Limitations and Tissue Artifacts

Sampling error in the diagnosis of rejection, myocarditis, and infection remains a major consideration in the clinical management of patients and the evaluation of new noninvasive diagnostic modalities. In general, the false-negative rate is low, particularly when four or more pieces of tissue are submitted. The issue of how many lymphocytes are normally found in the myocardium has been addressed. In an endomyocardial biopsy study, the mean number of lymphocytes is fewer than 5.0 per high-power field (30).

A variety of artifacts occur in endomyocardial biopsy specimens that may mimic pathologic lesions. The surgical pathologist must be aware of these patterns to avoid a

misdiagnosis that could lead to unnecessary therapeutic interventions. These have been reviewed in detail in a recent

publication and only selected topics will be briefly reviewed (31). The most common biopsy artifact is the presence of contraction bands in myocytes (Figure 20.31A). They are identical to the linear bands observed in acute ischemic necrosis and catecholamine (â€œpressorâ€•) effect. These changes are induced by the biopsy procedure itself and can be diminished by using fixatives stored at room temperature. In ischemic injury, the nuclei of surrounding myocytes are usually pyknotic (Figure 20.31B), while in artifactually induced contraction bands, the nuclei remain normal in appearance.

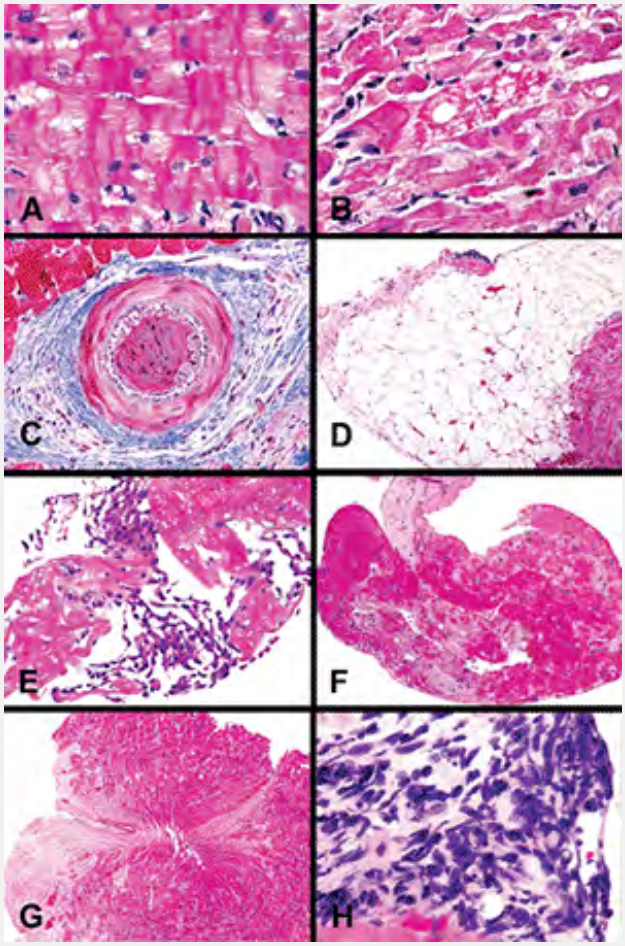

Figure 20.31 Artifacts of endomyocardial biopsy specimens: A. Contraction band artifact (H&E); note the normal appearance of myocyte nuclei. B. Contraction band necrosis with

hyperchromatic pyknotic nuclei and eosinophilic cytoplasm. The changes are contrasted with the common contraction band artifact in A. C. Telescoping of intramyocardial is highlighted by a trichrome stain. D. Intramyocardial adipose tissue. The presence of fat does not imply epicardial localization or perforation. E. Mesothelial cells admixed with fibrin indicative of ventricular perforation. F. Thrombus without attached myocardial tissue. G. Bioptome-induced â€œVictorian waistbandâ€• artifact. H. Crush artifactual distortion of cells.

Another frequent artifact is intussusception, or â€œtelescoping,â€• of small arteries that has been confused with luminal occlusion by thrombus and transplant-related arteriosclerosis. Connective tissue stains such as Masson's trichrome or elastic van Gieson highlight the internal elastic membranes of both vessel segments (Figure 20.31C). Intramyocardial accumulations of mature adipose tissue can simulate epicardial tissue, especially if associated with vessels of relatively large caliber (Figure 20.31D). Both can be found in the right ventricular apical region, and adipose tissue is found not uncommonly in woman and elderly patients. This should not be confused with arrhythmogenic right ventricular cardiomyopathy/dysplasia; clinical-pathologic correlation is essential for this purpose.

Ventricular perforation is identified by the presence of mesothelial cells (Figure 20.31E). Accumulations of fresh platelet- and fibrin-rich thrombus may be identified along the endocardial surface of biopsy fragments (Figure 20.31F). These form as a result of the repetitive placement of the bioptome along the endocardial surface and do not indicate chronic mural thrombi. A number of patterns of bioptome-induced tissue distortion or crush artifact can be observed in biopsy samples. The â€œhour-glassâ€• or â€œVictorian waistbandâ€• effect is caused by central constriction of the tissue by the bioptome mechanism (Figure 20.31G). A more problematic artifact is the

smearing of cytoplasmic and nuclear components of cells that yields strands of basophilic material (Figure 20.31H). In this setting, it may not be possible to distinguish the cell types (lymphocytes, endothelial cells, histiocytes, myocytes), and we do not attempt to evaluate these foci for allograft rejection or myocarditis. In some cases, procurement of additional leveled H&E-stained sections can provide less distorted foci in the deeper aspects of the biopsy sample. In our experience, immunohistochemical stains have not been consistent or helpful.

Summary

Because of the structural-functional nature of cardiac disease, the surgical pathologist should have a working knowledge of both anatomy and histology. Moreover, the alterations produced by the endomyocardial biopsy and the bioptome require familiarity with the myriad of tissue artifacts. With a practical understanding of these points, the evaluation of specimens ranging from endomyocardial samples to explanted hearts will be enhanced and the diagnostic information to clinicians more precise.

Serous Membranes

Darryl Carter

Lawrence True

Christopher N. Otis

Anatomy

The mesothelium lines the pleural, pericardial, and peritoneal cavities. Mesothelial cells on the serous surfaces appear as a simple or cuboidal epithelium, although they are of mesodermal origin. They are supported by a fibrous submesothelial layer, which becomes continuous with the outer layer of invested viscera. The serous membranes show functional differentiation according to their derivation from visceral or parietal mesoderm.

Because of space limitations, description of the gross anatomy of the mesothelium must be somewhat truncated, but some areas have functional differentiation that is reflected by their histologic features. The pleura is a continuous membrane that covers the chest wall and the lungs. The visceral pleura coats the entire pulmonary surface, including the major and minor fissures that divide the lung into lobes, whereas the parietal pleura extends over the ribs, sternum, and supporting structures and is reflected over the mediastinal structures on either side. Posteriorly in the

mediastinum, the two layers of parietal pleura are separated by a thin band of fibrovascular connective tissue. Superiorly, the cervical pleura is reflected into the retroclavicular area over the apex of the lung and is coated by a thickened layer of fibrous tissue and skeletal muscle; inferiorly, the diaphragmatic pleura represents its caudal extent. Anteriorly, the pleura is reflected over part of the pericardium. The posterior visceral pleura becomes continuous with the diaphragmatic pleura over the pulmonary ligament. The heart and great vessels lie in the pericardium, which is lined by a continuous layer of mesothelium. The visceral (epicardial) side is connected to the myocardium, and the parietal (pericardial) layer rests on a dense fibrous tissue layer containing branches of the internal mammary and musculophrenic vessels, descending aorta, and branches of the vagus, phrenic, and sympathetic nerves. The thoracic surface of the pericardium is coated with parietal pleura.

The peritoneum is a nearly continuous membrane lining the potential space between the intra-abdominal viscera and the abdominal wall. In the female, it is normally interrupted by the lumina of the fallopian tubes. Anatomically, it is more complex than either the pleura or pericardium. The parietal layer covers the abdominal wall, diaphragm, anterior surfaces of the retroperitoneal viscera, and the pelvis. The visceral peritoneum invests the intestines and other intra-abdominal viscera. The elongated structures in which the parietal and visceral layers come together are the mesentery, which contains blood vessels, lymphatics, lymph nodes, and nerves.

The greater omentum is a double sheet with four layers of mesothelium between which there are numerous blood vessels and adipose tissue, which may be abundant; lymphatics and lymph nodes are less prominent than in the

mesentery. The peritoneal cavity is grossly divided into the greater sac over the intestines, the retrogastric lesser sac, right

and left retrocolic areas, and the pelvis. Several outpouchings of peritoneum are often seen in pathology laboratories. Inguinal hernia sacs are pouches of parietal peritoneum, often invested with fibrous tissue and occasionally with skeletal muscle, which have been pushed through the abdominal musculature into the inguinal canal. Umbilical or ventral hernias are also outpouchings of peritoneum, but the specimens received by pathologists after surgery for their repair are usually preperitoneal fibroadipose tissue pushed ahead of the parietal peritoneum rather than mesothelium itself.

The scrotum acquires a lining of parietal mesothelium, the processus vaginalis, into which the testes descend during the seventh month of gestation. A mesothelial layer forms the surface of the tunica vaginalis. Distention of this mesothelial sac on the tunica vaginalis results in a hydroceleâ€”communicating with the peritoneal cavity when congenital but noncommunicating in acquired hydroceles. The sac of an inguinal hernia communicates with the peritoneal cavity and not with the mesothelium-lined space of the scrotum. Both hernia and hydrocele sacs are capable of a wide range of reactive changes.

Functional Anatomy

The functional anatomy of the pleura has been described by Sahn (1) and Pistolesi et al. (2). The pleura is a continuous membrane surrounding a space that normally contains approximately 10 mL of clear colorless fluid. The surface is lined by a single layer of mesothelial cells anchored to a basement membrane that lies on layers of collagen and elastic tissue containing vascular and lymphatic vessels. The lining mesothelial cells are 16 to 40 Âµm in diameter, have rounded nuclei, usually containing a nucleolus, and a relatively large amount of cytoplasm. Although the visceral and parietal pleurae are opposing parts of the same continuous membrane, there are major functional differences between them.

The human visceral pleura is thick relative to that seen in some other mammals (3) and is similar to that of horses, cattle, sheep, and pigs (4). It has an arterial blood supply from the bronchial arteries, with a venous return that passes first into the pulmonary veins and then into the left atrium except for certain hilar regions that are drained by bronchial veins into the right atrium. The lymphatics that pass through the visceral pleura are the superficial layer of pulmonary lymphatics with extensive connections to the peribronchial, perivascular, and interlobular lymphatic spaces and lymphoid tissue (5). Blood and lymphatic vessels are invested by collagen and elastic fibers, which are divided into two layers: an external elastic lamina supporting the mesothelial cells and an internal layer investing the vessels and becoming continuous with the pulmonary interstitium (Figures 21.1,21.2). Histologic identification of the layer of elastin has been considered clinically important in determining pleural invasion, which is significant for staging of primary lung cancer (6), but elastin may also be interrupted in nonneoplastic conditions that scar the pleura. In sheep, and probably in humans, the thickness of the external layer increases in both craniocaudal and ventrodorsal directions (7). The visceral pleura is innervated by branches of the vagus nerves and sympathetic nerve trunks.

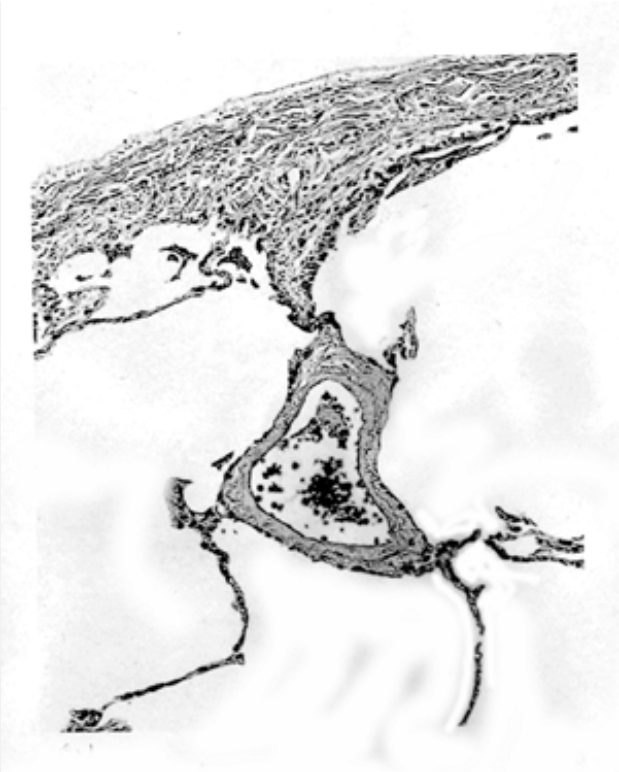

Figure 21.1 Visceral pleura. The mesothelial cells on the surface are thin, in profile, and not apparent. The dense submesothelial layer from the posterior surface of the left lower lobe is composed of collagen and elastin. It extends into adjacent pulmonary interstitium and around pulmonary vessels.

The parietal pleura is anatomically, histologically, and functionally different. Although the single layer of mesothelial cells that lie on the surface of the parietal pleura are cytologically similar to those that form the continuous membrane over the visceral pleura, they are interrupted by stomata which range in size from 2 to 12 Âµm in diameter (8,9,10,11,12). The stomata communicate directly with lymphatic lacunae that are surrounded by bundles of collagen and drain directly into intercostal lymphatics and then into the mediastinum, where they are particularly dense along the

retrocardiac surface (13,14,15,16). Fluid and particulate matter extravasated from the lung are collected in these lymphatics and passed into the mediastinum, where the mesothelium covers collections of macrophages called Kampmeier foci (17,18). The arterial and venous blood supply to the parietal pleura is from the intercostal

vessels. The thickness of the fibroelastic layer investing the parietal pleural lymphatics is relatively constant and considerably less than that of most of the visceral pleura, suggesting that it serves as a membrane across which fluid may diffuse. The parietal pleura is innervated by branches of the intercostal nerves, which are activated in pleurisy. The structures of the peritoneum are similar to those of the pleura (19,20).

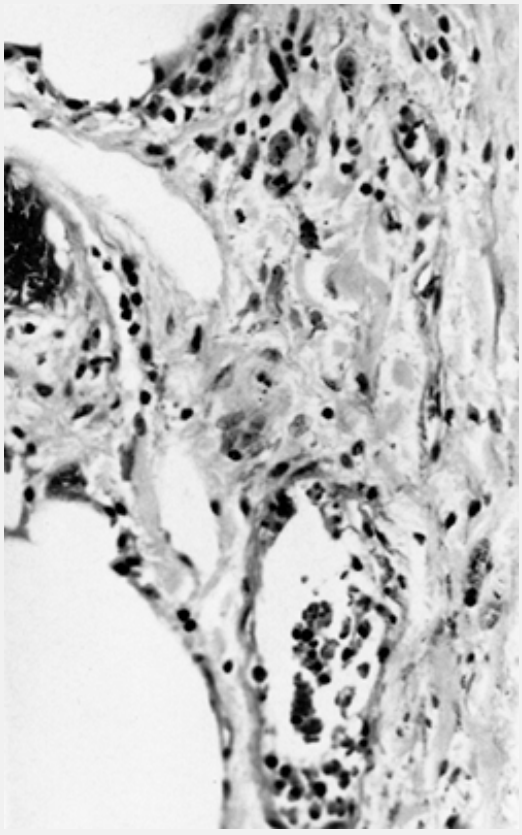

Figure 21.2 Visceral pleura. Capillaries are prominent. The lymphatics are dilated but deeply placed and entirely invested by the submesothelial layer.

Functions of Serous Membranes

The serous membranes serve as selective barrier for fluid and cells. A small volume of fluid is required for capillary action to facilitate adherence of visceral and parietal pleurae as the lungs and chest wall expand and contract. Elements of the serous membranes regulate fluid interchange to keep this fluid at a mimimal level to prevent compromise of the lung volumes. Control appears to be at the capillary level because fluid is freely diffusible through mesothelium and submesothelial stroma. Another level of control results in the relatively low protein content (1.0 to 1.5 g/dL) of pleural fluid. The point of protein regulation is unknown, although speculation is that it is at the level of mesothelial microvilli (21). In the thoracic cavity, the direction of flow appears to be via diffusion from capillaries of both visceral and parietal pleurae, with resorption primarily through parietal pleural capillaries. Turnover is estimated at 0.7 mL/hr (21) (Figure 21.3). Small molecules (less than 4 nm in diameter) diffuse through the intercellular spaces and junctions between mesothelial cells. Loss of control results in serous effusions such as those seen in congestive heart failure.

Larger molecules, up to 50 nm in diameter, are transferred across the mesothelium by pinocytotic uptake and transcellular transport. Larger structures, such as cells in bloody effusions, are transported via the stomata and â€œcrevices.â€• Loss of control of these mechanisms results in accumulations of exudative pleural fluid. Mesothelial cells express the secretory component of IgA, which is otherwise limited to surfaces with direct environmental contact (22). The glycoprotein-rich pleural fluid acts as a lubricant

to minimize friction between visceral and parietal pleurae. The site of synthesis and mechanisms of control of the carbohydrate-rich fractions of the pleural fluid are unknown. The submesothelial connective tissue distributes mechanical

forces from the pleura uniformly throughout the lungs. Such a redistribution of forces is not required of the abdominal serosa. Both mesothelial cells and fibroblasts contribute to collagen synthesis.

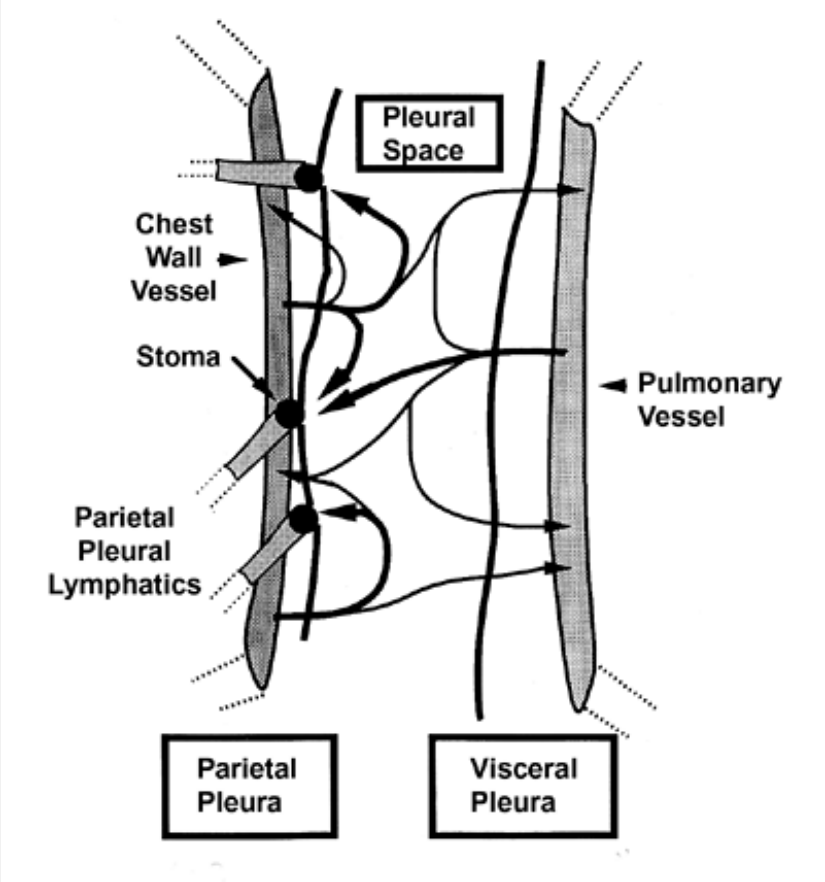

Figure 21.3 Model of the dynamics of pleural fluid formation. A transudate from capillaries in visceral and parietal pleura is partly reabsorbed by those capillaries and the rest diffuses into the pleural space, where it is resorbed via stomata into

parietal pleural lymphatics.

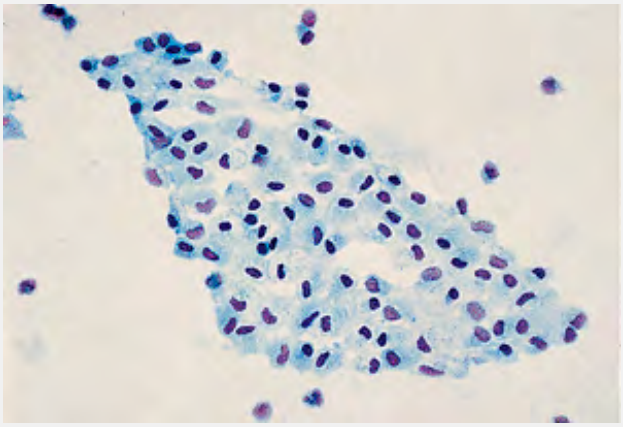

Figure 21.4 In this peritoneal wash specimen, a sheet of normal mesothelial cells has been detached.

Mesothelial Cells

Morphology

Normal mesothelial cells are rarely seen in histologic sections but may be evident in cytologic preparations of peritoneal washes taken during a laparotomy (Figure 21.4). When thus visualized, they have abundant clear cytoplasm with crisply defined cell borders, small and centrally placed nuclei with a homogeneous chromatin pattern, and usually without a nucleolus (Figure 21.5).

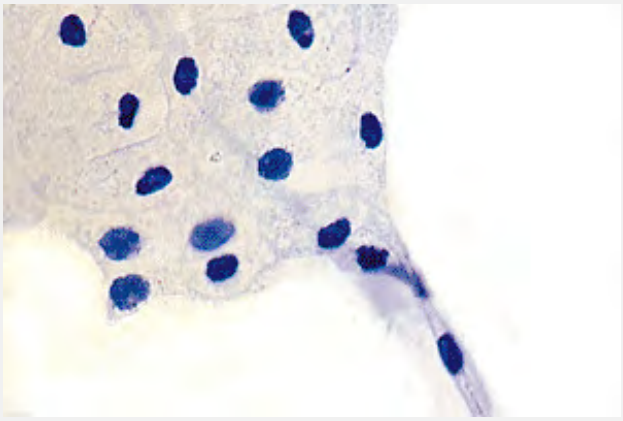

Figure 21.5 At higher magnification, a sheet of relatively normal mesothelial cells with abundant, clear cytoplasm and crisply defined cell borders. The centrally placed nuclei are small and have a homogenous chromatin.

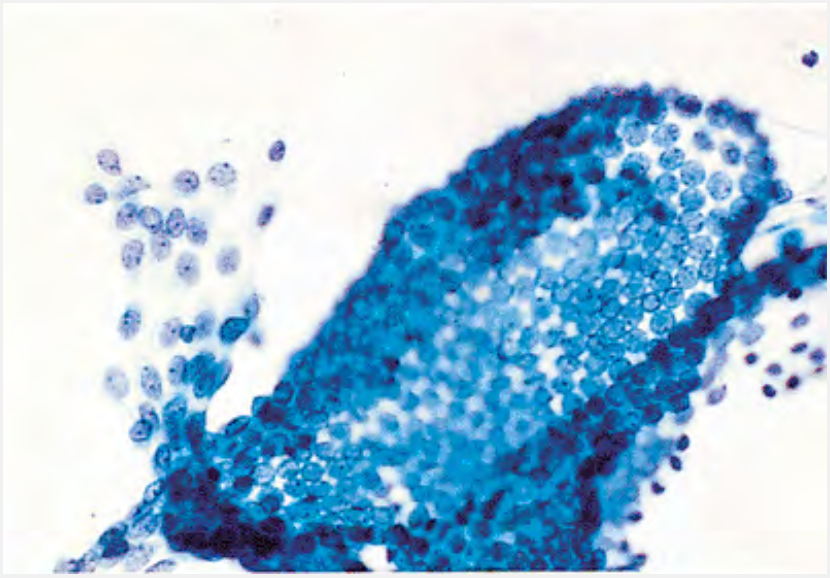

Figure 21.6 This detached fragment of reactive mesothelium shows an intact mesothelial layer with cells in two phases of the reactive process shown in Figures 21.7 and 21.8.

In a variety of reactive processes, the mesothelial cells undergo markedly proliferative and hyperplastic changes. A relatively abundant cytoplasm is maintained, but the cell borders are less sharply defined. The nuclei are larger, both absolutely and relatively, the chromatin pattern is more hyperchromatic, and nucleoli are often present and prominent (Figures 21.6,21.7,21.8,21.9).

As the hyperplastic changes in the reactive mesothelial cells progress, cell groups become smaller, and individual cells predominate. When clustered, reactive mesothelial cells present an irregular outside border. The nucleus, and especially the nucleolus, may enlarge dramatically, but the nuclei are similar in size, shape, and pattern from cell to cell. Mitotic figures may be seen. The cytoplasm may become multivacuolated as the cells degenerate and imbibe fluid (Figures 21.10,21.11,21.12,21.13,21.14,21.15,21.16,21.17,21.18).

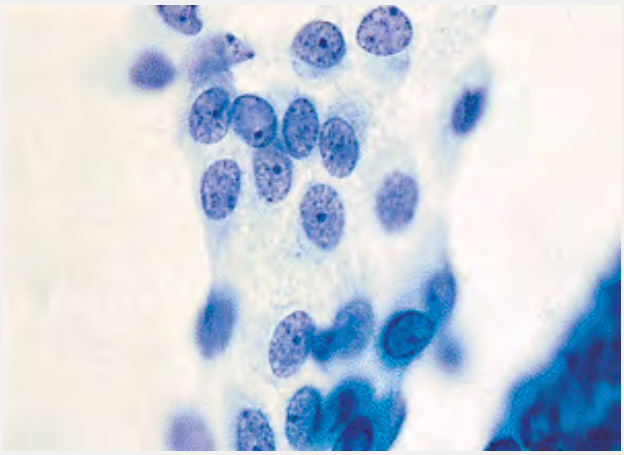

Figure 21.7 These reactive mesothelial cells from the left side of Figure 21.6 have abundant cytoplasm, and the nuclei are larger with a more vesicular chromatin pattern. Nucleoli are present but not prominent.

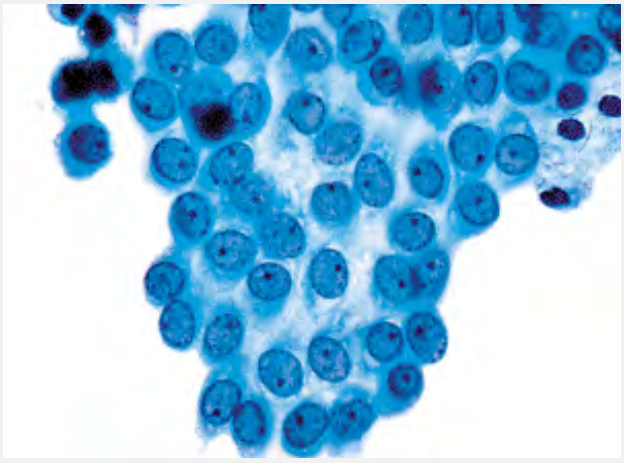

Figure 21.8 The more reactive mesothelial cells from the right side of Figure 21.6 have larger nuclei, a more vesicular chromatin pattern, and more prominently featured nucleoli. Less cytoplasm is present.

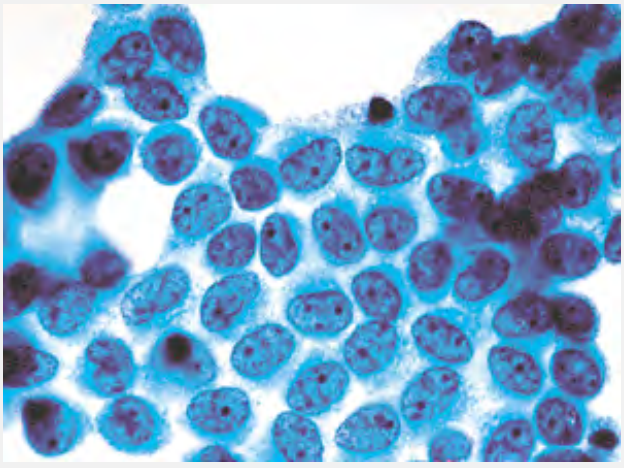

Figure 21.9 In this more reactive sheet of mesothelial cells,

the cytoplasm has grown smaller and the nuclei relatively larger. Irregularity of the chromatin pattern is more prominent.

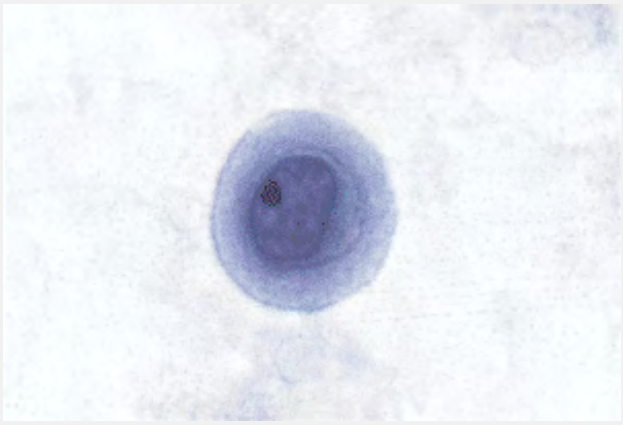

Figure 21.10 This individual reactive mesothelial cell has a restricted amount of cytoplasm and a relatively large nucleus with a nucleolus. The cell border is highly irregular and quezzy, suggesting the presence of the numerous elongated microvilli, which are evident on electron microscopy (see Figure 21.24). The cytoplasm is divided into an inner denser layer and an outer less dense layer. Ultrastructurally, the inner more dense layer corresponds to the presence of intermediate filaments with the characteristics of keratin (see Figure 21.25).

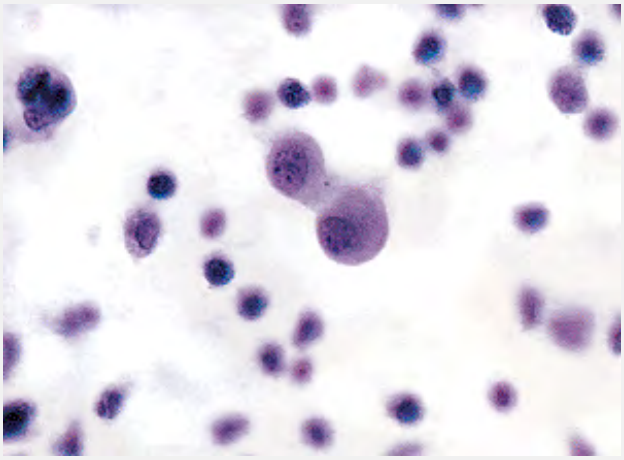

Figure 21.11 Mesothelial reaction is frequently associated with inflammatory cells. These reactive mesothelial cells are joined in pairs. Each is several times the size of either neutrophils or lymphocytes.

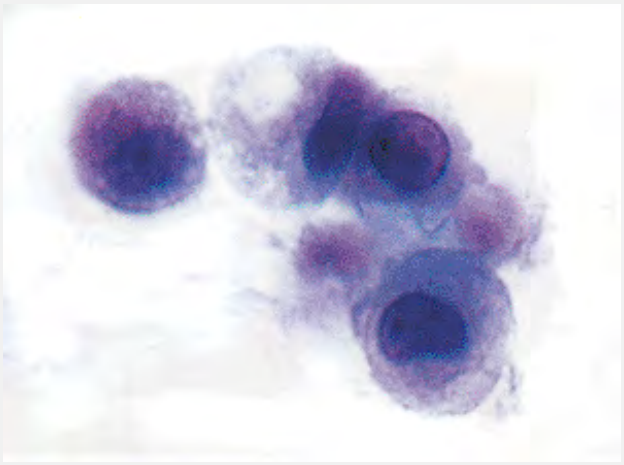

Figure 21.12 These reactive mesothelial cells are loosely joined together. The uppermost cell has a vacuole in the cytoplasm, which could be either a vesicle or an intracytoplasmic lumen.

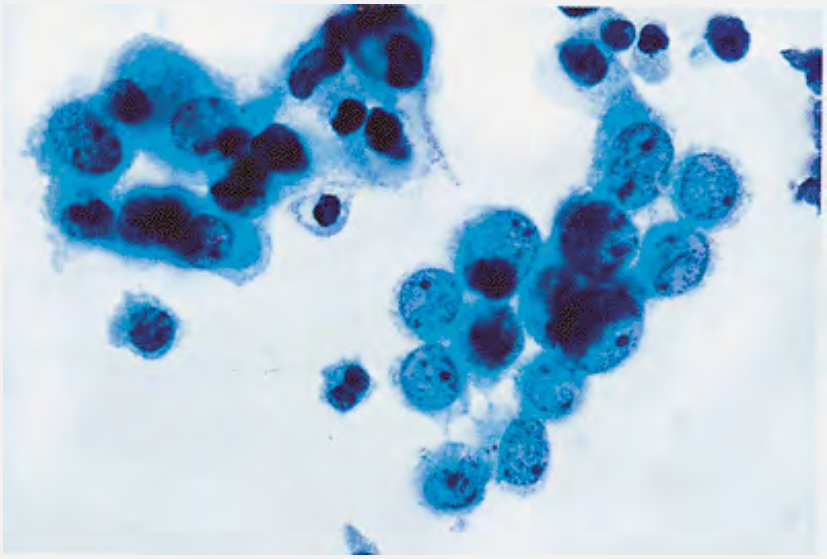

Figure 21.13 When reactive mesothelial cells are in groups, an irregular or â€œknobbyâ€• outside border is formed. Acini form a smooth outer border.

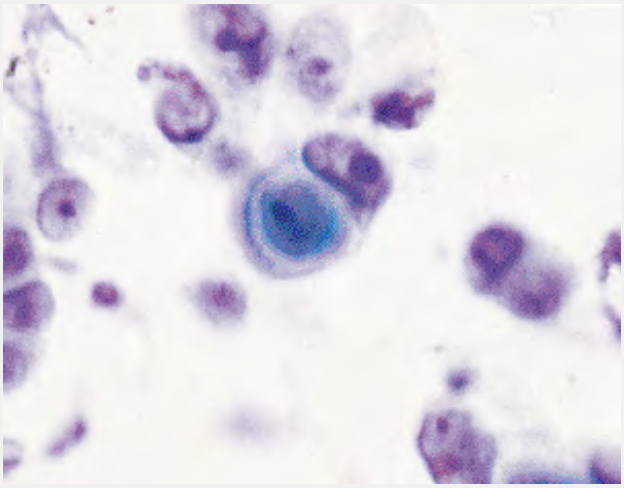

Figure 21.14 Occasionally, very reactive mesothelial cells may show cellular interactions similar to that of a keratin pearl.

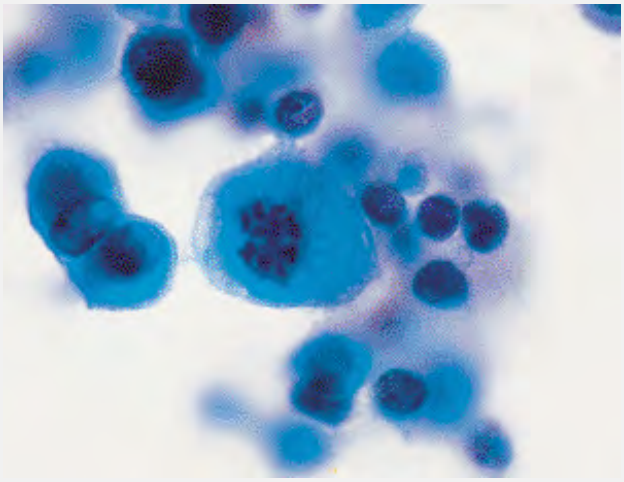

Figure 21.15 Mitotic figures may be seen in the proliferating cells of reactive mesothelium.

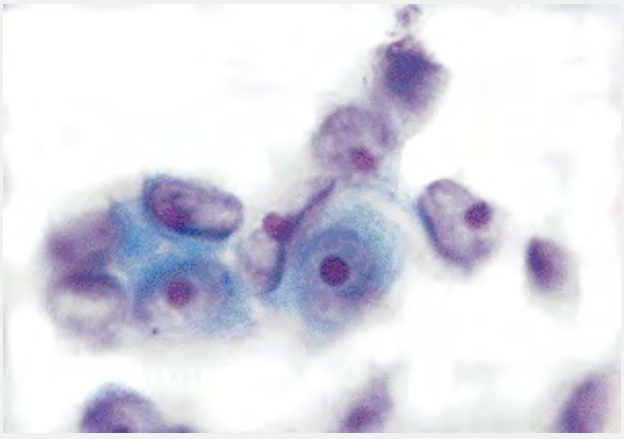

Figure 21.16 Markedly reactive mesothelial cells have large vesicular nuclei with a prominent nucleoli.

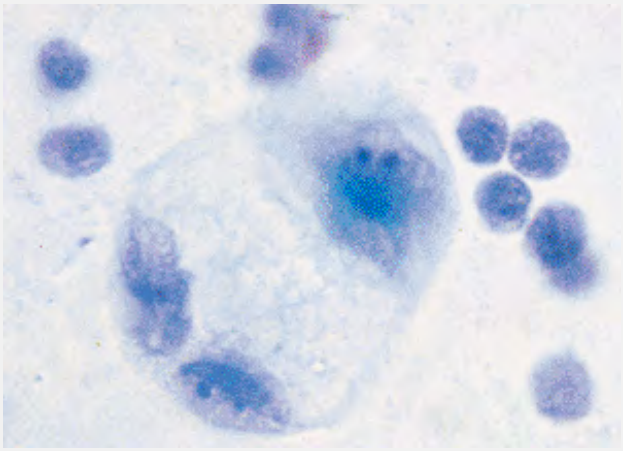

Figure 21.17 Reactive mesothelial cells may degenerate and swell. These three cells have abundant multivacuolated cytoplasm and the large nuclei of the reactive mesothelial cells.

Histochemistry

Histochemical stains have provided information about mucoprotein content of the mesothelium. Negativity for the periodic acid-Schiff (PAS) reaction is evidence that mesothelial cells lack significant quantities of neutral mucoproteins. In contrast, positivity for histochemical stains that detect negative groups, such as the positively charged dye Alcian blue, is evidence of acid mucoproteins. That the intensity of staining reactions for acid mucosubstances is diminished by preincubating the tissue sections in hyaluronidase is evidence that at least some of the terminal hexose groups of the mucosubstances are either hyaluronic acid or

chondroitin sulfate (Figure 21.19). Furthermore, the fact that histochemical mucin is decreased, but not abolished, by incubating cells in neuraminidase prior to histochemical

staining is evidence that some of the terminal carbohydrate groups are sialated (23). MacDougall et al. (24) have documented that neoplastic mesothelial cells may stain with mucicarmine.

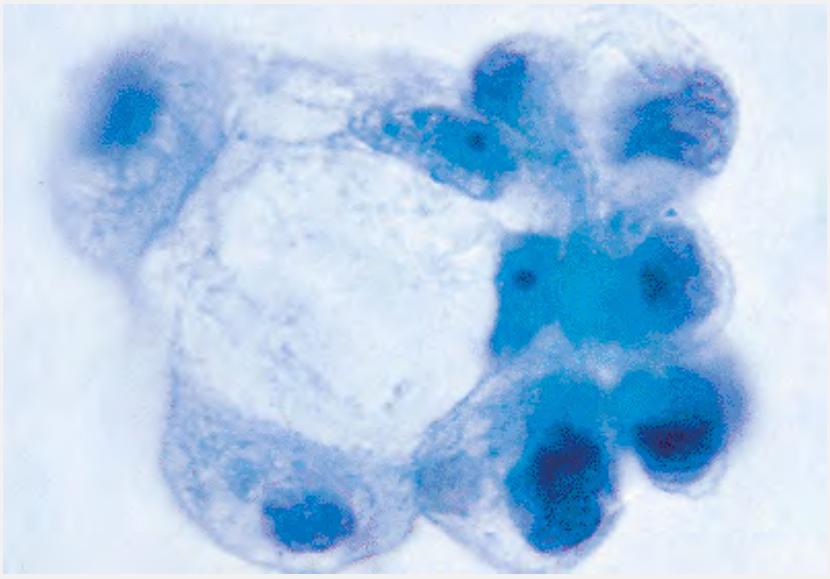

Figure 21.18 When markedly reactive mesothelial cells form irregular groups and combine with degenerating forms, they may mimic the appearance of a mucin-producing adenocarcinoma.

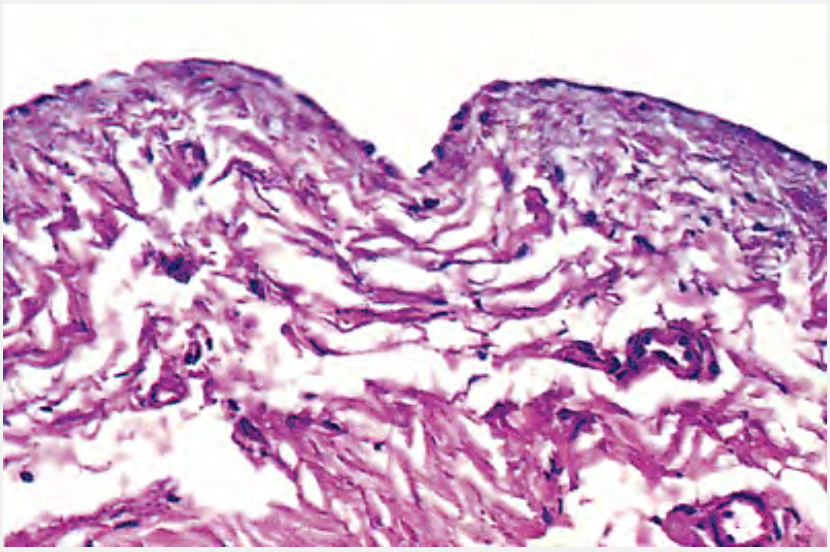

Figure 21.19 Alcian blue stain of serosal membrane. Note staining of both mesothelium and of the matrix proteins, which contain abundant acid mucoproteins.

The types of terminal carbohydrate groups of membrane proteins and lipids can also be characterized with lectins, which have specific and discrete ranges of sugar group affinities. Concanavalin A mesothelial cell reactivity indicates the presence of terminal groups that are either Î±-mannose or Î±-glucose.

Immunohistochemistry

Immunohistochemistry is the most commonly employed method for demonstrating mesothelial differentiation. Mesothelial cells preferentially express a group of so-called mesothelial markers (calretinin, cytokeratin 5/6, WT-1, HBME-1, thrombomodulin, and D2-40) relative to so-called epithelial markers (CEA, CD15, MOC-31, BER-EP4, B72.3, and TTF-1). However, overlap in the expression of any single marker has led to the use of a panel of antibodies to distinguish epithelium and, hence metastatic

carcinoma, from reactive mesothelium.

Calretinin, a calcium-binding protein of 29 kDa with similarity to S-100 protein, is found in both the nucleus and cytoplasm of reactive and neoplastic mesothelium but is also found in some adenocarcinomas (25,26,27,28) (Figure 21.20). Cytokeratin 5 is found in the cytoplasm of most mesothelial cells and squamous cell carcinomas, but few adenocarcinomas (29); WT-1, a product of the Wilms' tumor gene, is found in the nucleus of reactive and neoplastic mesothelium and in ovarian surface epithelium and tumors derived therefrom (30). Thrombomodulin, a transmembrane glycoprotein, gives a membranous stain in about half the mesotheliomas but also in some adenocarcinomas. Mesothelial cells also express mesothelin, epithelial membrane antigen (EMA), N-cadherin, E-cadherin, and vimentin (31). Recently, D2-40 (a marker of lymphatic epithelium) has been reported to identify mesothelial cells with a high sensitivity, but it also marks ovarian serous carcinoma (32).

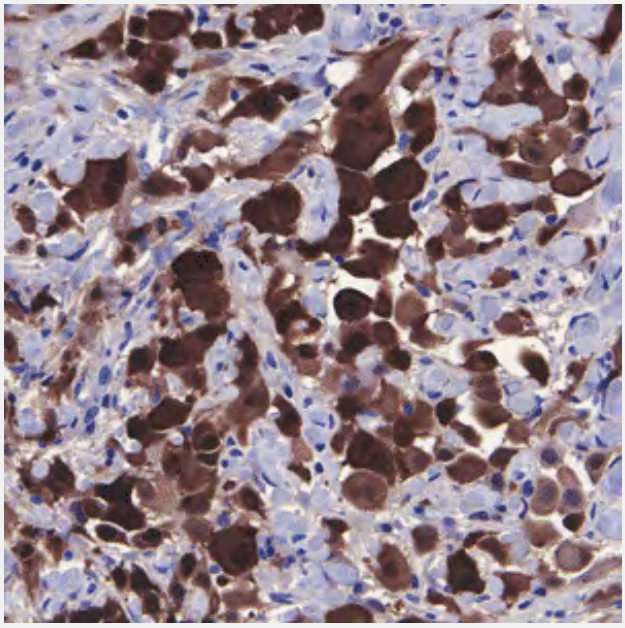

Figure 21.20 Immunohistochemical staining of mesothelial cells for calretinin. Note the nuclear and cytoplasmic staining.

Mesothelial cells usually lack the glycoproteins detected by antibodies to CEA, MOC-31 and BER-EP4 and the determinant detected by Leu-M1 (CD15) (33,34,35,36). Latza et al. (37) and Sheibani et al. (38) reported that BER-EP4 was used to distinguish malignant epithelium (adenocarcinoma) from malignant mesothelioma, but Gaffey et al. (39) and Otis (40) reported BER-EP4 immunoreactivity in high proportions of both benign and malignant mesothelial tumors, as well as adenocarcinomas. The tissue specific nuclear transcription protein TTF-1 is important in embryogenesis of thyroid and lung and is found in nuclei of pneumocytes and many adenocarcinomas of the lung but not in mesothelium (41).

Overlap between reactive and neoplastic mesothelium in the expression of even a panel of antibodies leaves only the demonstration of invasion of parietes or organs to confirm the diagnosis of malignant mesothelioma in most cases. The diagnosis of mesothelioma-in-situ requires demonstration of invasive mesothelioma elsewhere in the same specimen or in a subsequent specimen.

Nonproliferating mesothelial cells express both vimentin and a variety of keratins (K7 of 55 kDa, K8 of 53 kDa, K18 of 44 kDa, and K19 of 40 kDa) that can be detected with monoclonal antibodies immunoreactive with the small, acidic, type I keratins (42) (Figures 21.21,21.22).

Mesothelium does not express cytokeratin 20, using monoclonal antibodies (43). These keratins are distinct from those of epithelia, including the epidermis, glandular epithelia, and transitional epithelium (44). Ovarian epithelial tumors express a

spectrum of keratins similar to that of mesothelium (44).

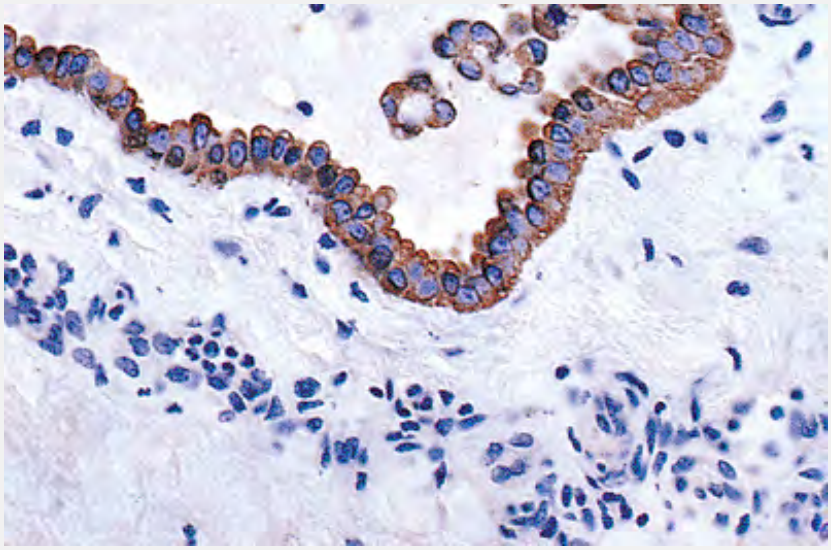

Figure 21.21 Keratin expression by mesothelium and detached mesothelial cells, demonstrated by a mixture of monoclonal antikeratin antibodies (AE1/AE3). Note that the immunohistochemical pattern of staining is similar to the distribution of intermediate filaments seen at the ultrastructural level.

The plasticity of the immunophenotype of mesothelial cells is demonstrable in abnormal states. Although mesothelium normally lacks sex steroid receptors, reactive mesothelium adjacent to endometriosis expresses focal immunoreactivity for estrogen and progesterone receptors (45). Furthermore, reactive mesothelial cells can express the muscle cell cytoskeleton proteins desmin and muscle-specific actin (46). There is experimental evidence that the pattern of intermediate filament expression by mesothelial cells is dependent on shape and cell-cell interaction. Induction of a spindle morphology inhibits keratin synthesis. In contrast, induction of an epithelioid morphology (for example, with

retinoids) stimulates keratin synthesis and inhibits vimentin synthesis; the ability of cells to respond in this manner also depends on the presence of cell-cell interactions (47). The pattern of intermediate filament expression by intact mesothelium has not been analyzed in such detail (Figures 21.20,21.21).

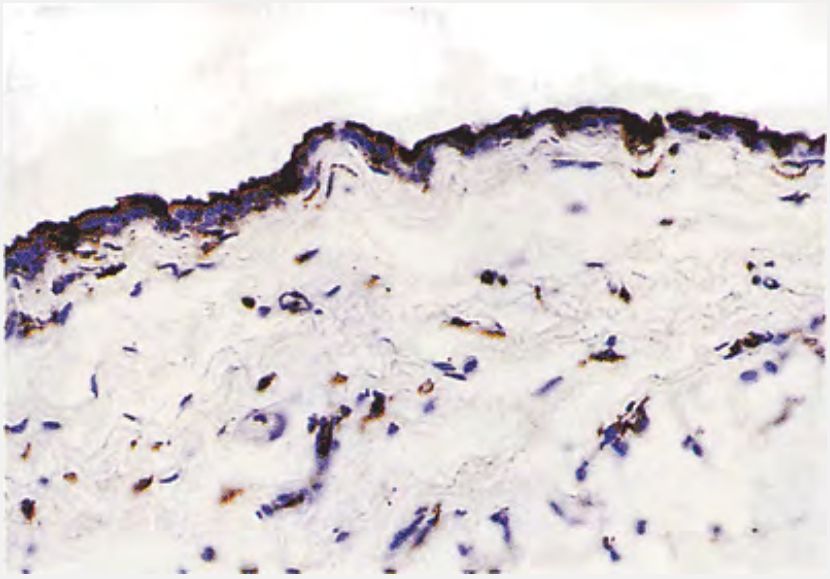

Figure 21.22 Vimentin immunoreactivity of mesothelial cells and fibroblasts.

Ultrastructure

Numerous long microvilli (Figures 21.23,21.24), measuring up to 3 Âµm in length and 0.1 Âµm in diameter, are present and are more numerous in caudal portions of the parietal pleura and in the visceral pleura. The other organelles found in mesothelial cells are not specific for them. Junctions of all types are foundâ€”tight junctions that serve as a barrier to certain molecules, gap junctions for cell-cell transport, and desmosomes for cell-cell adherence. Intermediate filaments are somewhat prominent;

although they do not aggregate into bundles, they are often arranged in a perinuclear, circumferential distribution (Figures 21.25,21.26).

Submesothelial Layer

Normally, the submesothelial layer contains few cells, and most of these are fibroblasts. Much of the submesothelial layer is composed of collagen, elastin, and other extracellular proteins. During reactive processes, the submesothelial layer may become much more prominent as cells proliferate there.

Histochemistry

The main constituents of the submesothelial tissue are glycosylated proteins, including glycosaminoglycans. Because the majority of carbohydrate groups are negatively charged (as a result of an abundance of hyaluronic acid and other acidic groups), this extracellular matrix stains in a manner characteristic of acidic mucoproteins; that is, it is Alcian blueâ€“positive (Figure 21.19). That staining intensity can be diminished by treating the section with hyaluronidase before histochemical staining is evidence that hyaluronic acid groups are responsible, in large part, for the intensity of staining (21).

Immunohistochemistry

The antigens of the submesothelial layer can be categorized into matrix constituents and antigens of the mesenchymal cells. The extracellular matrix materials are those typical of most connective tissue. Types I and III collagen and fibronectin are abundant. Elastin fibers are plentiful and basement membrane proteins, including type IV collagen and laminin, are found at the mesothelial cell-stromal interface.

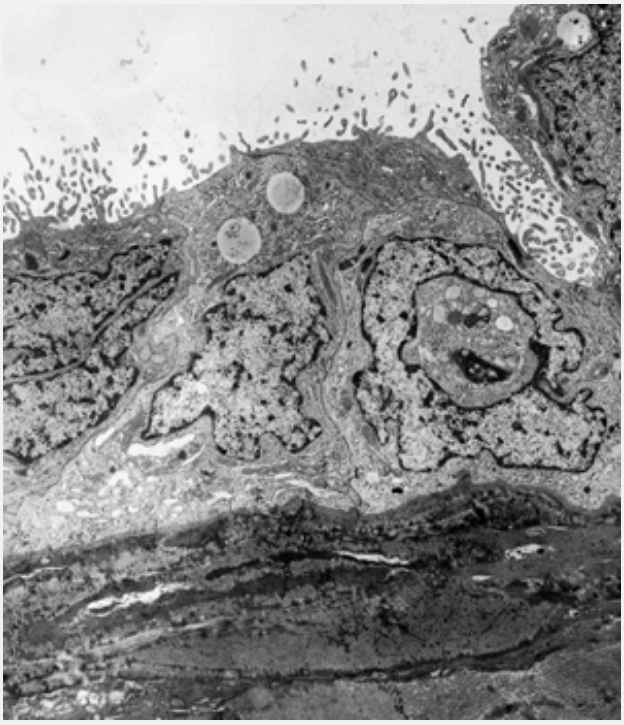

Figure 21.23 Mesothelial cells with their elongated microvilli, cover the surface of the serosa. The subjacent stroma is composed of collagen and fibroblasts.

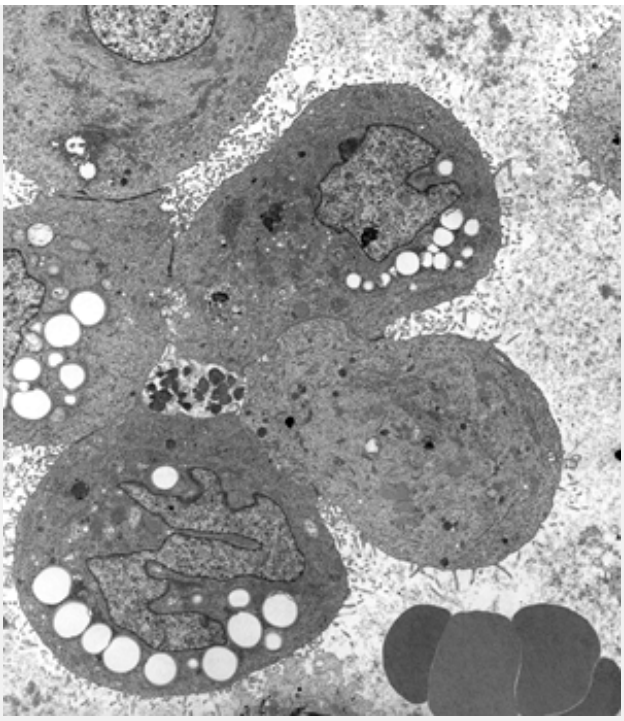

Figure 21.24 EM of a cluster of detached mesothelial cells within a pleural effusion. Cytoplasmic lipid droplets impart a vacuolated appearance to some cells. Note the long microvilli, which impart the â€œfuzzyâ€• appearance to these cells at the light microscopic level.

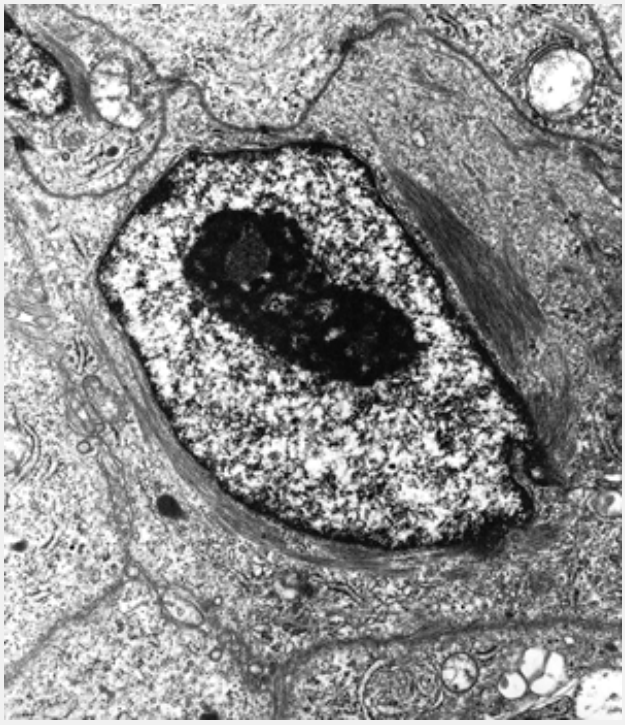

Figure 21.25 Ultrastructure of a mesothelial cell. Intermediate filaments are arranged in a perinuclear distribution.

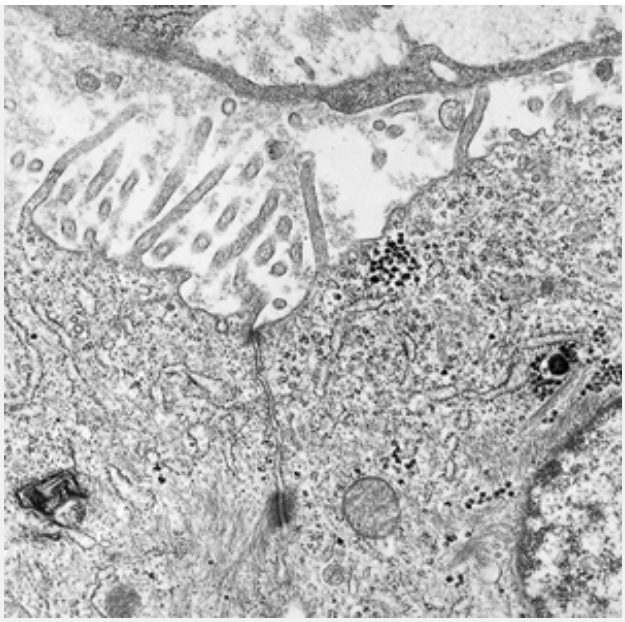

Figure 21.26 High magnification of the luminal aspect of two mesothelial cells. Note the small tight junction, subjacent desmosome, and the cytoskeletal filaments within the microvilli.

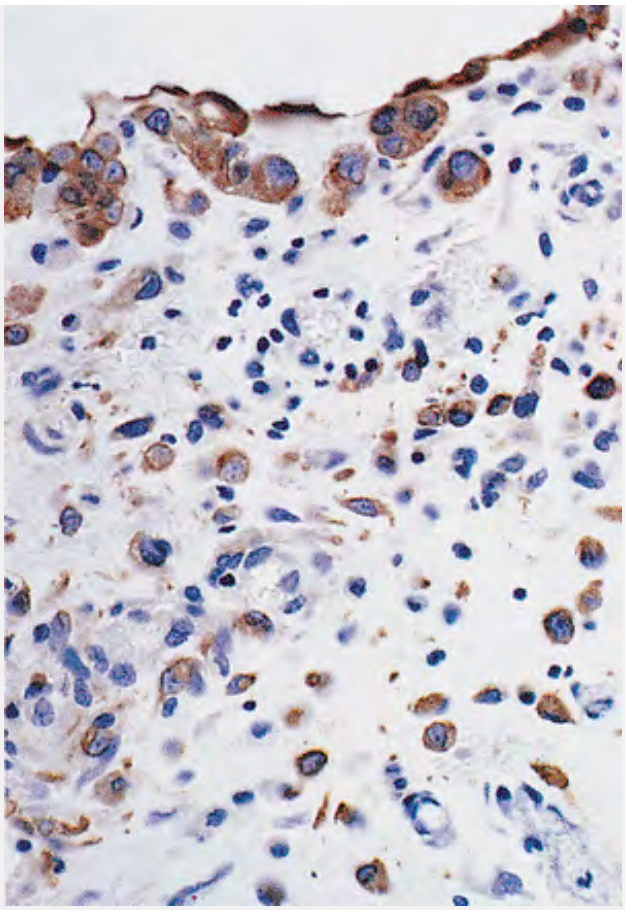

Figure 21.27 Keratin (AE1/AE3) immunoreactivity of proliferating submesothelial spindle cells.

Proteoglycans are plentiful. The pattern of intermediate filament expression by the submesothelial stromal cells varies with their state of â€œexcitation.â€• Quiescent cells contain only vimentin, but stromal cells in regions of injury or inflammation also synthesize keratin detectable with antibodies to type I keratins (47) (Figure 21.27).

Relationship of Mesothelial and Submesothelial Cells

The submesothelial mesenchymal cell population serves as the anchoring substratum for the mesothelium. Both mesothelial and submesothelial cells contribute to the extracellular proteins that comprise the matrix. Up to 3% of the total protein synthesized by mesothelial cells are collagens and laminin.

A controversial topic is whether submesothelial cells serve as a source of mesothelial cell renewal, either in normal development, which is the basis for regarding mesothelial cells as mesodermal in origin, or in conditions of rapid mesothelial cell turnover. Earlier ultrastructural and kinetics studies, using thymidine incorporation, suggested that the stromal cells contribute to the repopulation of denuded mesothelium (48,49). Consistent with this scheme is the observation that submesothelial cells, when stimulated to proliferate, synthesize keratin and assume a more epithelioid morphology. However, later studies have demonstrated that healing of injured serosa progresses by multiplication and migration of mesothelial cells at the edges of the wounded area (50).

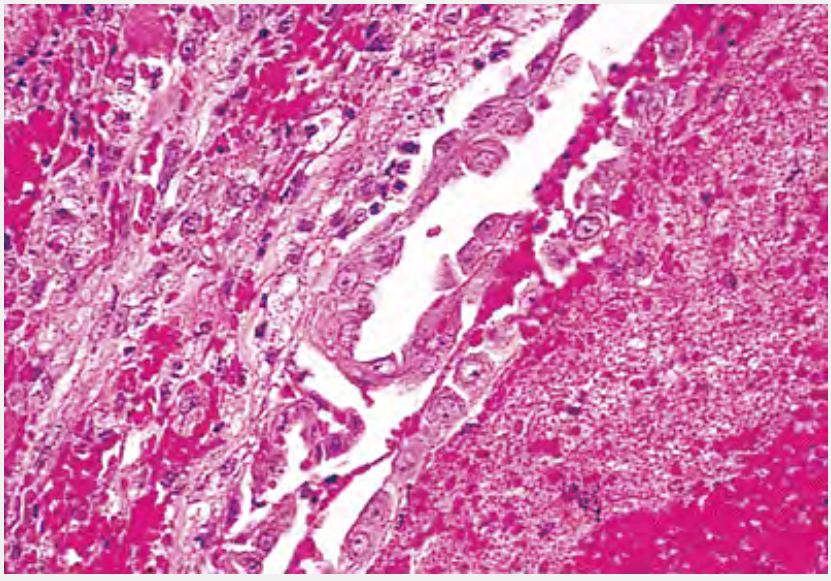

Figure 21.28 In a variety of reactive processes, the

mesothelial cells lining serosal surfaces undergo markedly proliferative and hyperplastic changes. This is a section through the pleura of a patient with severe active rheumatoid arthritis.

Reactive Mesothelium

The capacity for mesothelial and submesothelial cellular elements of serous membranes to react and proliferate to produce morphologic patterns mimicking neoplasia is well known and frequently a source of diagnostic confusion (51,52). The process may be diffuse or localized (Figure 21.28). Mesothelial hyperplasia in herniorrhaphy specimens is well described (53) and may be nodular, demonstrate nuclear atypia and frequent mitotic figures, and be accompanied by spindle cell elements (Figures 21.29,21.30).

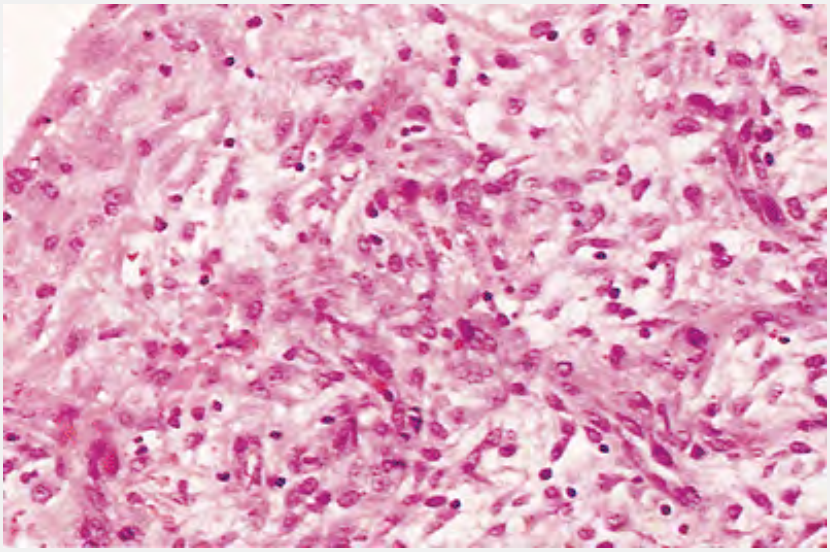

Figure 21.29 This photomicrograph is from a hernia sac of an 18-month-old boy. The reactive mesothelium is composed of proliferative epithelioid cells on the surface and subjacent

spindle-shaped cells that give the impression of proliferating fibroblasts.

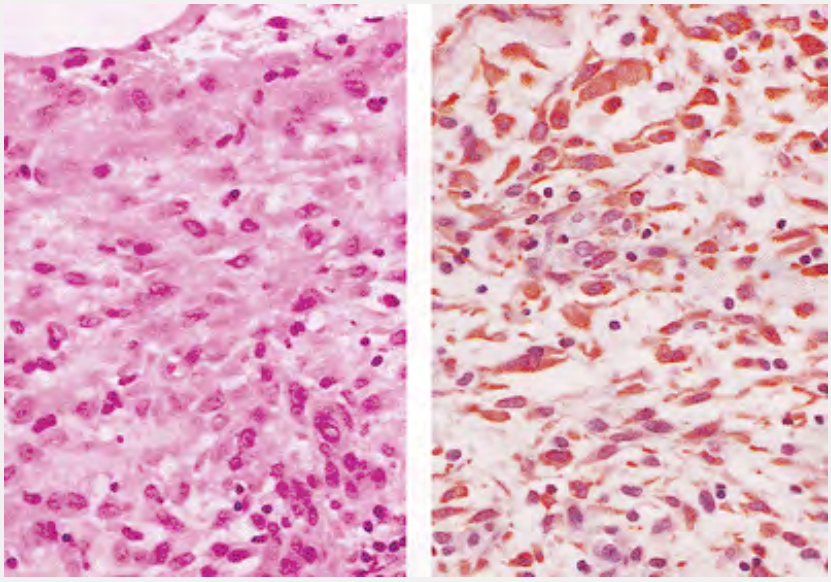

Figure 21.30 The reactive peritoneum in the hernia sac shown in Figure 21.29 (A). The immunohistochemical stain for keratin (AE1/AE3) (B) illustrates that both the surface lining mesothelial cells and the subjacent spindle-shaped cells are heavily decorated.

Reactive mesothelial cells in mediastinal lymph nodes have been reported by Brooks et al. (54) and Parkash et al. (55), although the mechanisms by which they enter lymphatics and survive in the sinuses of nodes are not known. This rare event may produce a difficult differential diagnosis. Clear demonstration of the mesothelial nature of these cells is necessary to exclude metastatic carcinoma. If the cells are shown to be mesothelial by electron microscopy or immunohistochemistry, it should be noted

that Sussman and Rosai (56) reported that mesothelioma may present as a lymph node metastasis. Therefore, follow-up may be required to make the distinction between reactive benign mesothelial cells and metastatic malignant ones (Figures 21.31,21.32).

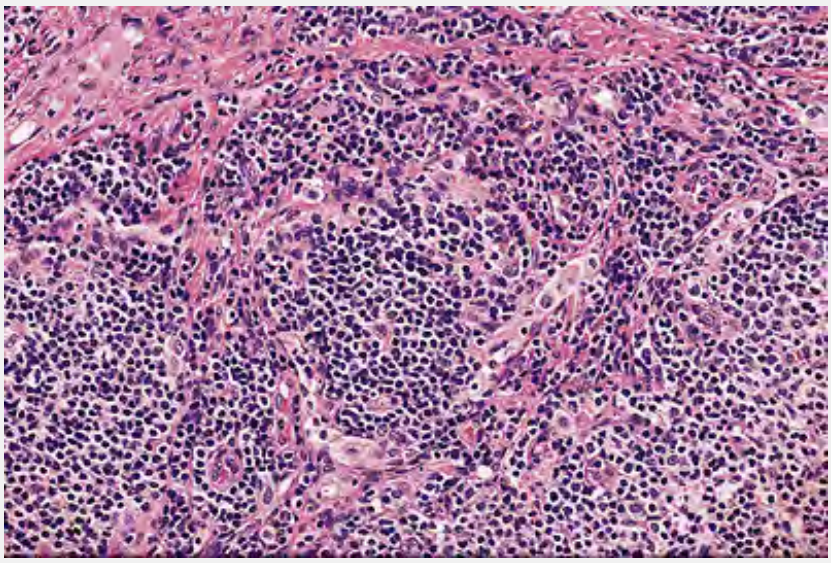

Figure 21.31 Internal mammary lymph node with large epithelioid cells in the sinuses found during coronary artery bypass graft surgery in a 61-year-old man. No pleural lesion was present.

An uncommon manifestation of mesothelial proliferation is the psammoma bodyâ€”a laminated calcific structure that most likely arises through concentric calcification following cell death. Psammoma bodies are usually nonspecific because they may be observed in inflammatory processes accompanied by mesothelial hyperplasia, malignant mesothelial neoplasia, or epithelial neoplasia (Figure 21.33).

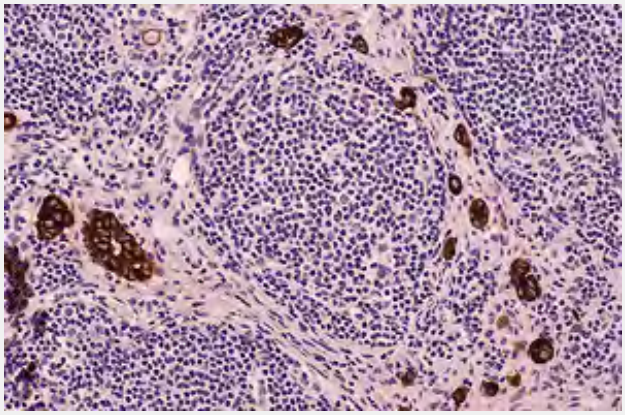

Figure 21.32 Immunohistochemical stain for keratin AE1/AE3 demonstrates the epithelioid cells that were negative for CEA, Leu-M1, BER-EP4, and B72.3 and hence are considered reactive mesothelial cells.

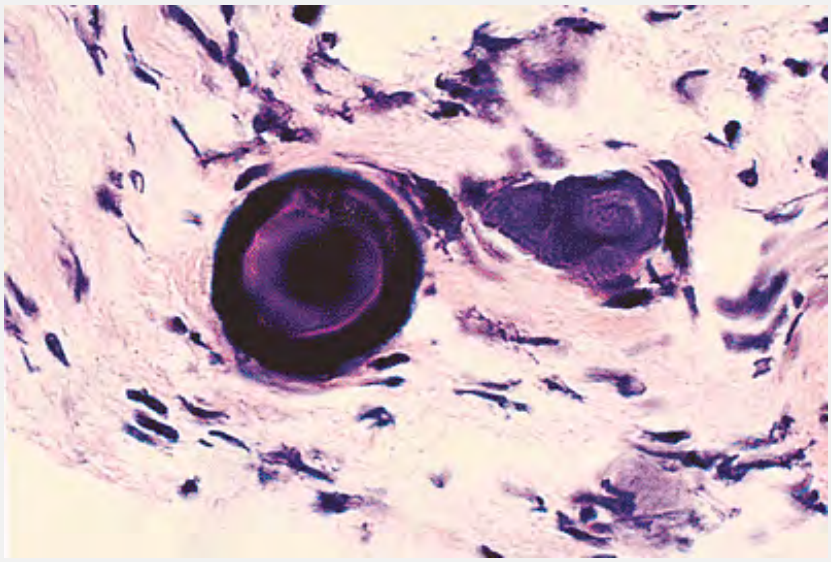

Figure 21.33 Psammoma bodies in the left pelvic peritoneum of a 58-year-old female.

Endosalpingiosis and Endometriosis

Epithelial elements may be observed in glandular arrangements throughout the peritoneum, omentum, and within lymph nodes. Such glandular structures were recognized in the early 1900s and misinterpreted by some as metastatic carcinoma, a mistake that is unfortunately still committed today. Endometriosis and endosalpingiosis were expounded upon by Sampson (57,58,59) earlier in this century, with reference to mechanisms of pathogenesis that are still debatable.

Endosalpingiosis refers to glandular spaces lined by epithelium similar to uterine tube epithelium, with three cell types (ciliated, secretory, and intercalated cells) (60) (Figure 21.34). On occasion, psammoma bodies are present. Periglandular stroma containing chronic inflammatory cells is separated from epithelium by PAS-positive basement membrane. Endosalpingiosis may be differentiated from endometriosis by the lack of endometrial stroma or evidence of stromal hemorrhage associated with endometriosis (57,60,61,62,63). This condition is seen exclusively in women and has been reported in 12.5% of omenta removed at surgery in females. A large proportion of these women have coexisting benign disease of the uterine tube (60). The origin of the glandular inclusions is debated but is most likely either related to the influence of mÃ¼llerian development on the peritoneal mesothelium (coelomic lining) or is a sequela of disease within the uterine tube resulting in extratubal growth of displaced tubal epithelium (60,62). Although definitive evidence of neoplasia arising in endosalpingiosis has not been documented (64), considerable difficulty may be encountered when differentiating extraovarian tumor implants removed in the setting of common epithelial ovarian tumors from endosalpingiosis with cellular atypia. Evaluation of the severity of epithelial atypia, mitotic

activity, the presence of ciliated cells, and the presence of invasive characteristics may aid in establishing malignancy in this setting (60). Metaplasia in endosalpingiosis may also be a source of diagnostic difficultyâ€”particularly mucinous metaplasia, which may be mistaken for metastatic mucinous adenocarcinoma (Figures 21.35,21.36).

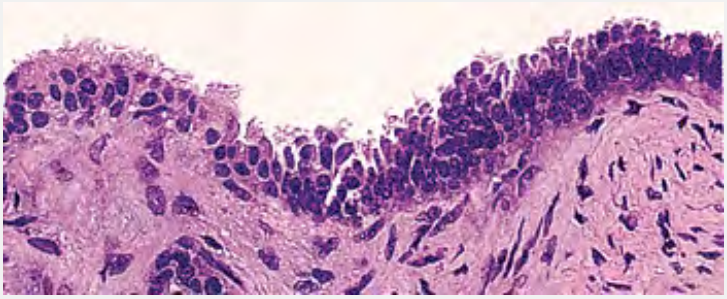

Figure 21.34 Endosalpingiosis involving the serosa of the uterus of a 56-year-old woman. Serous, intercalated, and occasional ciliated cells are present, but endometrial stroma is not.

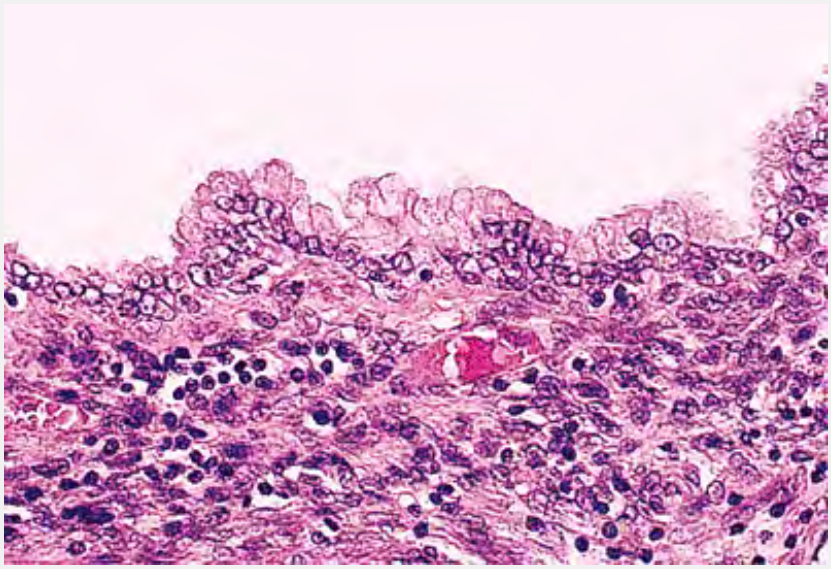

Figure 21.35 Endosalpingiosis involving the omentum contains cystic glands lined by mucinous epithelium with basally oriented nuclei and apical cytoplasm. Periglandular stroma contains mononuclear inflammatory cells.

Endometriosis may be defined by the presence of glands lined by endometrial-type epithelium surrounded by endometrial stroma, outside the uterine endometrial mucosa

and myometrium (64). The condition occurs most frequently in women of childbearing age. It may occur in a variety of body sites, ranging from the pelvic peritoneum to distant organs such as lung, kidney, and skin, but the most frequent site is the peritoneal lining of the pelvic organs (Figure 21.37). Although the histogenesis of endometriosis remains unclear, two general theories have been proposed. The ectopic growth of endometrial elements may result from displacement of endometrial tissue, whether through local means (such as entry of endometrium into the pelvis through the uterine tubes) or via vascular routes to distant organs (57,58).

Another possibility includes metaplastic change of the pelvic peritoneum along mÃ¼llerian lines of differentiation (65,66). Each mechanism may play a role in the histogenesis of endometriosis.

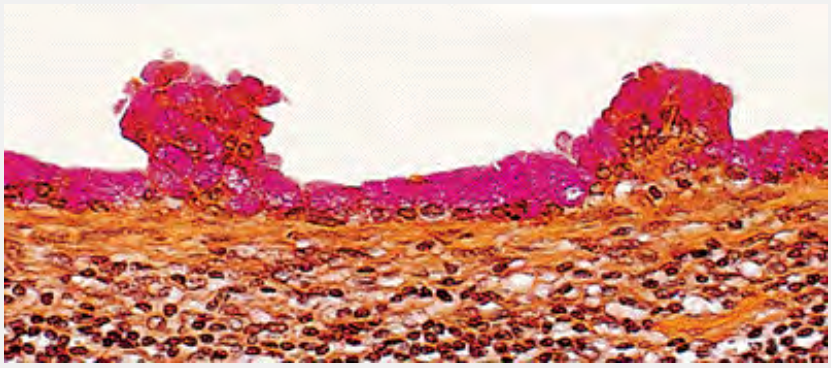

Figure 21.36 Mucicarmine stain of mucinous change in endosalpingiosis demonstrates intracytoplasmic mucin in apical cytoplasm.

Endometriosis may appear as brown-maroon foci on the peritoneal surfaces and be accompanied by fibrosis or adhesions. Microscopically, endometrial stroma surrounding endometrial epithelium is present (67). Response to hormonal influences is often seen and may be synchronous with intrauterine endometrium. Metaplasia occurs in both epithelial and stromal elements, similar to metaplasias encountered in the endometrium of the uterus. The presence of hemosiderin-laden macrophages and fibrosis may be the only evidence that endometriosis had once been present. However, a definitive diagnosis of endometriosis may not be rendered unless both endometrial glands and stroma are seen.

Another common type of metaplasia, more frequently observed in pregnant than in nonpregnant women, is decidual change.

Although usually encountered in the submesothelial layer of pelvic peritoneal surfaces, decidual change may be seen in distant sites including the serosal surfaces of the liver, spleen, diaphragm, and within lymph nodes. In these locations, decidual change may be mistaken for metastatic carcinoma or malignant mesothelioma (Figure 21.38) (66).

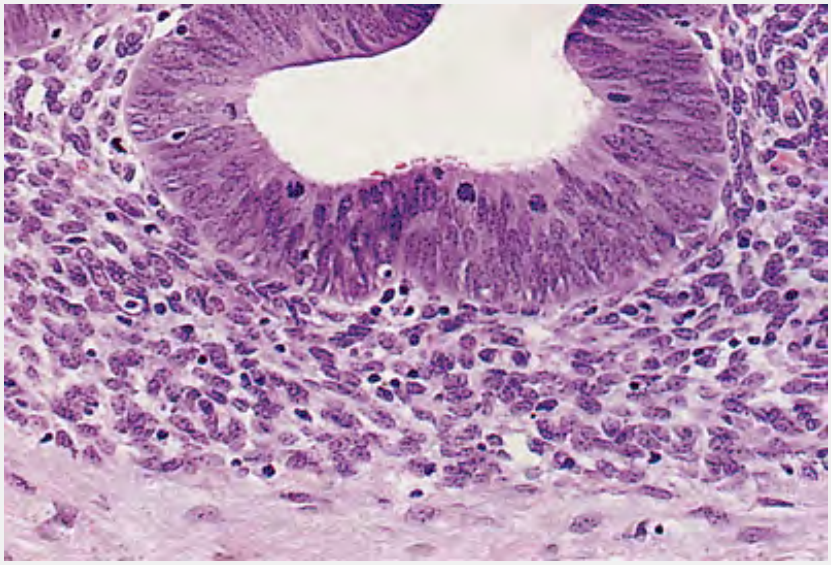

Figure 21.37 Endometriosis involving the peritoneum with extension into the soft tissue of the anterior abdominal wall of a 23-year-old woman. Endometrial glands and stroma are present.

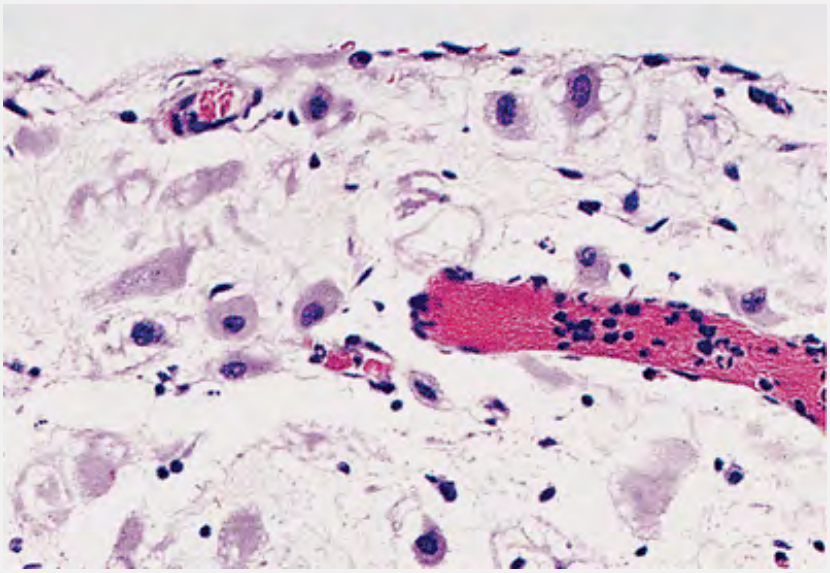

Figure 21.38 Decidual change in the pelvis during pregnancy is seen in subserosal tissue. Loosely cohesive cells with abundant eosinophilic cytoplasm are present.

Fibrous Pleurisy

Fibrous pleurisy is a benign reactive process that usually occurs in the setting of organizing pleural effusions. The differential diagnosis of fibrous pleurisy and desmoplastic mesothelioma may be extremely difficult: both may have regions of increased cellularity in a predominantly fibrous background containing spindle cells that are immunoreactive to keratin antibodies. Fibrous pleurisy tends to have a higher cellularity immediately beneath the fibrinous exudative surface of the pleura and demonstrates a â€œlayeringâ€• of spindle cells parallel to the fibrosis with intervening fibrinous exudate. This organization imparts a histologic sense of order to the reactive process that may assist in its recognition. Invasion, bland necrosis, and sarcomatous foci are not seen in fibrous pleurisy (67,68) (Figure

21.39).

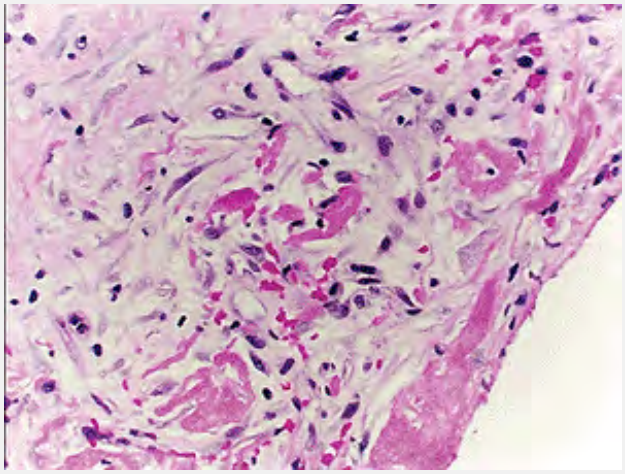

Figure 21.39 The histologic appearance of fibrous pleurisy reflects its inflammatory nature, with granulation tissue, fibrin, and a zonal pattern ranging from active inflammation to quiescent dense fibrosis.

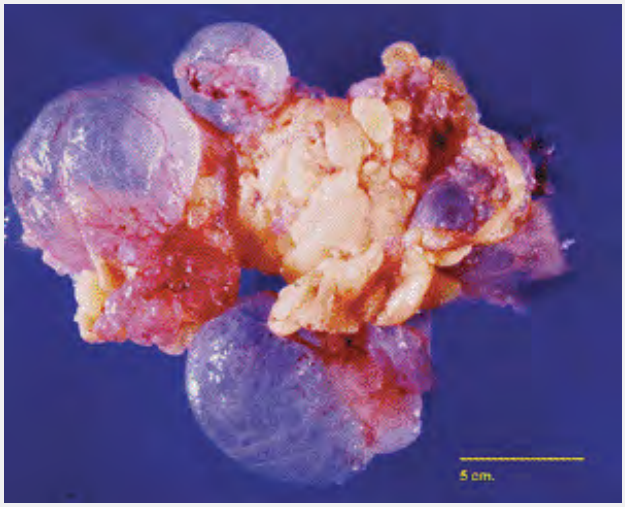

Figure 21.40 Multilocular peritoneal inclusion cyst in the omentum of a 73-year-old patient discovered incidentally at surgery for urogynecologic repair procedure. The cysts vary in size, some being translucent while others are fibrotic, particularly toward the center of the mass.

Multilocular Peritoneal Inclusions Cyst

Multilocular peritoneal inclusions cyst (MPIC) is a mesothelial-lined multilocular lesion that occurs almost exclusively in women. The lesion usually involves the pelvis, although it may occur in other abdominal locations, including the omentum and mesentery. Usually MPIC is mass forming and may attain diameters up to 20 cm. Grossly, it is composed of multiple cysts, some of which may be thinwalled and translucent (Figure 21.40). Histologically, the septa range from thin and delicate to thickened and inflamed. The mesothelial lining ranges from single flattened cells to hobnail-type cells. Squamous metaplasia of the lining mesothelium may be present. Some regions may resemble the cellular pattern of an adenomatoid tumor (Figures 21.41,21.42) (69).

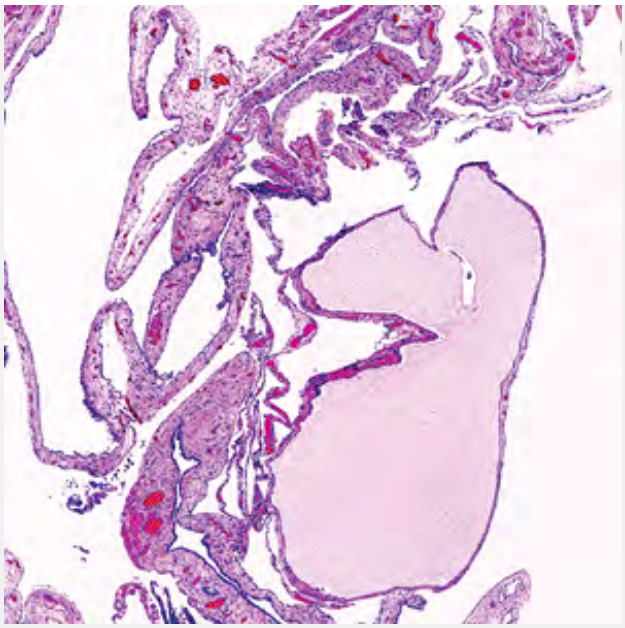

Figure 21.41 Histologically, multilocular peritoneal inclusions cysts (MPIC) reflect the gross features, with septae that vary in thickness and cysts that vary in size.

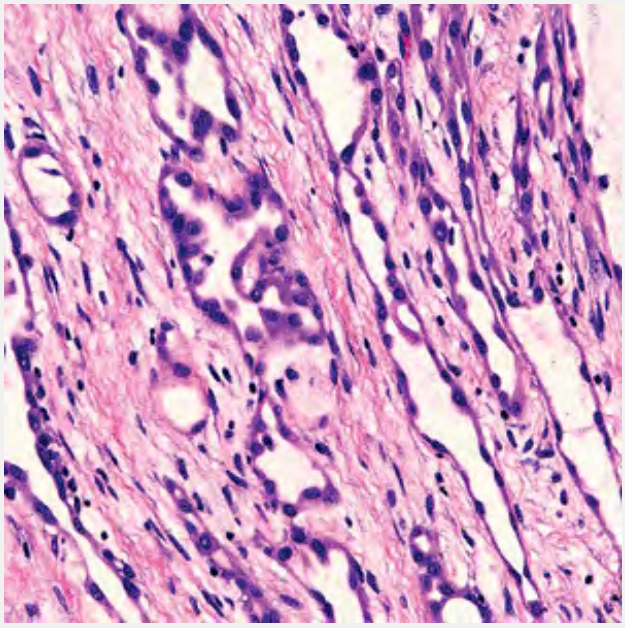

Figure 21.42 Some regions in multilocular peritoneal inclusions cysts may contain mesothelial proliferations that closely resemble an adenomatoid tumor.

The true nature of MPIC remains somewhat controversial, with some authors maintaining that it is a neoplasm while others assert it is a reactive lesion that develops in response to injury or even endometriosis. The original designation of *multicystic mesothelioma* reflects the notion that the lesion is neoplastic. Recurrences are frequent, although MPIC-related deaths probably do not occur (70).

Esophagus

Franco G. DeNardi

Robert H. Riddell

Embryology

In the early stages of development, the notochord induces the formation of the foregut from endoderm (1). At about 21 days' gestation, septa arise from the lateral walls of the foregut, fuse, and divide the foregut into the esophagus and trachea. This process of septation begins at the carina and extends cephalad, being completed by five to six weeks' gestation (Figure 22.1).

The esophagus is initially lined by a thin layer of stratified columnar epithelium, which proliferates to almost occlude the lumen (2). At six to seven weeks, the lumen is reformed as a result of epithelial vacuolization (2) (Figure 22.2). As early as eight weeks' gestation and beginning in the middle one-third of the esophagus, ciliated cells appear and extend cephalad and caudally to almost cover the entire stratified columnar epithelium (2,3,4). At approximately 10 weeks a single layer of columnar cells populates the proximal and distal ends of the esophagus (2). At approximately four months' gestation, the esophageal cardiac-type glands form as a result of the downward growth of these columnar cells into the lamina propria, with subsequent proliferation and differentiation (3,5). They go distally as far as the oxyntic mucosa, so that similar glands can be found in the

cardia. Some have used this to argue that the cardia is therefore intrinsically part of the esophagus (6), although it could just as easily be interpreted that they are just present in all mucosae proximl to oxyntic mucosa.

At approximately five months' gestation, stratified squamous epithelium initially appears in the middle one-third of the esophagus and extends cephalad and caudally, replacing the ciliated epithelium (3,4). The upper esophagus is the last area to be replaced by squamous epithelium; and, if this process of squamous replacement is not completed at birth, there may be persistence of ciliated cells in the upper esophagus (2,4) (Figure 22.3). These residual cells are usually short lived, being replaced by squamous epithelium within two to three days postpartum (4,7). However, in some patients they either persist into adult life or there is metaplasia back to ciliated cells (8). The single layer of

columnar cells is also replaced by squamous epithelium, although some cells may persist at birth, usually located over the esophageal cardiac glands. The submucosal glands develop after the appearance of the squamous epithelium and are likely derived from this squamous epithelial layer (4,7).

Figure 22.1 Fetal esophagus (late first trimester). Transverse section overview of the esophagus demonstrating inner mucosal layer, middle submucosal layer, and thin outer muscle layer. Note the vagus nerves lying over the esophagus.

Development of the gastrointestinal neuromuscular system begins at four weeks with neural crest cells entering the foregut and migrating rostrocaudally. The myenteric plexus develops first, followed by formation of the submucosal plexus two to three weeks later. At about six weeks' gestation, the circular muscle layer develops, followed by the development of the longitudinal layer at approximately nine weeks' gestation. Initially, the muscularis propria consists entirely of smooth muscle, after which striated muscle gradually develops in the upper esophagus so that by five months the normal ratio and arrangement of both muscle types are established (4). Interstitial cells of Cajal appear at week nine and become closely

associated with the myenteric plexus (9). By week 14 the fetal gut has a mature appearance (9).

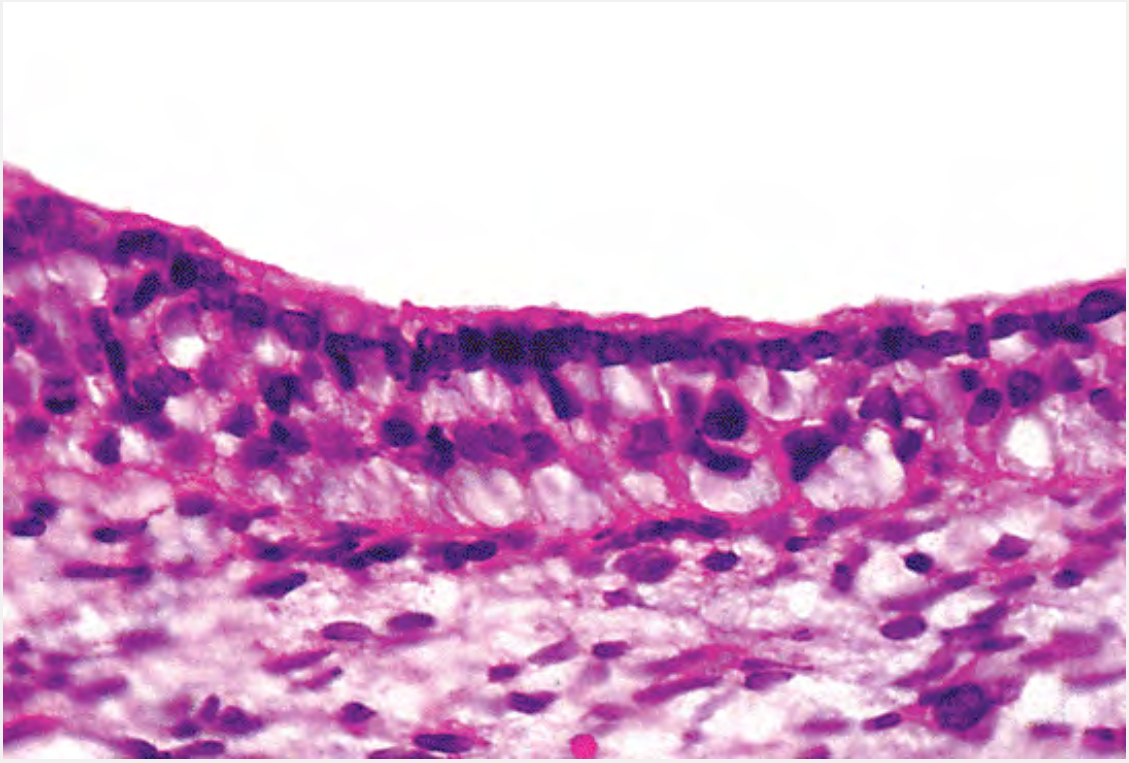

Figure 22.2 Fetal esophagus (late first trimester). The epithelial layer is composed of stratified columnar epithelium. Note the lack of muscularis mucosae.

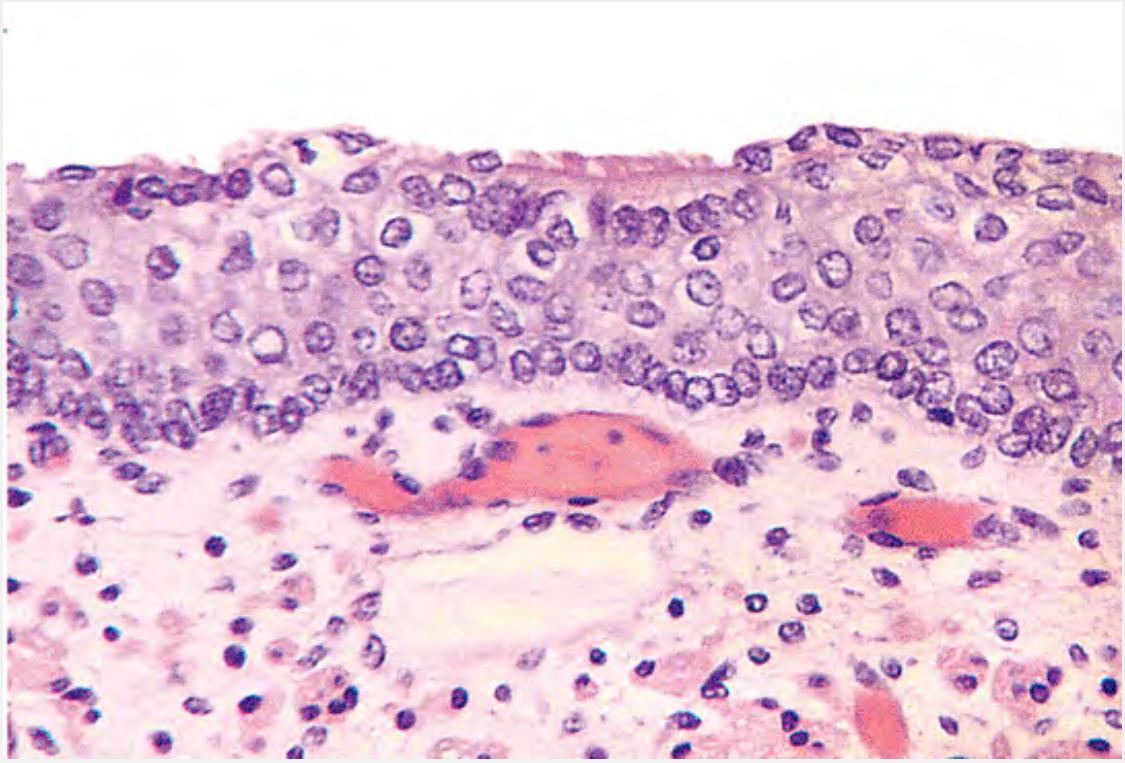

Figure 22.3 Fetal esophagus (third trimester). The epithelial layer at this stage consists of stratified squamous epithelium with occasional ciliated cells on the surface. Note the individual smooth muscle cells of developing muscularis mucosae.

Developmental defects of the esophagus can be attributed to errors in this morphogenetic sequence. The notochord can induce the formation of the neural tube, gastrointestinal tract, and other organ systems. It has been shown experimentally that a split notochord can result in the duplication of any region of the gastrointestinal tract (1), which may include duplications of the esophagus ranging from the more common cysts to esophagus segments of variable length (1,10,11). As a consequence of this ability to induce development of more than one organ system, any patient presenting with duplications, segmental or cystic, should undergo radiologic evaluation that specifically explores for axial skeletal defects.

Occurence of abnormalities during the phase of foregut septation is one proposed mechanism for the formation of tracheoesophageal fistulas (with or without atresia) or of mediastinal cysts of bronchogenic or esophageal origin (12,13). It has been suggested that esophageal duplications also may occur as a result of segments of fused vacuoles formed during the vacuolization phase persisting and differentiating toward esophageal structures (1).

Topography and Relations

The esophagus begins in the neck at the cricoid cartilage, passes through the thorax within the posterior mediastinum, and extends for several centimeters past the diaphragm to its junction with the stomach. The overall length varies with trunk length, but in the adult the average length is approximately 23 to 25 cm. In practice, endoscopic distances are measured from the incisor teeth; and, in the average male, the junction of the esophagus and stomach is generally considered to be approximately 40 cm from the incisors. This length may vary from approximately 38 to 43 cm. Although convenient and commonly used in practice, the use of this distance is a crude and unreliable measurement for locating the gastroesophageal junction. It

has been found that the esophageal length correlates with height in children (14).

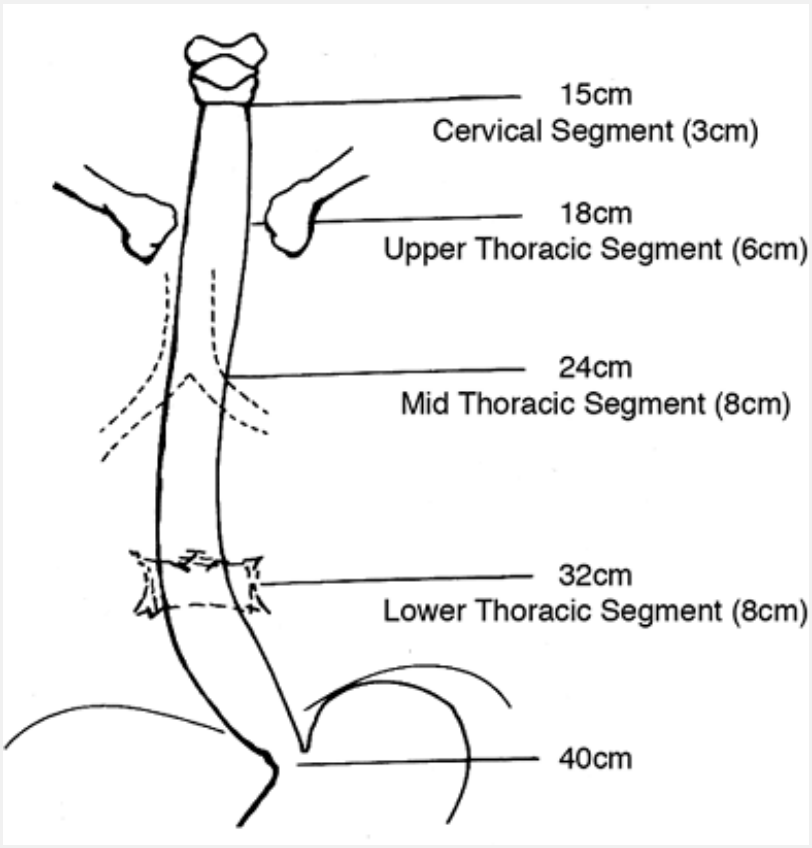

Figure 22.4 Esophageal segments with approximate lengths and distances from the incisors.

For the purpose of classification, staging, and reporting of esophageal malignancy, the International Union Against Cancer suggests division into four segments, with distances measured from the incisors (15) (Figure 22.4). The cervical esophagus extends from the cricoid cartilage (roughly 15 cm) to the level of the thoracic inlet (approximately 18 cm). The upper thoracic segment extends from the thoracic inlet to the tracheal bifurcation (around 24 cm). The midthoracic segment extends to the level of the eighth thoracic vertebra (approximately 32 cm), and the lower thoracic segment extends to the junction with the stomach (40 cm).

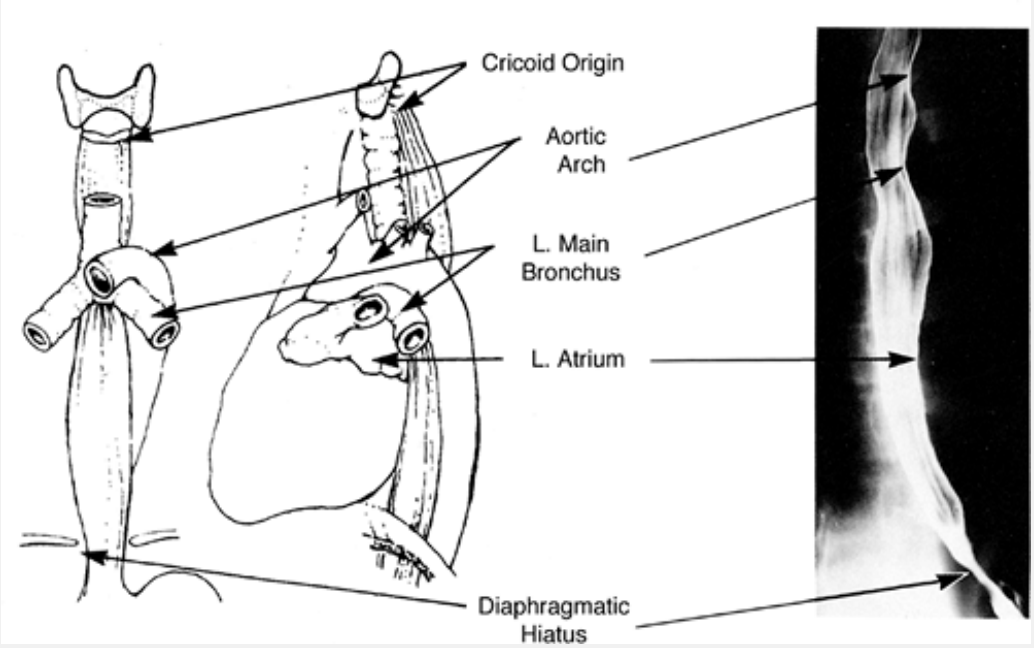

Figure 22.5 Relationship of the esophagus with normal esophageal constrictions. Barium swallow of the normal esophagus (*right*) demonstrates narrowing of the lumen at the sites of constriction.

Along its course, the normal esophagus has several points of constriction (Figure 22.5). These occur at the cricoid origin of the esophagus, along the left side of the esophagus at the aortic arch, at the crossing of the left main bronchus and left atrium, and where the esophagus passes through the diaphragm. These constrictions may become clinically significant if food or pills become lodged at these sites of luminal narrowing, with the possibility of contact mucosal injury. The most common sites for lodgement are at the level of the aortic arch and left atrium, where, especially in patients with left atrial enlargement, compression may become significant (16,17,18).

Knowledge of the relationships of the esophagus with other anatomic structures is important because these relationships may be directly

affected by esophageal diseases such as carcinoma or diverticula. Disease of adjacent structures may cause local compression of the esophagus, resulting in dysphagia or lodgement of food or pills. The cervical esophagus is posterior to the trachea and bounded on both sides by the recurrent laryngeal nerve and the carotid sheath and its structures. The thyroid gland overlaps the esophagus in its cervical segment. In the thoracic segment,

the esophagus continues posterior to the trachea to the level of bifurcation, a site for the formation of the rare midesophageal diverticula secondary to traction from inflamed mediastinal lymph nodes (19). The esophagus courses posterior to the left atrium. The azygous veins ascend on either side of the thoracic segment.

Initially, the right and left vagus nerves run lateral to the esophagus, giving branches that form plexi on the posterior and anterior esophageal surfaces. At variable sites in the lower thoracic segment, the left and right nerves course onto the anterior and posterior surfaces of the esophagus, respectively, divide to form the anterior and posterior plexuses, and then reunite to form the anterior and posterior vagal trunks that course down to the stomach. An awareness that variations of this pattern exist is most important for the surgeon performing vagotomies. In the abdomen, the liver forms an impression on the anterior aspect of the esophagus. On the right side the junction with the stomach is smooth, whereas on the left the junction forms a sharp angle known as the incisura or angle of His.

The esophagus enters the abdomen by passing through the esophageal hiatus, which is formed by muscles of the diaphragm and contains the phrenoesophageal ligament. In most cases, the muscle sling encircling the esophagus is formed entirely from the right diaphragmatic crus (20), although variations of this pattern do occur. The phrenoesophageal ligament arises from the fascia of the abdominal diaphragm and divides into an ascending and descending leaf. The former passes up through the hiatus to insert approximately 2 to 3 cm above the hiatus, whereas the descending leaf has a

variable insertion at or below the gastroesophageal junction or even into the gastric fundus (21). Proposed functions of the phrenoesophageal ligament include (a) assisting in maintaining the pressure differential between the thorax and abdomen, (b) providing fixation mechanisms with maintenance of the gastroesophageal junction within the abdomen during episodes of increased intra-abdominal pressure, and (c) contributing to the competence of the lower esophageal sphincter (LES), thus representing a possible mechanism for the absence of reflux in some patients with hiatal hernias (21,22,23).

Macroscopic/Endoscopic Features

In the empty state, the esophagus has an irregular outline as a result of the mucosa and submucosa being thrown into longitudinal folds. During endoscopy, insufflation causes distension so that these folds may not be appreciated, and the mucosa is seen to be a uniform white-pink.

Glycogenic Acanthosis

Glycogenic acanthosis can be seen in up to 25% of the population with the combined use of endoscopy and barium studies (24,25,26). Macroscopically, glycogenic acanthosis interrupts the uniformity of the mucosa and presents as white nodules or small plaques on the mucosal folds, primarily in the distal one-third of the esophagus. These lesions vary in size, may be up to 1 cm in diameter, and, if extensive, may coalesce to larger plaques. Microscopically, glycogenic acanthosis consists of hyperplasia of the cells of the prickle layer containing abundant glycogen. Glycogenic acanthosis may resemble, and thus may be confused macroscopically with, monilial plaques or leukoplakia. Glycogenic acanthosis should be considered a variant of normal with as yet no defined relationship to infection or malignancy.

Heterotopias

Heterotopias are defined as normal tissue occurring in sites not expected for that tissue. In the literature, structures accepted as esophageal heterotopias are inconsistently defined. Esophageal cardiac-type glands and ciliated epithelium have been considered as heterotopias (7,8,27,28) or as embryologic remnants (4) by some investigators. The categorization of melanocytes and argyrophilic cells, including Merkel cells and endocrine cells, presents a similar problem because these cells have not been regularly found in the esophagus (29,30). Melanosis has also been described (31,32,33).

Gastric bodyâ€“type mucosa has been described occurring in the upper one-third of the esophagus, usually within 3.0 cm of the upper esophageal sphincter (4,7,27), hence the designation â€œinlet patchâ€• (Figure 22.6). These heterotopias have been found in approximately 2 to 4% of esophagi and can be found at all ages. Macroscopically, they have a deep pink, velvety appearance, and the junction with squamous epithelium is similar in appearance to the

mucosal gastroesophageal junction (27). Associated small peptic erosions or ulcers occasionally are identified nearby.

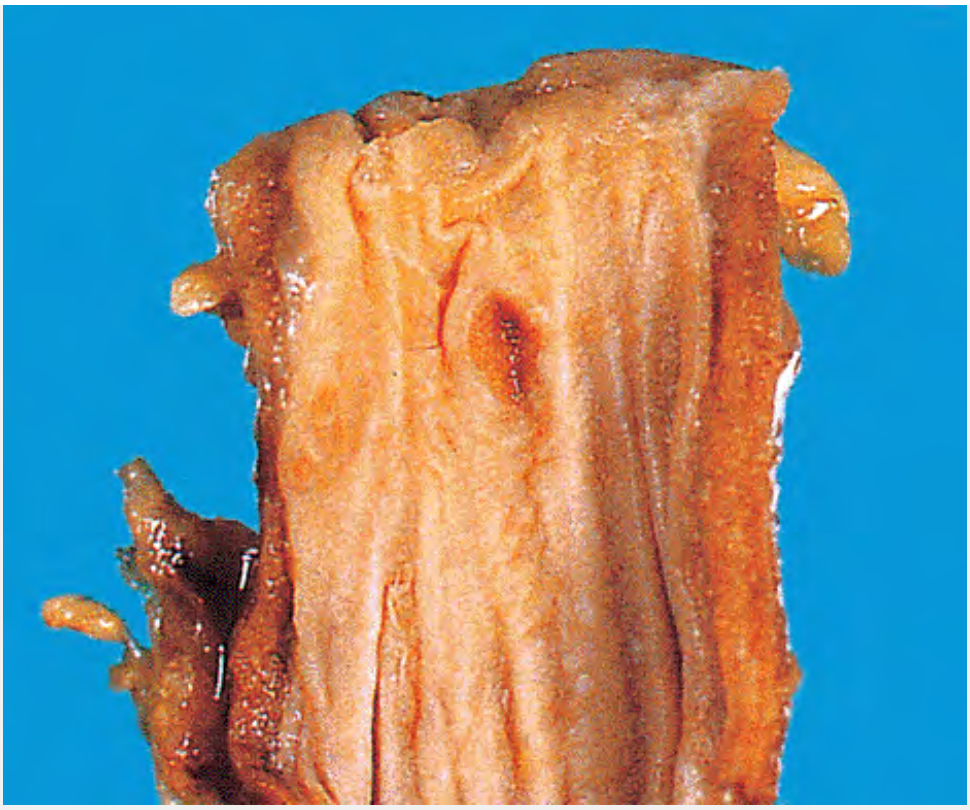

Figure 22.6 Proximal esophagus. Gastric body heterotopia situated slightly distal from the esophageal origin.

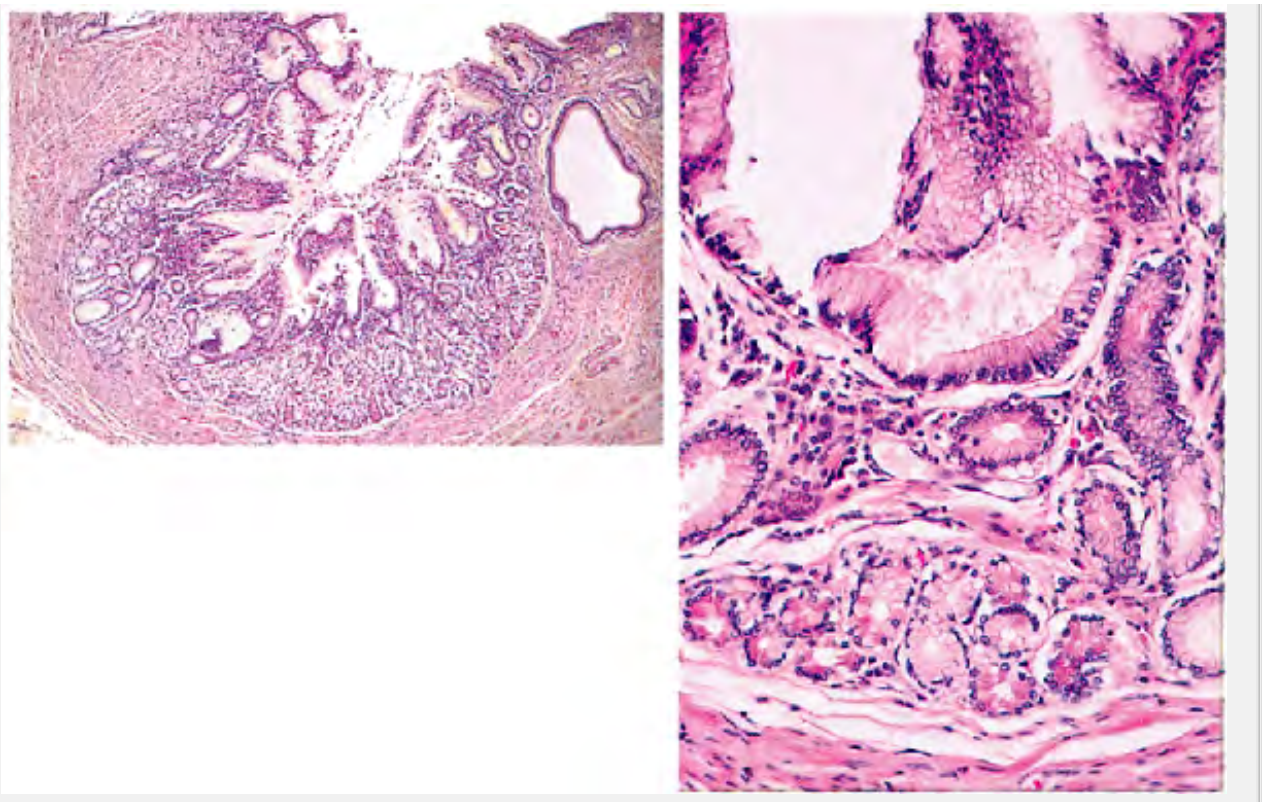

Figure 22.7 Proximal esophagus. Gastric body heterotopia composed of cardiac-type mucosa with scattered chief cells and a mild chronic inflammatory cell infiltrate.

Microscopically, the heterotopic mucosa contains a variable number of parietal and chief cells with a variable chronic inflammatory cell infiltrate usually related to *Helicobacter* infection (27) (Figure 22.7). Acid production and symptoms have been attributed to heterotopias of larger size. These heterotopias along with the esophageal cardiac-type glands have been implicated as possible origins for the rare occurrence of adenocarcinoma of the upper esophagus (34,35). Theories for the origin of these heterotopias include a metaplastic change in preexisting cardiac-type glands, cell arrest where cells destined to become body mucosa remain in the esophagus rather than descend to the site of the future stomach, or otherwise unexplained heterotopia (4,27).

Sebaceous glands are occasionally found in the esophagus (Figure 22.8) and have been accepted as heterotopias without controversy (36,37). Thyroid tissue also has been described as heterotopic tissue in the esophagus (38). Pancreatic metaplasia is probably the most common form of metaplasia in the cardia, usually close to the Z line, although it also may be found in Barrett's esophagus and in an inlet patch (39,40,41) (Figure 22.9). While it has no known significance, if it secretes activated pancreatic juice, then it may well potentiate Barrett's esophagus, as it is a normal consituent of duodenal juice, the regurgitation of which into the esophagus is involved in its pathogenesis. Indeed, it is also possible that an alkaline pH or bile in the esophagus stimulates its formation. Endocrine tissue can be observed (personal observation) but is vanishingly rare.

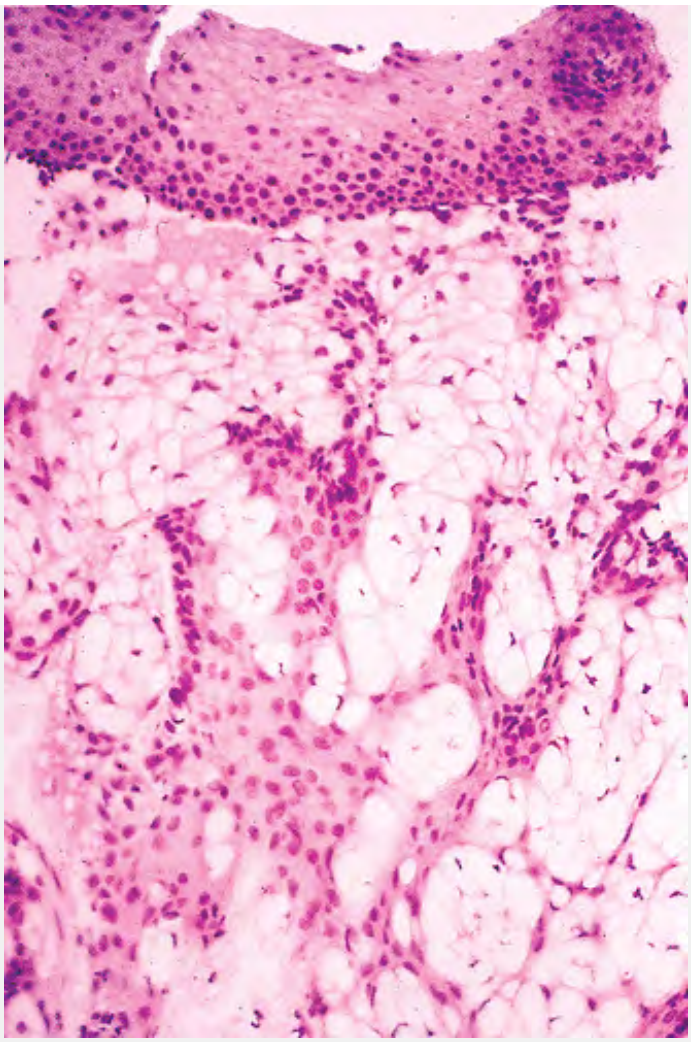

Figure 22.8 Sebaceous glands that in this case formed a nodule that was examined via biopsy.

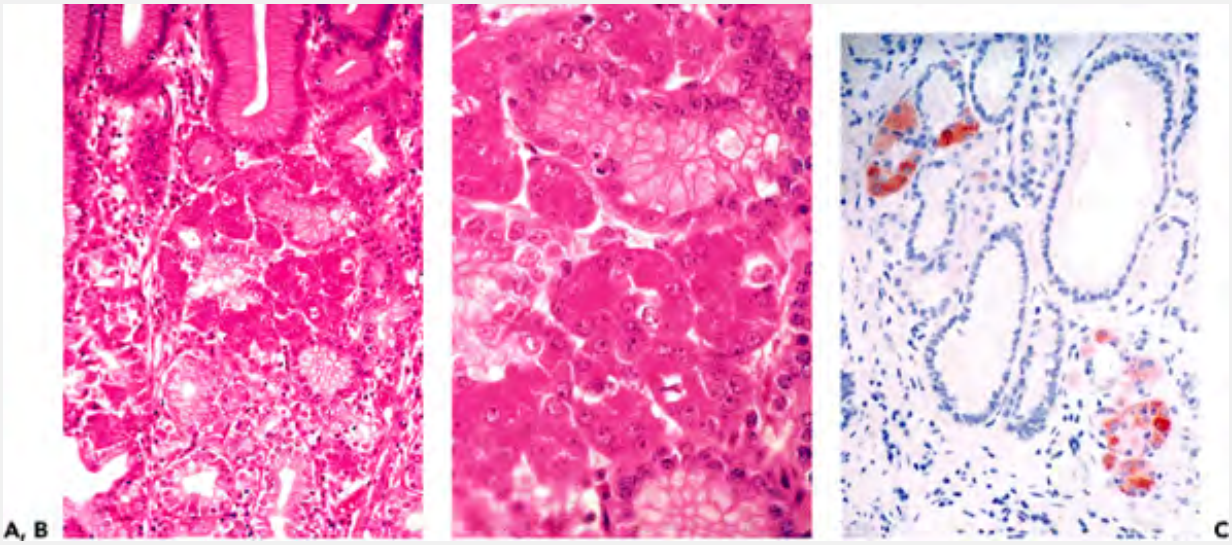

Figure 22.9 Pancreatic metaplasia in a biopsy from the cardiac side of the Z line. A. and B. Glands are an admixture of mucus glands and eosinophilic granular cells superficially resembling a cross between gastric chief cells and Paneth's cells. C. Immunocytochemical reactivity is found to pancreatic exocrine hormones, amylase in this case.

Esophageal Musculature

The muscular coat of the esophagus consists of an outer longitudinal and inner circular layer. The esophageal entrance is bounded superiorly by the cricopharyngeal and inferior pharyngeal constrictor muscles, both of which contribute muscle fibers to the esophageal musculature (22,23). Horizontal fibers from both these muscles form the upper esophageal sphincter, which manometrically is a localized zone of increased pressure measuring 2 to 4.5 cm in length (20,42,43). Together these muscle groups act in tandem to control the act of swallowing.

The longitudinal layer originates as two bands from its origin at the cricoid cartilage. The muscles sweep dorsally where they incompletely interdigitate, leaving a bare V-shaped area (area of Laimer) exposing the underlying circular layer. This area represents an area of potential weakness where a posterior pulsion diverticulum (Zenker's) may form. Theories regarding Zenker's diverticulum center upon a structural or physiologic abnormality of the cricopharyngeus muscle (44). The circular layer of the esophagus is slightly thinner than the longitudinal layer, a pattern that is reversed from the remainder of the gastrointestinal tract (22,23).

At the gastroesophageal junction, the esophageal longitudinal layer is continuous with the outer longitudinal layer of the stomach. The circular layer continues over the stomach, dividing in the region of the cardia to form the middle circular and inner oblique muscle layers of the stomach. The fibers of the inner oblique layer pass in a slinglike manner at the incisura and cross at right angles with the more horizontally oriented fibers of the middle layer, forming a muscular ring (collare Helvetti) to which a possible sphincter function has been ascribed (22,23).

Lower Esophageal Sphincter

The LES is best defined manometrically, where it presents as a 2- to 4-cm zone of pressure that is higher than intragastric or intraesophageal pressure. The distalmost end of the LES defines the muscular component of the gastroesophageal junction (42). At rest, the sphincter maintains an average pressure of 20 mm Hg (range: 10â€“26) (20). The function of the LES is to keep the lumen closed during rest, thus preventing reflux, and to relax during swallowing, thereby allowing food to pass through. Physiologically, a competent sphincter exists, and various changes in the musculature of the distal esophagus, thought to represent such a sphincter, have been described (43,45,46,47).

Gastroesophageal Junction

The gastroesophageal junction can be defined physiologically, anatomically, microscopically, or endoscopically and can be considered as being either muscular or mucosal in nature. The muscular gastroesophageal junction is most accurately defined physiologically by manometric studies in which the distalmost segment of the LES defines the junction (42). Unfortunately, in disease states such as severe gastroesophageal reflux disease (GERD) or Barrett's esophagus, the pressure may be so low as to not allow for localization by these means.

Anatomic landmarks that can be used to define the gastroesophageal junction include the peritoneal reflection from the stomach onto the diaphragm or the incisura (angle of His) (22,23); however, their use is limited to the resected surgical specimen.

Endoscopically, there are several landmarks that can be used, the most common of which is the mucosal squamocolumnar junction, or Z line. Sometimes this is accompanied by a ring (Shatzki's ring) that has squamous mucosa above and glandular mucosa distally (48,49), which is sometimes associated with dysphagia. The mucosal squamocolumnar junction is seen macroscopically and endoscopically as a serrated line of contrast known as the Z line or ora serrata (Figure 22.10). The Z line consists of small projections of red gastric epithelium, up to 5 mm long and 3 mm wide, extending upward into the squamous epithelium. Although extension of this gastric mucosa may be circumferentially symmetric, it often is asymmetric. The mucosal gastroesophageal junction may be straight rather than serrated, this occurring most often in the presence of a lower mucosal (Schatzki's) ring.

The mucosal gastroesophageal junction does not correspond to the muscular gastroesophageal junction as defined above; and, particularly if the mucosa is red and inflamed, it may not correspond

to the supposed endoscopic junction either. The mucosal junction normally lies within the LES and is therefore found usually within 2 cm of the muscular junction as defined by the proximal edge of the gastric folds (50); thus, the distal 2 cm of the esophagus may be lined by columnar cells of the gastric cardia (it was this fact that led to Barrett's esophagus originally being defined as 3 cm or more of glandular mucosa within the tubular esophagus, as it ensured at least 1 cm of what should be Barrett's mucosa). Irregularities and proximal extensions of the Z line may extend 3 cm into the esophagus and thus endoscopically resemble early Barrett's esophagus. Indeed it is quite possible that some of these are tongues of Barrett's esophagus in which sampling fails to reveal goblet cells, or they may be absent. In one study, 23% of these patients had goblet cells in these tongues if rebiopsied (51).

The upper margin of the diaphragmatic indentation has been used as a guide to define the gastroesophageal junction; however, in the presence of a hiatal hernia, this demonstrates variable movement (22,23).

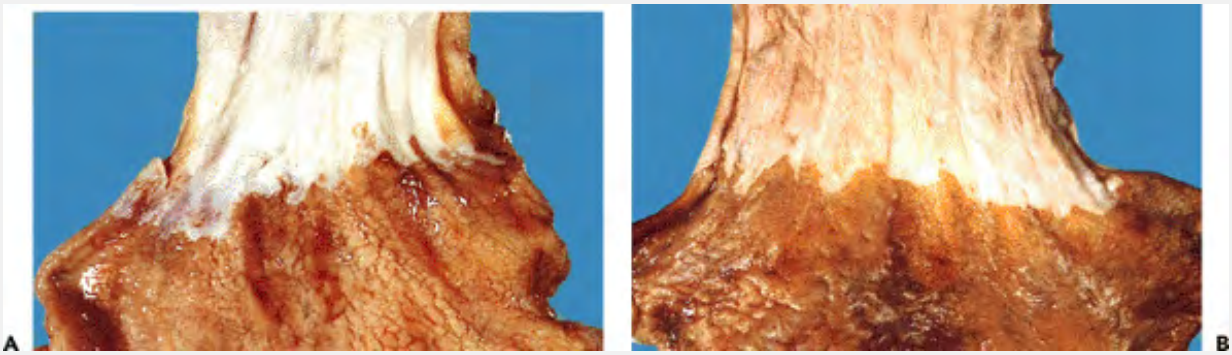

Figure 22.10 Gastroesophageal region. Formalin-fixed specimen demonstrates the variation of the normal squamocolumnar junction (Z line).

The proximal margin of the gastric folds has been shown to closely approximate the muscular gastroesophageal junction and thus may provide a fixed and reproducible anatomic landmark for the muscular gastroesophageal junction (50).

In the lower esophagus, the submucosal vessels of the distal esophagus are connected to the gastric submucosal vessels at the first gastric folds by a series of vessels referred to as longitudinal (vertical) vessels. These vessels, present in the lamina propria, are about 2 to 4 cm in length and can be often seen through the squamous or columnar mucosa (52,53). Their lower visible limit is also supposed to mark the original site of the gastroesophageal junction so that â€œshiftsâ€• in this caudally should be apparent. However, in some patients these are quite difficult to visualize, while in others they clearly extend into the gastric rugae. They may therefore be a less sensitive or specific marker of Barrett's esophagus than originally thought, so great care should be taken in making an endoscopic diagnosis of Barrett's esophagus without the usual biopsy confirmation. Even in the studies cited, the endoscopic diagnosis was not confirmed histologically so that the sensitivity and other characteristics of this technique are still unclear.

The longheld view that the distal 2 to 3 cm of the esophagus is normally lined by cardiac-type mucosa has been challenged. In both autopsy and endoscopic based studies (27,40,54,55,56) that included pediatric aged patients, columnar/cardiac mucosa was either not identified in up to 65% of cases, present as a short segment of less than 1.0 cm., combined with oxyntic (oxyntocardiac) mucosa, or demonstrated considerable circumferential variation within individuals. The authors suggest either that (a) cardiac mucosa of the gastroesophageal junction is not normal (but rather acquired) and that only squamous (esophagus) and oxyntic (stomach) mucosa are normal for this region or (b) it is a physiologic response to gastroesophageal reflux; but, either way it develops in response to a stimulus that includes some degree of acid reflux. To some extent it

becomes a matter of semantics as to whether one regards

reflux as pathologic or physiologic. One could also argue that the normal physiologic position of the anal sphincter is to be closed, but it would cause all sorts of problems if it remained that way permanently! Conversely, it is difficult to see what useful function permitting gastroesophageal reflux serves except that other sphincters (e.g., pylorus) also reflux with some degree of frequency, which may have a physiologic benefit in aiding digestion as well as predisposing to Barrett's esophagus. Furthermore, studies have demonstrated that the length of cardiac or oxyntocardiac mucosa was shown to correlate with the severity of acid reflux suggesting that this metaplastic epithelium results from acid reflux (reflux carditis) (56,57).

Lower Esophageal Rings

Two (possibly three) thin, annular structures known as the lower muscular ring (type A) and lower mucosal ring (Schatzki's, type B) (Figure 22.11) may be identified in at least 10% and 5% of normal esophagi, respectively (48,49,58). A third ring (type C) rarely exists distal to either of these.

The lower muscular ring is the most proximal and is situated slightly more proximal than the Schatzki's ring, often by a centimeter or two. Some have equated the lower muscular ring with the lower esophageal sphincter (43,58). Microscopically, this ring is composed of a thickened circular smooth muscle with overlying squamous mucosa.

The lower mucosal ring (Schatzki's ring) is thought to mark the mucosal gastroesophageal junction. Histologically, the upper surface of the lower mucosal ring is lined by stratified squamous epithelium, whereas the undersurface is lined by columnar-type epithelium with the junction of both usually, but not invariably, being found at the apex of the ring. The core of the ring consists of connective tissue

plus fibers of the muscularis mucosae without contribution from the muscularis propria. These rings are usually asymptomatic but may be associated with intermittent dysphagia, sometimes becoming progressive or associated with attacks of sudden dysphagia (20). A â€œC ringâ€• is rare, the most distal, and is said to consist of the diaphragmatic pinch, in which case it can be enhanced by sniffing.

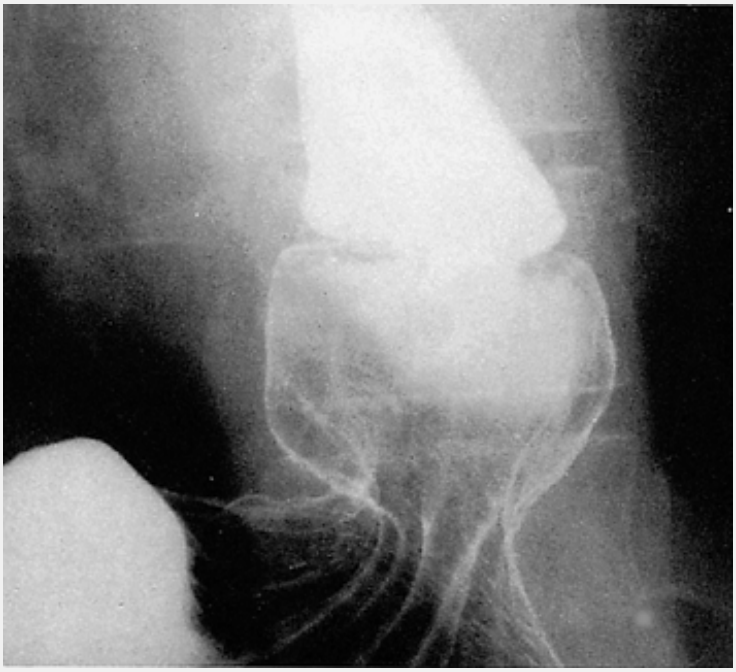

Figure 22.11 Lower esophageal mucosal ring (Schatzki's ring). The mucosal ring is outlined by the column of barium.

Histology

The four layers that characterize the gastrointestinal tractâ€”mucosa, submucosa, muscularis propria, and serosaâ€”form the wall of the esophagus.

Mucosa

The mucosa consists of a nonkeratinizing, stratified squamous epithelium, lamina propria, and muscularis mucosae (Figure 22.12).

Epithelium

The squamous epithelium can be divided into the basal, prickle, and functional cell layers. In addition, argyrophilic positive endocrine cells, melanocytes, Merkel cells, intraepithelial antigen-presenting cells and intraepithelial lymphocytes that are virtually impossible to distinguish in routine sections (and therefore perhaps best called collectively intraepithelial mononuclear cells) can be found in the epithelium of the normal esophagus. The basal layer occupies approximately 10 to 15% of the epithelium, being one to three cells thick; however, in the distal 3 cm, approximately 60% of normal individuals (without objective or subjective evidence of gastroesophageal reflux) may show basal cell hyperplasia of greater than 15% (59,60). The upper extent of the basal zone has been arbitrarily defined as the level where the nuclei are separated by a distance equal to their diameter (61). Periodic acid-Schiff (PAS) stain may be used to demonstrate the upper extent of the glycogen-poor basal cells (Figure 22.13). Above the basal cell layer, the

prickle and functional cell layers consist of glycogen-rich cells that become progressively flatter toward the surface. Glandular mucosa of the distal esophagus is typical cardiac mucosa with variable numbers of specialized gastric cells and cardiac glands as described in the following chapter.

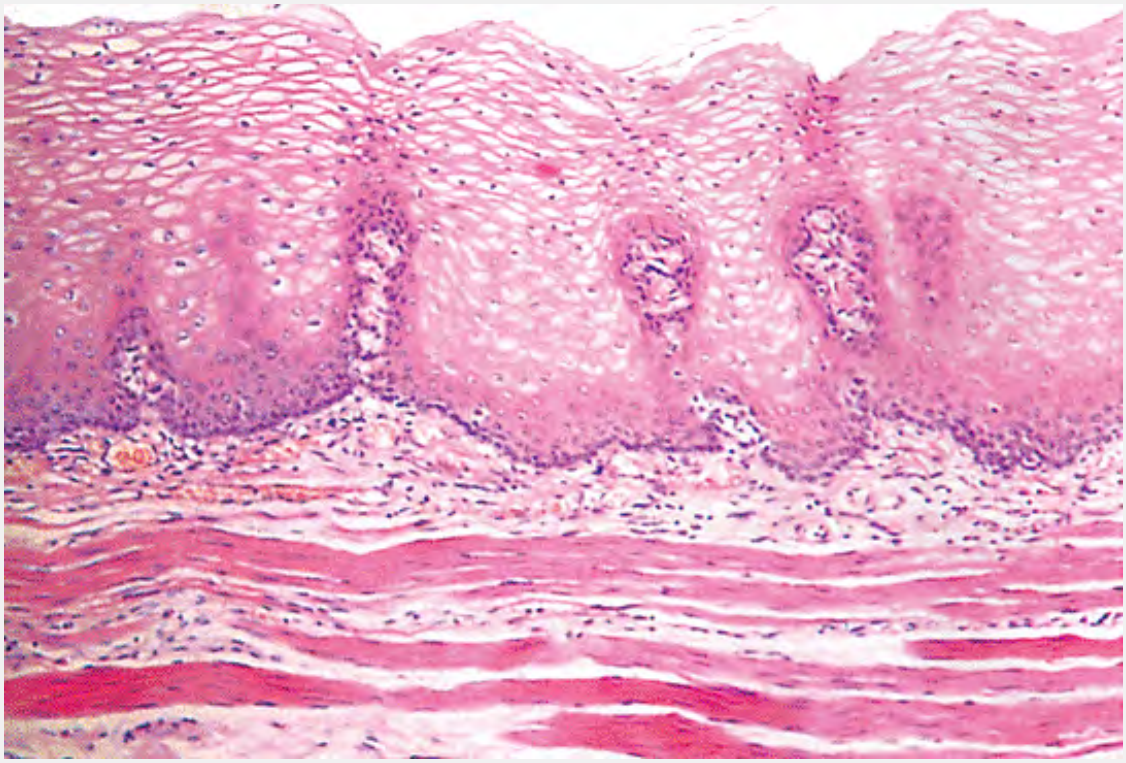

Figure 22.12 Midesophagus. The esophageal mucosa consists of a surface epithelial layer, middle lamina propria, and lower muscularis mucosae, which consists of longitudinally oriented smooth muscle bundles.

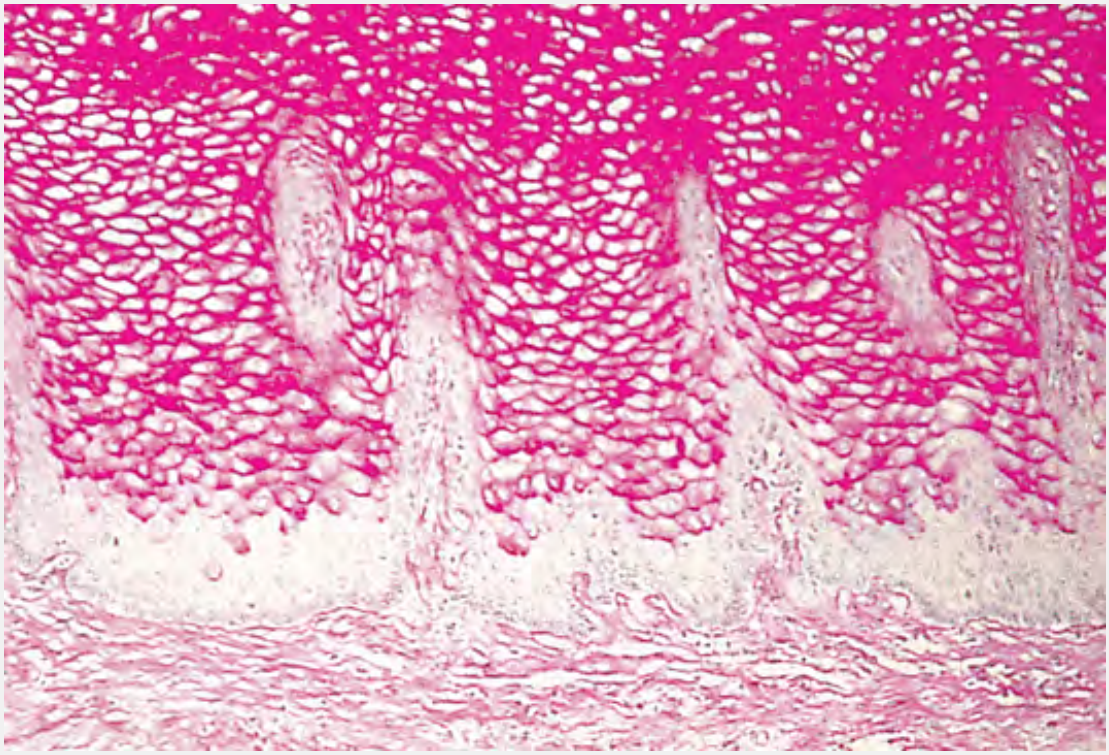

Figure 22.13 Midesophagus. The basal cell layer of the esophageal epithelium shows lack of glycogen, allowing for ready distinction from the overlying glycogen-rich cells (PAS-D).

Argyrophilic positive endocrine cells and melanocytes have been found scattered among the basal cells in approximately 25% (62) and 4 to 8% of normal individuals, respectively, while Merkel cells are also described (29,30). The presence of melanocytes, referred to as melanosis (31,32,63), accounts for the occurrence of primary melanoma of the esophagus (64,65) and rare blue nevi (66), whereas the presence of argyrophilic positive cells accounts for the rare occurrence of pure small cell carcinoma (67).

Occasional lymphocytes are a normal finding in the epithelium and usually are located in a suprabasal location (68,69,70). As they interdigitate between the epithelial cells, their nuclei become

convoluted and may be confused with the nuclei of neutrophils. The term *squiggle cell*, or *intraepithelial cells with irregular nuclear contours*, is used to describe this appearance (Figure 22.14). As in the rest of the gastrointestinal tract, intraepithelial lymphocytes are CD3+/CD8+, indicating suppressor/cytotoxic function. Langerhans cells, which are S-100+, CD6+, and CDla+, also are located in a suprabasal location (Figure 22.15); they function as antigen-presenting cells, similar to Langerhans cells of the skin (68,69).

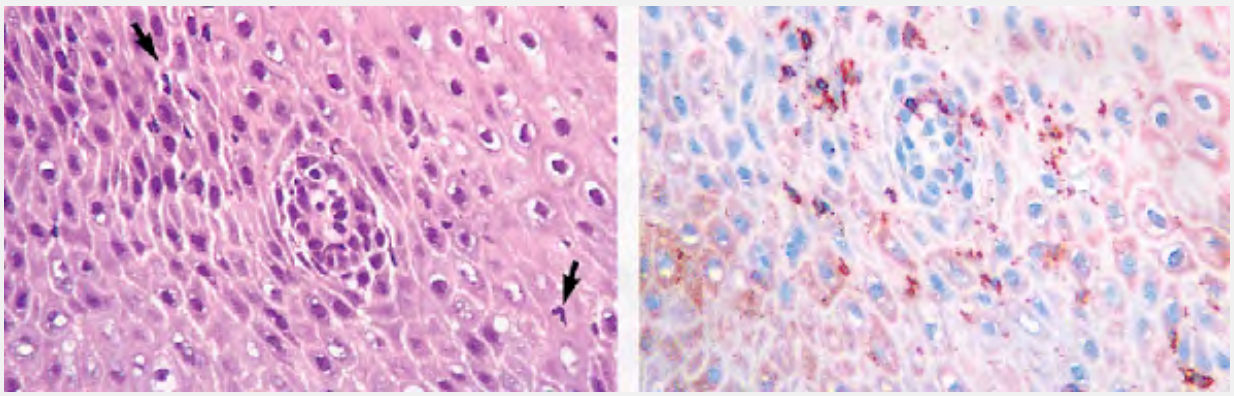

Figure 22.14 A. Numerous lymphocytes within the esophageal epithelium, some of which have a â€œsquiggleâ€• appearance (*arrows*). In addition, the intercellular spaces are dilated causing very prominent prickles, while some of these have formed small â€œbubblesâ€• primarily at the junction between epithelial cells (best seen in the upper right quadrant). Care needs to be taken not to include perinuclear vacuolization/cytoplasmic retraction or paranuclear vacuoles as dilated intercellular spaces. B. Intraepithelial lymphocytes are of T-cell origin, as demonstrated using the T-cell marker UCHL-1, and are primarily suppressor (CD8+) cells.

The cytology of the esophagus is represented by stratified squamous

epithelium, gastric-type epithelium representing the distal 1 to 2 cm, and contaminants from the oropharynx, respiratory tract, and foreign material such as food particles. The squamous epithelium in cytologic material consists predominantly of superficial and intermediate squamous cells, with the deeper parabasal cells or squamous â€œpearlsâ€• occasionally observed. The gastric-type epithelium from the lower 1 to 2 cm of the esophagus is brushed as cohesive fragments of uniform cells displaying a honeycomb arrangement. The peripheral cells of the cluster are flattened. The nuclei are regular and paracentrally situated and contain a few granules of chromatin and occasionally a small nucleolus.

The electron microscopic appearance of the epithelial layer demonstrates similarities to nonkeratinizing squamous epithelium elsewhere (Figure 22.16). The cuboidal basal cells are attached to the basement membrane by hemidesmosomes. Progressing superficially, the epithelial cells become more flattened and the nuclei more pyknotic (68). Cell processes and desmosomes are most extensive in the prickle cell layer, becoming fewer and more simplified superficially (71). Membrane-bound, acid phosphataseâ€“containing structures measuring 200 to 300 nm in diameter are identified within the epithelial cells and are

postulated to have a lysosomal function, possibly involved in the digestion of cell junctions necessary for epithelial sloughing (71,72).

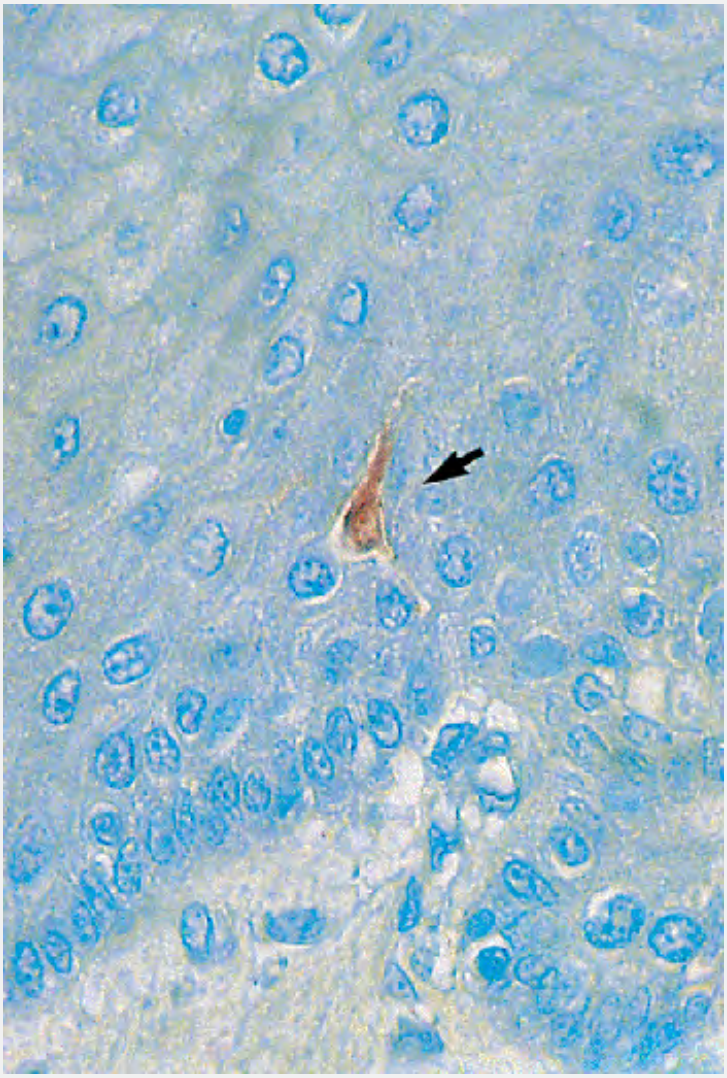

Figure 22.15 Langerhans cell (*arrow*) in a suprabasal position (S-100).

Cell kinetics of the human esophagus have not been studied extensively. The basal cells are responsible for epithelial regeneration; and, although data on human esophageal mucosal renewal are not available, epithelial turnover in the esophagus is slower than in the small bowel (73). In the mouse, basal cell proliferation has been shown to have a circadian rhythm (74), and

the epithelial turnover time in the normal rat esophagus is approximately seven days (75). In patients with GERD, there is an increased proliferative activity of the basal cells, resulting in basal cell hyperplasia (76).

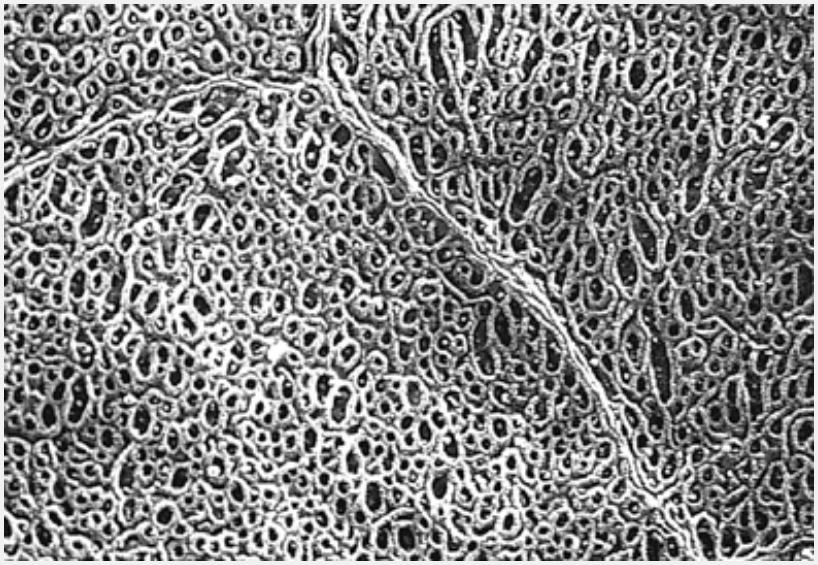

Figure 22.16 Scanning electron micrograph of the surface esophageal mucosa in which intercellular junctions are readily appreciated.

Stem cells in the esophagus consist of a single layer of cells attached to the basement membrane that lie between the papillae (interpapillary basal cells) and have a low proliferative activity, being almost entirely Ki-67â€“ (Figure 22.17). In animal models, when these cells divide, one remains attached to the basement membrane, while the

other migrates and differentiates. They therefore have a high proliferative capacity, divide relatively infrequently in vivo, and are phenotypically â€œprimitive.â€• Under experimental conditions, such stem cells â€œhomeâ€• to damaged esophagus, while it can

also be shown that bone marrowâ€“derived cells can also home to the esophagus and differentiate into esophageal stem cells, including squamous epithelium (77). As such, basally situated stem cells do not show differentiation characteristics, possessing a different immunophenotype from the more differentiated cells in being CK13 immunoreactive; CK13 is expressed at high levels in the cells of both the papillary basal layer (PBL) and epibasal layers but is absent from the keratinocytes of the interpapillary basal layer (IBL). In addition, CK14 and CK15 are patchy in the IBL, which contrasts with the high levels of expression in the PBL and epibasal layers. Also, mRNA for the differentiation marker CK4 is detectable in the papillary region from the second epibasal layer onwards but does not appear in the interpapillary region until the third epibasal layer (78,79). Therefore, IBL cells appear to be the least differentiated cell type in the tissue (79). Suprabasal integrin expression is a consistent finding at the tips of the esophageal papillae, so PBL cells probably migrate to this site (80). This concept is illustrated in Figure 22.18.

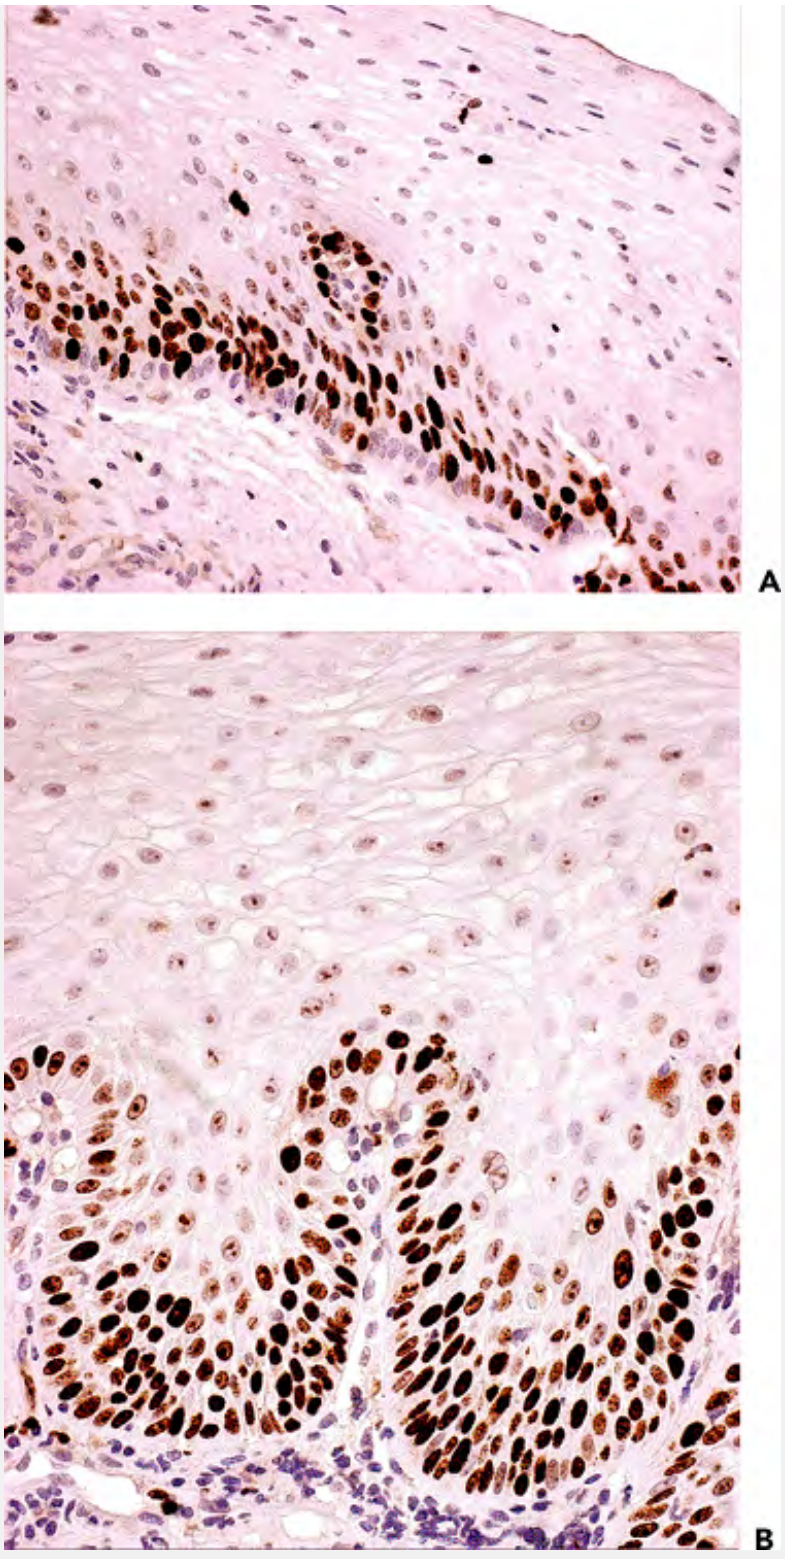

Figure 22.17 Basal layer of esophagus immunostained with MIB-

1. A. The basal cell layer is relatively thin and unstimulated, consisting of only about 3 cell layers. Many of the cells in the basal layer are completely unstained, therefore representing likely stem cells, while the proliferating cells with black nuclei are in the cell layer immediately above. B. In this biopsy, the basal layer is much thicker and therefore more proliferative, and there are fewer noncycling stem cells in the basal layer.

Lamina Propria

The lamina propria is the nonepithelial portion of the mucosa above the muscularis mucosae; it consists of areolar connective tissue and contains vascular structures, scattered inflammatory cells, and mucus-secreting glands. In adults, the presence of scattered inflammatory cells, including lymphocytes and plasma cells, is considered a normal finding and does not correlate with acid reflux (61). Lymphocytes identified in the lamina propria are both CD4+ and CD8+, with the T4 population predominating (68). Immunoglobulin (Ig)A-producing B cells (plasma cells) predominate, with a smaller population of IgG- and IgM-producing B cells (plasma cells) (68). Fingerlike extensions of lamina propria, termed papillae, extend into the epithelium, with the maximum depth of extension allowable in the normal esophagus varying from 50% (81) to 75% (81,82). Practically it is easy to use the â€œrule of thirdsâ€• when examining biopsies, in which papillae should not extend into the upper one-third, and basal cells should not get higher than halfway up the basal one-third (adapted from:
Ismail-Beigi F, Horton PF, Pope CE II. Histological consequences of gastroesophageal reflux in man. *Gastroenterology* 1970;58:163â€“174
). In the distal 3 cm of the esophagus, up to 60% of individuals without objective evidence of reflux demonstrate papillary lengths that may exceed these values (59). Conversely increasing basal cell

hyperplasia and papillary height does correlate with increasing severity of reflux (83).

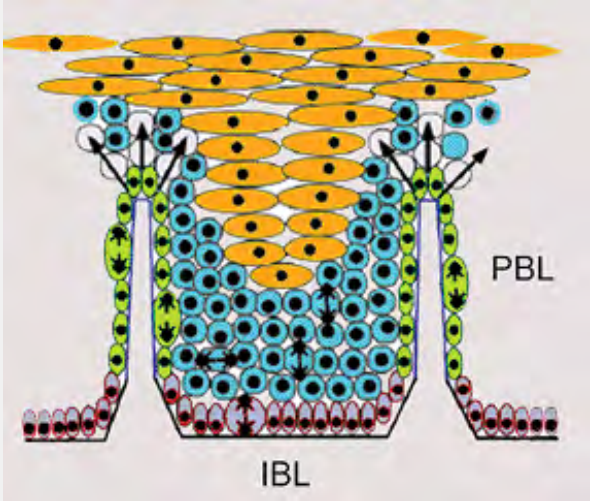

Figure 22.18 A model of the cellular organization in the esophageal epithelium. The interpapillary basal layer (*IBL*) cells (blue-grey) constitute the epithelial stem cell compartment. IBL cells proliferate infrequently and asymmetrically. Proliferating cells reside in the epibasal (suprabasal) layers (blue). Papillary basal cells (*PBL*) (green) are proliferative and intermediate in behavior between IBL and epibasal cells (see text). Differentiated squamous cells are shown in orange. Esophageal cardiac-type glands are diffusely scattered in the lamina propria through all levels of the esophagus, predominating in the distal and proximal regions (4,27). While they have been variably considered as heterotopias (7,27), normal constituents, or embryologic remnants, there is little doubt that they perform a

lubricating function and are physiologically necessary to facilitate bolus passage. However their number is highly variable, and they are not always identified in the esophagus, having been found in 1 to 16% of esophagi in various studies (7,27,62). Histologically, these glands are located within the lamina propria, resemble the cardiac glands of the stomach, and are composed of cells secreting neutral mucins (Figure 22.19). They resemble pyloric glands, even to the extent that they are MUC6 immunoreactive, and may contain variable numbers of both parietal and chief cells and Paneth-like granules. Their ducts are lined by simple mucus-producing cells, in contrast to the submucosal gland ducts, that are frequently squamous-lined. These duct- lining cells may also extend onto the surface for a variable distance, even producing small islands of simple mucus-producing islands with an abrupt junction with squamous mucosa (H. Watanabe, personal communication).

Muscularis Mucosae

The muscularis mucosae is composed of smooth muscle bundles oriented longitudinally (42), rather than having both a circular and longitudinal arrangement as in the stomach and intestines. The muscularis mucosae begins at the cricoid cartilage of the pharynx and become thicker distally. At the gastroesophageal junction, the esophageal muscularis mucosae is thicker than that of the stomach and

may be so thick as to be mistaken for muscularis propria on biopsy (Figure 22.20). This thicker appearance, along with the longitudinal arrangement, is used sometimes to indicate an esophageal origin for the biopsy, and the differences between the muscularis mucosae of the stomach and esophagus can be used to identify the muscular gastroesophageal junction.

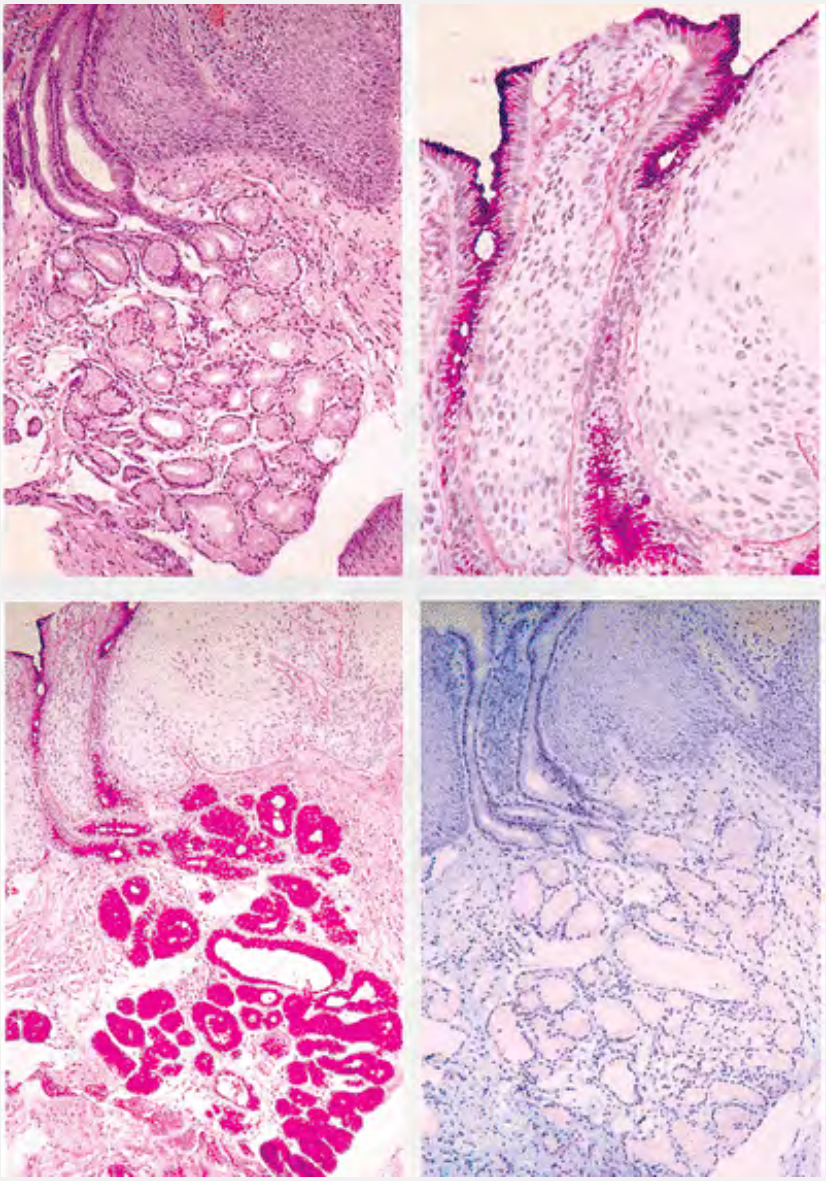

Figure 22.19 Midesophagus. A. Esophageal cardiac-type glands are located within the lamina propria. The ducts are lined by gastric foveolarâ€“like cells. B. The duct-lining cells may extend over the stratified squamous epithelium for variable distances (PASD). C, D. The glands stained PASD positive and alcian blue at pH 2.5 negative, characteristic of neutral mucins.

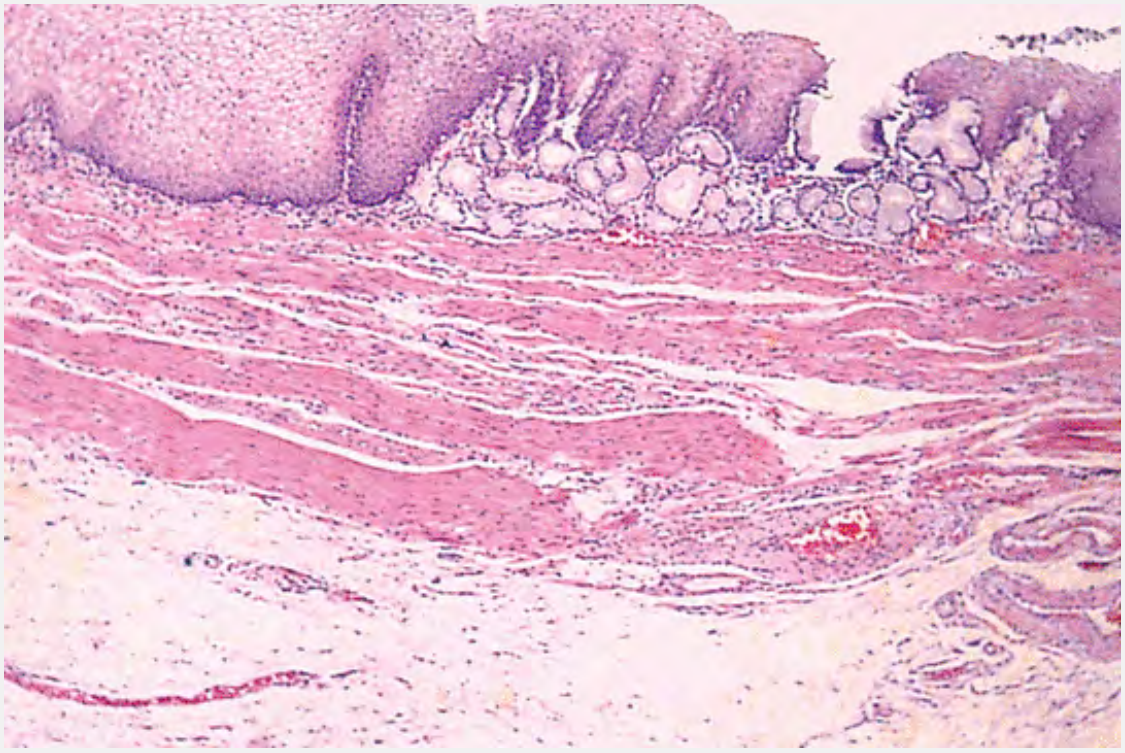

Figure 22.20 Distal esophagus. The mucosal layer at the gastroesophageal junction is characterized by muscularis mucosae that is thicker than the muscularis mucosae of the more proximal esophagus (compare with Figure 22.12). Note the esophageal cardiac-type gland situated above the muscularis mucosae.

Submucosa

The submucosa consists of loose connective tissue containing vessels, nerve fibers (including Meissner's plexus), lymphatics, and submucosal glands (Figure 22.21). The submucosal glands are considered to be a continuation of the minor salivary glands of the oropharynx and are scattered throughout the entire esophagus, but they are more concentrated in the upper and lower regions (4). The

glands consist of mucinous cells, with or without a minor serous component, and produce acid mucins (Figure 22.22)

as well as bicarbonate, which may have a local protective effect. The glands are drained by ducts, initially lined by a single layer of cuboidal epithelium, becoming stratified squamous in type, which penetrate the muscularis mucosae and epithelium to open into the esophageal lumen. This duct epithelium has been immunohistochemically shown to be CK14+/CK19+/CK7+/CK8/18+/variable CK20+ (84). This profile is similar to normal esophageal squamous epithelium and multilayered epithelium (ME), the latter representing a possible intermediate or early stage of Barrett's esophagus (84). Microscopic periductal aggregates of chronic inflammatory cells and duct dilatation are not uncommon findings in the normal esophagus (85). The presence of submucosal glands is indicative of an esophageal origin because these glands are not present in the stomach; unfortunately, submucosal glands are almost never present in mucosal biopsy specimens. However the ducts of the glands may be seen in the lamina propria of mucosal biopsies but are still only demonstrable in up to 14% of biopsies from the lower esophagus (86,87). Esophageal intramucosal pseudodiverticulosis is said to arise from postinflammatory obstruction of the ducts with subsequent duct dilatation (85,88).

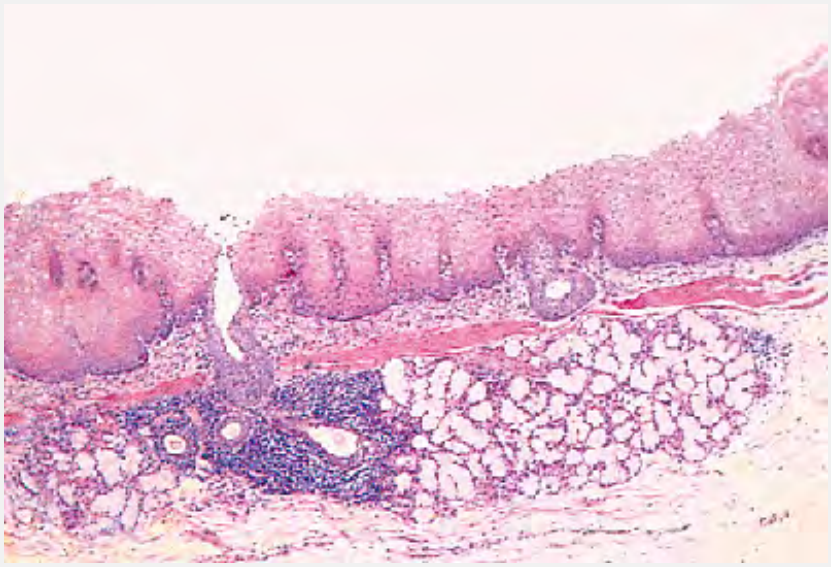

Figure 22.21 Midesophagus. Submucosal glands of the esophagus are located within the submucosa just beneath the muscularis mucosae. Periductal and periglandular chronic inflammation can be a normal finding. Note that in contrast to the columnar-lined glands of the lamina propria, the ducts of the submucosal glands are lined by squamous epithelium.

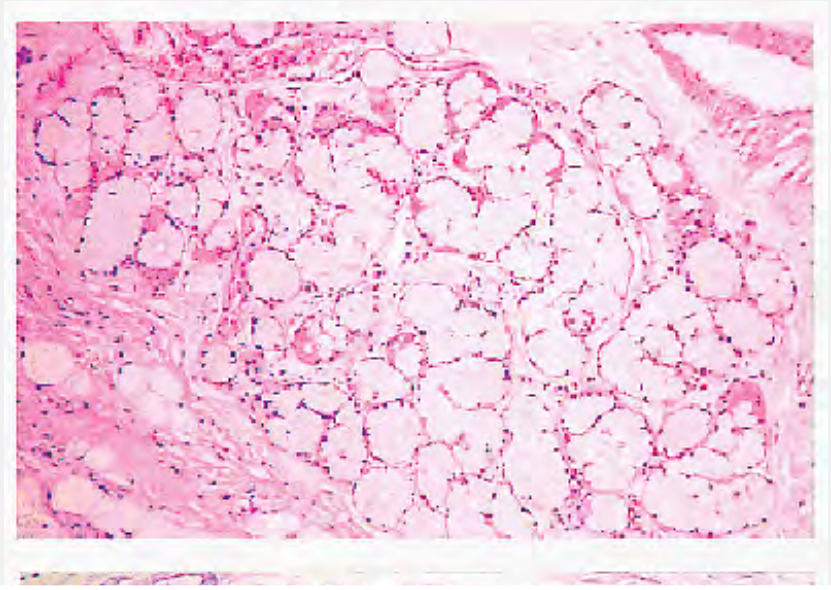

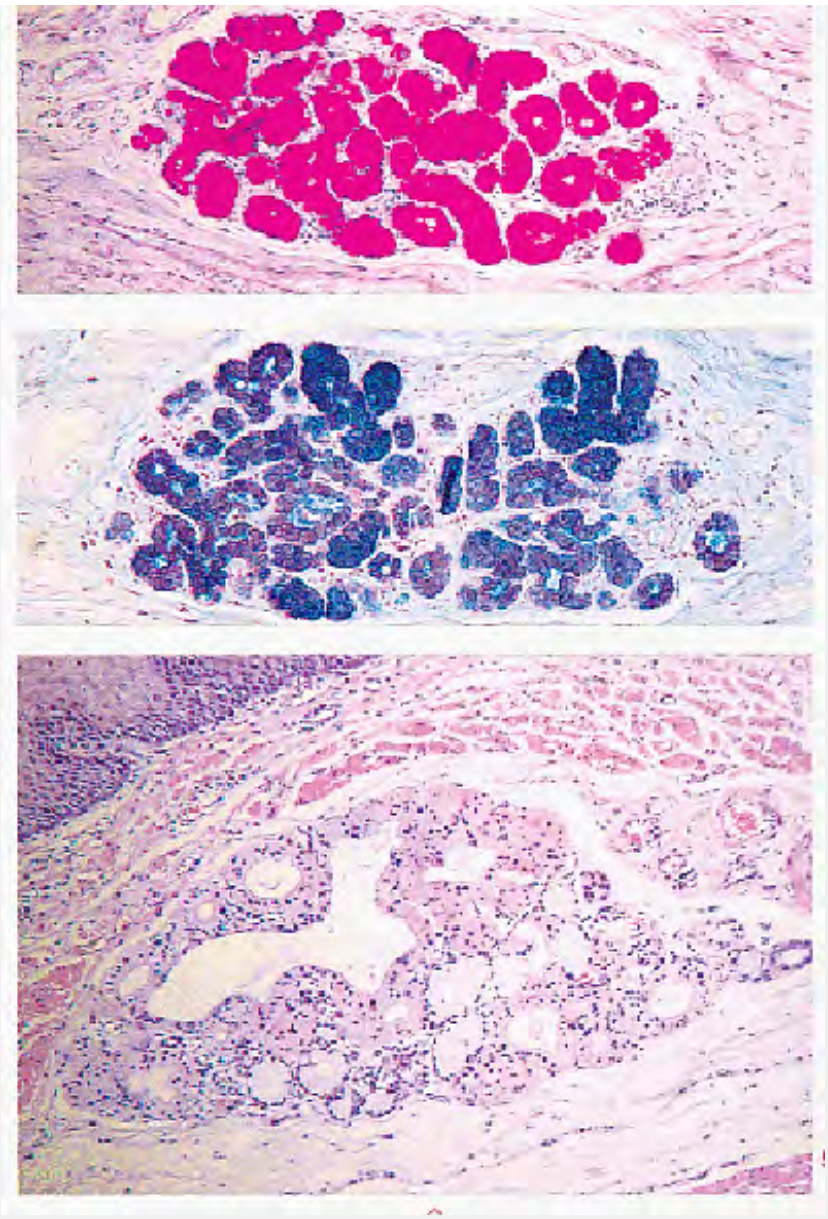

Figure 22.22 Midesophagus. A. The submucosal glands are composed predominantly of mucus-secreting cells with a variable serous component. B. and C. The submucosal glands stained positive with PAS-D and Alcian blue at pH 2.5, a characteristic of acid mucins. D. Submucosal glands may demonstrate oncocytic metaplasia.

Muscularis Propria

It is generally stated that as much as the upper quarter to upper one-third of the proximal muscularis propria is composed of striated muscle (22,23); however, only a short length (approximately 5%) of the proximal muscularis propria is composed of striated muscle (89). Immediately distal to this, smooth and striated muscle intermix, with smooth muscle predominating, whereas slightly more than 50% of the distal muscularis propria is composed solely of smooth muscle (89) (Figure 22.23). Despite the presence of these two different muscle types, they can function as a unit. Auerbach's plexus is found between the two muscle layers. Disease processes may preferentially involve only one of the muscular layers, as in scleroderma (in which atrophy predominantly involves the circular layer) or in achalasia (in which the circular layer may become hypertrophied) (4).

Serosa

Only short segments of the thoracic and intra-abdominal esophagus are lined by serosa derived from the pleura and peritoneum, respectively (4). The majority of the esophagus is surrounded by fascia, which condenses around the esophagus, forming a sheathlike structure. In the upper mediastinum, the esophagus is given support as this fascial tissue extends out to surround and form a similar sheathlike arrangement around adjacent structures (22,23).

Arterial Supply

The cervical portion of the esophagus is supplied by branches of the inferior thyroid artery with contribution from various intercostal arteries. Branches of the bronchial arteries, intercostal arteries, and aorta supply the thoracic segment, whereas the abdominal segment is supplied by branches of the left gastric and inferior phrenic artery (4,22,23,90). Branches from these arteries run within the muscular layer, giving rise to branches that course within the submucosa.

Anastomoses are extensive, explaining the rarity of esophageal infarction (4,90).

Venous Drainage

The venous return from the upper two-thirds of the esophagus drains into the inferior thyroid vein and azygous system, eventually reaching the superior vena cava. The lower esophageal segment drains into the systemic system through branches of the azygous vein and left inferior phrenic vein. The lower esophageal segment also drains into the portal system from branches of the left gastric vein and through the short gastric veins that empty into the splenic vein (4,22,23,90).

The anatomy of the lower esophageal system has been shown to consist of four layers (91). Radially arranged intraepithelial channels drain into the superficial venous plexus, which is found in the upper submucosa. This superficial venous plexus, consisting of three to five main trunks located in the lower submucosa, communicates with the deep intrinsic veins. Perforating veins connect this layer with the adventitial layer of veins located on the esophageal surface. The venous system appears to be mainly distributed within the esophageal mucosal folds (92).

The portal and caval systems communicate through the esophageal and gastric submucosal veins; and, with increased blood flow, as occurs in portal hypertension, all the venous channels of the normal esophagus dilate and are referred to as varices. In portal hypertension, varices are complicated by ulceration and rupture with hemorrhage. It has been suggested that a major variceal hemorrhage occurs as a result of rupture of a varix of the deep intrinsic veins, whereas minor variceal hemorrhages occur as a result of rupture of a varix in the superficial venous plexus or even from the intraepithelial channels (91).

Lymphatic Drainage

A rich network of lymphatics in the lamina propria and submucosa connect with lymphatics in the muscular and adventitial layers. Lymphatics in the muscular layer are predominantly oriented in a longitudinal direction (4). In

view of this longitudinal arrangement, extensive intramucosal and submucosal spread beyond a grossly visible tumor is not uncommon. This becomes an important consideration when assessing resection margins at frozen section.

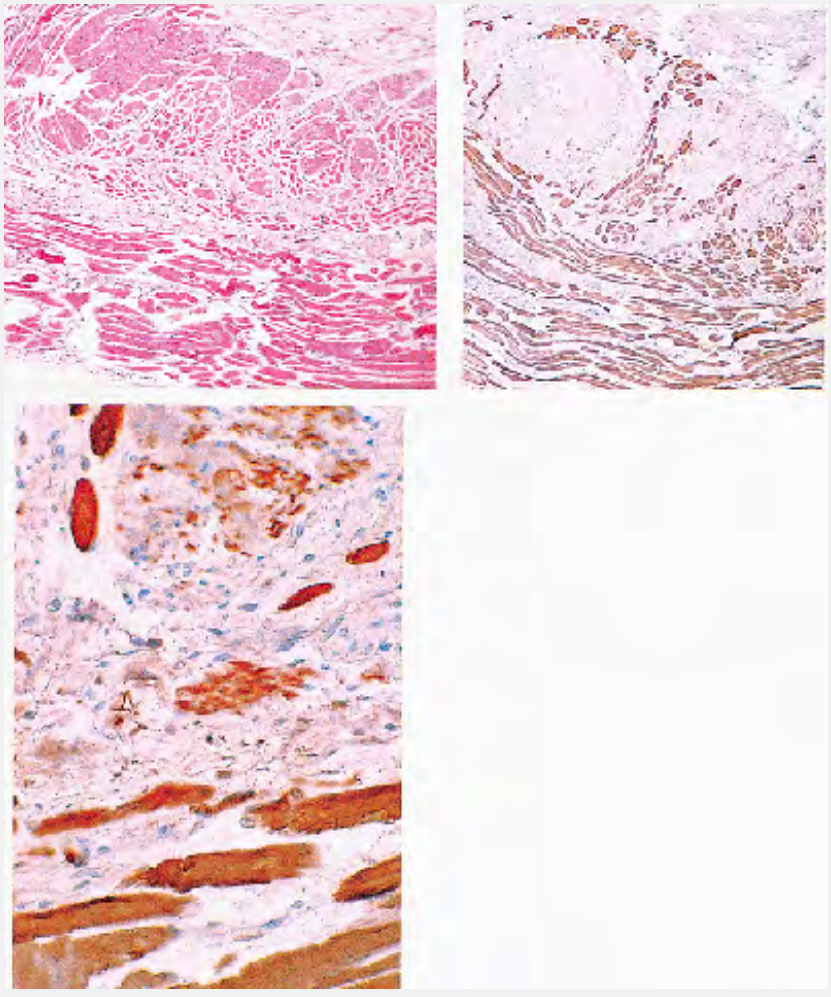

Figure 22.23 Proximal esophagus. A. The muscularis propria demonstrates a mixture of smooth and striated muscle bundles. B. This mix of smooth (weakly stained) and striated (strongly stained) muscle is demonstrated using a myoglobin antibody. C. Detail photomicrographs of myoglobin-stained section demonstrates peripherally located nuclei typical of striated muscle.

In general, the cervical esophagus drains into the internal jugular and upper tracheal lymph node groups. The thoracic esophagus drains into the superior, middle, and lower mediastinal lymph node groups, whereas the abdominal segment drains into superior gastric, celiac axis, common hepatic artery, and splenic artery lymph nodes (93). Despite this drainage pattern, in practice the extensive communication of lymphatics results in a varied and unpredictable metastatic pattern (93).

Innervation (Nerves and Interstitial Cells of Cajal)

The esophagus receives both parasympathetic and sympathetic nerve supplies containing afferent and efferent fibers that innervate glands, blood vessels, and muscles of the esophagus. The vagus nerve carries both parasympathetic and some sympathetic fibers. Sympathetic fibers originating in cervical and paravertebral chains run with vascular structures and end at the esophagus.

As in the rest of the gastrointestinal tract, the esophagus has an intrinsic innervation system. This consists of ganglion cells in the submucosa (Meissner's plexus) and between the

circular and longitudinal muscle layers (Auerbach's plexus). These plexuses are less well developed in the esophagus when compared with the remainder of the gastrointestinal tract, and the density of

neurons increases as one proceeds toward the stomach (22,23). The submucosal plexus is less well developed than the myenteric nerve plexus.

The plexuses of the esophagus receive input from postganglionic sympathetic and preganglionic and postganglionic parasympathetic fibers, as well as from other intrinsic ganglion cells (20). Three cell types are described in the plexuses (89). Type I neurons are multipolar and confined to Auerbach's plexus, and their axons establish synapses with type II cells. Type II neurons are more numerous, are multipolar, and are found in both Auerbach's and Meissner's plexuses. These cells supply the muscularis propria and muscularis mucosae and stimulate secretory activity.

Interstitial cells of Cajal (ICC) are widely distributed within the submucosal, intramuscular, and intermuscular layers associated with the terminal networks of sympathetic nerves. In the few studies that have examined the distribution of ICCs in the esophagus, they have been identified in the distal one-third of the esophagus in close association with smooth muscle, as well as in the middle one-third associated with both smooth and striated muscle (94). Gastrointestinal stromal tumors (GISTs), including those of esophageal origin, originate from these ICCs. Peculiar to the esophagus, when compared to the rest of the gastrointestinal tract, is that tumors of stromal origin are more frequently benign leiomyomas rather than GISTs (95).

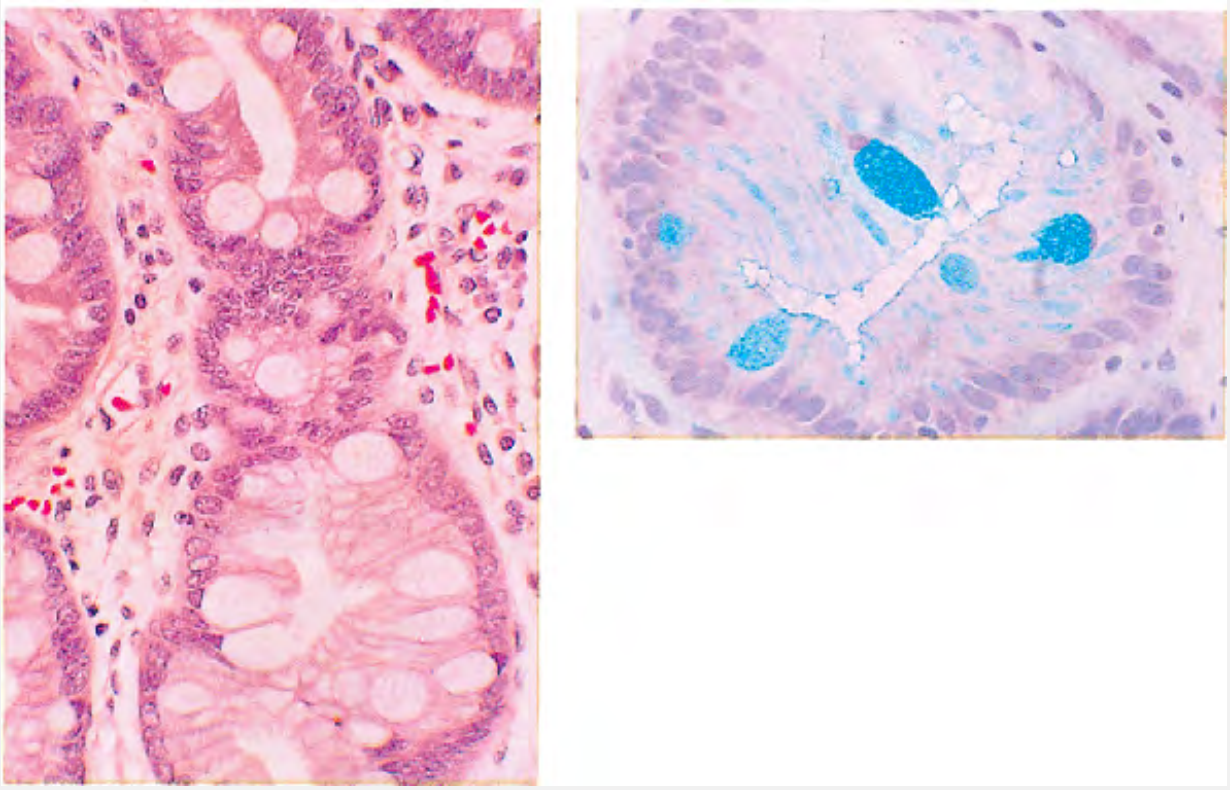

Figure 22.24 Barrett's esophagus. A. Intestinal metaplasia is recognized by the presence of goblet cells. Incomplete intestinal metaplasia (lower half of gland) is characterized by goblet cells associated with gastric foveolarâ€“like columnar cells, whereas complete intestinal metaplasia (upper half of gland) is characterized by goblet cells associated with small intestinal, absorptive-like columnar cells. B. Goblet cells in intestinal metaplasia stain positive with Alcian blue at pH 2.5.

Regulatory peptides identified within nerve fibers and around smooth muscle bundles include vasoactive intestinal peptide (VIP), substance P, enkephalin, and neuropeptide Y (NPY) (96,97). Nerve fibers containing VIP and NPY are the most abundant types present in the esophagus, and the pattern of innervation by these peptide-containing neurons differs from that in the stomach and small

intestine (98). Cholecystokinin (CCK) receptors are found in both the mucosa and nerves of the cardia (99).

Diagnostic Considerations

Commonly received biopsy specimens from the esophagus are for the diagnosis of reflux esophagitis or Barrett's esophagus. The problems of interpretation present in these cases involve the mucosal changes occurring primarily within the confines of the LES.

Barrett's Esophagus

Barrett's esophagus can be defined as the replacement of the esophageal squamous epithelium by metaplastic specialized (ideally intestinalized) columnar epithelium (100) (Figure 22.24). Both macroscopic and microscopic definitions exist, each proposed in an effort to address diagnostic problems encountered in this disease. That most accepted is the presence of an appropriate endoscopic

abnormality that is accompanied by intestinal metaplasia on biopsy (100). This works well except (a) in patients with a highly irregular Z line or very small tongues in whom the endoscopic interpretation of what is within normal limits (or not) may vary considerably; (b) in children, in whom it is rarely found in the first decade of life; and (c) tongues may also fail to yield goblet cells, especially in patients who have been on long-term proton pump inhibitors (PPIs). Indeed, fully 20% of patients rebiopsied for tongues yield goblet cells at the repeat endoscopy (51), a figure virtually identical to that described in long-segment disease (101). Little is known about the dynamics of goblet cells in Barrett's and, if the stimulus for their formation is removed (duodenogastroesophageal reflux) or the amount of gastric secretion reduced (e.g., by use of PPIs), whether their number may diminish or even disappear.

Macroscopically, Barrett's esophagus demonstrates a red velvety

mucosa corresponding to the columnar epithelium, with an apparent focal or diffuse cephalad migration of the Z line relative to the previous normal mucosal gastroesophageal junction (Figure 22.25). Barrett's mucosa merges imperceptibly with the gastric mucosa distally. The junction with the esophageal squamous epithelium may appear as a symmetric or asymmetric Z line (as at the normal gastroesophageal junction) or as islands of columnar mucosa alternating with the squamous epithelium (â€œisland patternâ€•). Foci of squamous epithelium occasionally are identified within Barrett's mucosa. Inflamed squamous mucosa may be indistinguishable from Barrett's mucosa endoscopically, and therefore also the squamo-Barrett junction, when both are present.

The diagnosis of Barrett's esophagus should always be confirmed histologically. If potential Barrett's mucosa is identified endoscopically, it should be examined via biopsy (as outlined below) to confirm the presence of specialized epithelium, as well as to exclude dysplasia or carcinoma, both of which may be inapparent endoscopically. Histologic confirmation is also important in cases of short-segment Barrett's esophagus (in which the short tongues of mucosa present may endoscopically resemble hiatal hernias, which are lined by gastric mucosa), inflammatory changes at the gastroesophageal junction, or an exaggerated and asymmetric yet normal mucosal gastroesophageal junction (102,103,104). Histologic confirmation is also necessary in cases of suspected childhood Barrett's esophagus, where Barrett's mucosa may be indistinguishable from the normal squamous epithelium (105,106,107). While the term *ultra-short Barrett's esophagus* has been used, primarily for lesions less that 1 cm (108), the interobserver variability of when an irregular Z line stops and Barrett's starts is problematic, rendering the term relatively useless. There also seems little sense in using it for patients with just intestinal metaplasia in an apparently normal cardia.

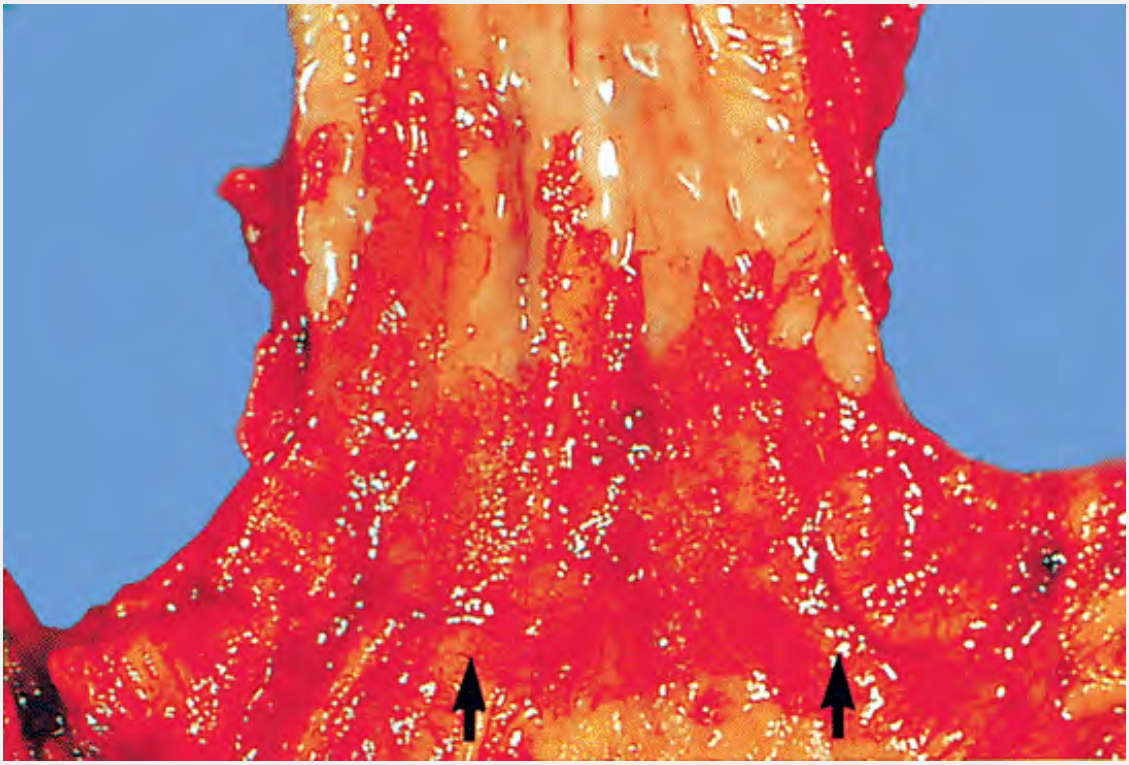

Figure 22.25 Gastroesophageal region. Barrett's esophagus, demonstrating proximal extension of columnar-lined mucosa well into the tubular esophagus. This columnar-lined mucosa extends more than 2 cm from the proximal gastric folds (*arrows*).

In adults, specialized epithelium is by far the most frequent epithelial type identified, so much so that the presence of this epithelium is increasingly being used as the sole criterion for the diagnosis of Barrett's esophagus (100). Other epithelial types are of much less value diagnostically and include fundic, junctional, metaplastic pancreatic acinar, and multilayered epithelium. Superimposed dysplasia, primarily of intestinalized epithelium, also may be present.

Specialized-type epithelium is characterized by the presence of goblet and columnar cells (Figure 22.24). The goblet cells contain acid mucins, predominantly sialomucins, thus staining positive with

Alcian blue at pH 2.5, MUC2, or CD10 if there is complete intestinal metaplasia. The nongoblet cell population may also show an intestinal phenotype, showing expression of the intestinal markers sucrase-isomaltase and dipeptidilpeptidase IV immunoexpression in the majority of patients examined (109). Similarly goblet cells in Barrett's associated intestinal metaplasia are much more likely to express the mucin antigens MUC1 and MUC6 (110). The columnar epithelial cells may therefore resemble either small intestinal absorptive cells (complete intestinal metaplasia) or gastric foveolar cells, which frequently show evidence of an intestinal phenotype (incomplete intestinal metaplasia); however, these metaplastic cells demonstrate abnormal features that distinguish them from their normal counterparts (Figure 22.24). In the case of complete intestinal metaplasia, the small intestinal-like columnar cells may demonstrate a brush border, but it is not well developed and lacks the uniform enzymatic activity normally found in the brush border of the small intestine (111). Ultrastructurally, these metaplastic cells have been shown to contain mucin granules, which are not present in the absorptive cells of the small intestine, while the gastric foveolar-like columnar cells frequently contain Alcian blueâ€“positive acid mucin, in contrast to those that normally populate the stomach, which contain Alcian blueâ€“negative neutral mucins (111).

Other types of gastric mucosa may be present in Barrett's esophagus but cannot easily be distinguished from mucosa arising from the â€œnormalâ€• gastric cardiac mucosa; their definitive presence in Barrett's esophagus can be accepted only in resections or other circumstances under which specialized mucosa has been identified above the gastroesophageal junction. In the adult, fundic-type mucosa is uncommon and, if present, resembles the transitional epithelium seen at the junction of the gastric body with the antrum or cardia, with only a scattering of parietal and chief cells. Fundic-type mucosa without intestinalization and resembling normal gastric fundus mucosa can be seen in childhood Barrett's esophagus;

otherwise, it is rare, and if present one must consider the possibility that the invariably present hiatal hernia has been examined via biopsy. The lack of intestinalized mucosa is a feature usually confined to children; it is likely that specialization occurs later in early adult life. Similarly, junctional-type mucosa that histologically is indistinguishable from normal gastric cardiac mucosa may be presentâ€”so much so that, if seen as the only mucosal type in a case of suspected short-segment Barrett's esophagus, a normal exaggerated Z line cannot be excluded.

Multilayered epithelium is a distinctive type of epithelium, histologically characterized by multiple layers of basaloid cells with an overlying layer of columnar epithelium (Figure 22.26). This epithelium has been shown to have mucin and immunohistochemical qualities similar to normal squamous epithelium, duct gland epithelium, and Barrett's epithelium (84); and it is associated with reflux-induced injury (112) and intestinal metaplasia in patients with Barrett's disease (113). As such, it is postulated that multilayered epithelium may represent an early/transitional phase of columnar metaplasia in Barrett's esophagus, although some believe that this is ciliated ultrastructurally and therefore represents simple metaplasia (8,28).

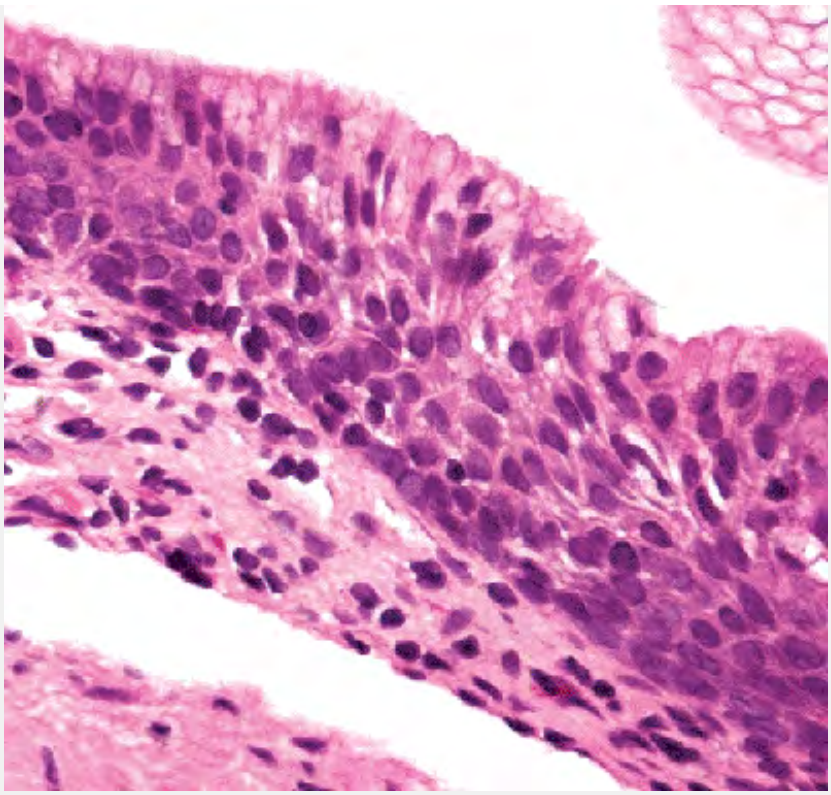

Figure 22.26 Multilayered epithelium, in which there is apical mucin production at the luminal surface (*top*), but the remainder of the epithelium appears squamous with intercellular bridges.

The diagnosis of Barrett's esophagus is best established by taking biopsy samples from various levels of the gastroesophageal region (114), beginning in the stomach just distal to the upper end of the gastric folds, ideally along the lesser curve, and then every 1 to 2 cm, up into the tongues of mucosa or the most irregular portion of the squamocolumnar junction until squamous epithelium is reached. Obvious islands of columnar-lined epithelium also should be examined via biopsy. This series of biopsy samples yields tissue that initially originates in a site that is clearly of gastric origin (thereby excluding gastric intestinal metaplasia as a cause of proximal intestinalized epithelium), continues through mucosa in which intestinalized epithelium is present (thereby confirming the diagnosis

of Barrett's esophagus), and finishes in squamous mucosa. Intestinal metaplasia may be focal and thus may be missed on biopsy. In such cases, if the diagnosis of Barrett's esophagus is suspected, follow-up with repeat biopsy is necessary.

Although there is uncertainty as to the cell of origin for Barrett's esophagus, the cells lining the gland duct may be considered as a possible source (115). Conversely, re-epithelialization of the esophagus following ablation may well be from the squamous-lined submucosal gland ducts.

Intestinal Metaplasia Limited to the Cardiac Region

Intestinal metaplasia (IM) is common and found in up to one-third of patients (116); but, it also depends to some extent on how many biopsies are taken and where a highly irregular but normal Z line stops and short-segment Barrett's esophagus (defined as less than 3 cm of columnar-lined esophagus with goblet cells) begins, a feature with quite marked interobserver variability. In one study, a total of 811 (84.6%) patients had 0 to 0.9 cm of questionably abnormal columnar epithelium between normal oxyntic mucosa and squamous epithelium. Of these, 161 (19.9%) patients had no abnormal epithelium, 158 (19.4%) patients had oxyntocardiac mucosa, 372 (45.9%) patients had cardiac mucosa, and 120 (14.8%) patients had intestinal metaplasia. The prevalence of intestinal epithelium increased progressively with increasing length of abnormal columnar epithelium, being present in 70.4% in the 1- to 2-cm group, 89.5% in the 3- to 4-cm group, and 100% within the greater than or equal to 5 cm group (117).

This raises several issues. First, metaplasia has several causes, although the principle two are GERD and *Helicobacter*. Second, because the diagnosis of Barrett's esophagus requires both intestinal metaplasia and an appropriate endoscopic appearance, the

identification becomes key, especially in defining what is unequivocally

abnormal and where an irregular but normal Z line stops and Barrett's begins (118,119). Clearly, Barrett's esophagus has to begin somewhere, but this distinction is currently impossible to determine because, although some differences between metaplasia in native cardiac mucosa and metaplasia in what was formerly squamous mucosa exist (9), it is unclear how reliable these are. The third issue regarding the type of epithelium in which intestinal metaplasia is occurring is in part the pathogenesis issue but also its implication. Does intestinal metaplasia in what is believed to be the native cardiac side of the Z line have the same malignant potential as recognized Barrett's mucosa? If it does not, then it becomes critical to attempt to separate the two; but, if it does, then the exercise is futile because both diseases are premalignant and the issue becomes the extent of the risk and whether this justifies surveillance. Because metaplasia at the cardia in *Helicobacter* gastritis tends to be complete, while that in Barrett's is often both complete and incomplete, it is likely that Barrett's esophagus is at increased risk of developing carcinoma. This is also supported by mucin immunohistochemistry using MUC1 and MUC6 (110).

Gastroesophageal Reflux Disease (GERD)

The problems encountered in GERD are related to squamous epithelial changes in the distal 3 cm of the esophagus and to the significance of intraepithelial inflammatory cells.

Reactive Squamous Changes

Reflux-associated squamous hyperplasia (RASH) consists of basal cell hyperplasia of greater than 15% and extension of the papillae into

the upper one-third of the epithelium (60) (Figure 22.27). Practically, in well-oriented biopsy samples, the esophageal mucosa can be divided into thirds; the papillae should not be seen extending into the upper one-third, and the basal cell layer should not extend more than halfway into the lower one-third. This is operatively a simple and rapid technique for assessing the degree of RASH. However, similar changes have been described in the distal 3 cm of the esophagus in approximately 60% of patients without objective or subjective evidence of acid reflux (59); thus, if present in biopsy samples originating from this zone, such hyperplastic changes should be considered normal, despite the fact that these changes are much more likely to be found in patients with GERD and NERD (nonerosive reflux disease) (83). Changes of RASH are much more likely to be a more specific indicator of reflux if the biopsy samples are taken above the distal 3 cm of the esophagus (59,61). It should be remembered that squamous hyperplasia is a nonspecific reaction to any form of esophageal injury and needs to be interpreted in light of the clinical context.

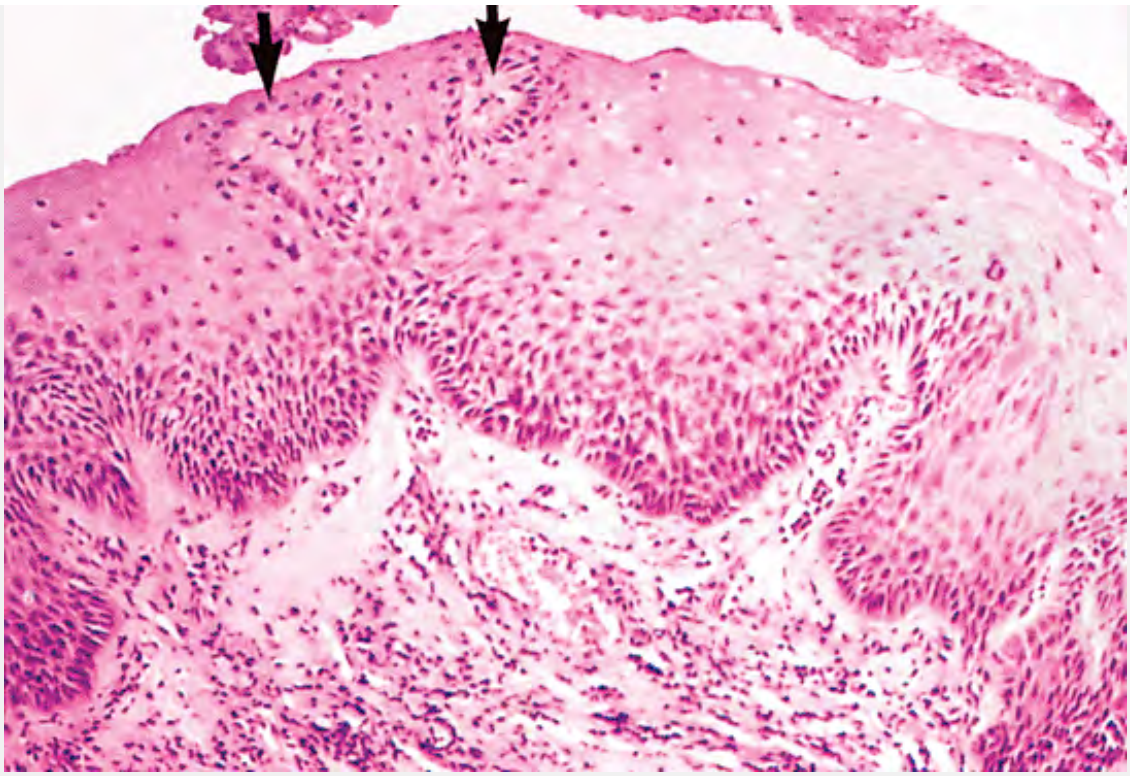

Figure 22.27 Reflux esophagitis. Basal cell hyperplasia and lengthening of the papillae are present. The papillae have extended almost to the surface of the mucosa (arrows).

Dilated Intercellular Spaces

Apart from squmaous hyperplasia, dilatation of the intercelluar spaces of the squamous epithelium as a result of gastroesophageal reflux has been demonstrated at both the electron and light microscopic level (120,121,122) (Figure 22.14). This early epithelial damage is morphologically characterized by irregular dilatation of the intercellular spaces of the basal and prickle cell layers in both erosive and nonerosive esophagitis. Using ultrastructural measurement, it seems that dilatation of more than 2.4 Âµm is highly suggestive of GERD (123). This is approximately half the diameter of an intaepithelial lymphocyte. Further, patients with NERD

have a DIS measurement of approximately half of this at 1.5 Âµm, which is still about three times the normal value of 0.45 to 0.5 Âµm (124). Readers will no doubt be pleased to know that these measurements were made ultrastructurally! Treatment with omeprazole results in complete recovery of DIS (125). DIS have also been shown to be one of the histological changes (along with basal cell hyperplasia) seen in biopsies from endoscopic lesions referred to as â€œred streaksâ€• (86), along with newly re-epithelialized lesions or granulation tissue beneath squamous epithelium. Its utility as a marker of GERD when unaccompanied by other morphological features of reflux disease has yet to be fully determined.

Intraepithelial Inflammatory Cells

Intraepithelial eosinophils (IEEs) and intraepithelial neutrophils (IENs) are generally not considered to be normal constituents of the epithelium throughout its entire length, although rare IEEs in the distal 3 cm of approximately one-third of adult patients is considered normal (61). The presence of IEEs has long been considered a sensitive indicator

of reflux esophagitis (61,82,126), although this sensitivity is in question, and not infrequently it is the only pathologic change (Figure 22.28A). Intraepithelial eosinophils are not absolutely specific, having been described in esophagitis due to alkaline reflux, allergic disorders, and infections (82) (Figure 22.28B). In children, although not an absolute criterion, eosinophils within the lamina propria are a significant finding in GERD. However, it is also clear that there is a second syndrome that can be seen in both adults and children in whom the primary symptom may be dysphagia rather than GERD; it tends to occur in younger males, and when fully developed is characterized endoscopically by rings reminiscent of allergic esophagitis. It has therefore been called feline esophagus, ringed esophagus, or trachealization of the esophagus. The esophagus is fragile and can perforate if dilatation of areas of narrowing is

attempted. Histologically, the features are massive (usually 20â€“40/HPF) numbers of eosinophils, that also tend to extend throughout the esophagus, and also tend to be superficial. Patients often have other evidence of allergies and may respond to steroids or allergen withdrawal, including an elemental diet, rather than to PPIs (127,128,129,130,131,132,133).

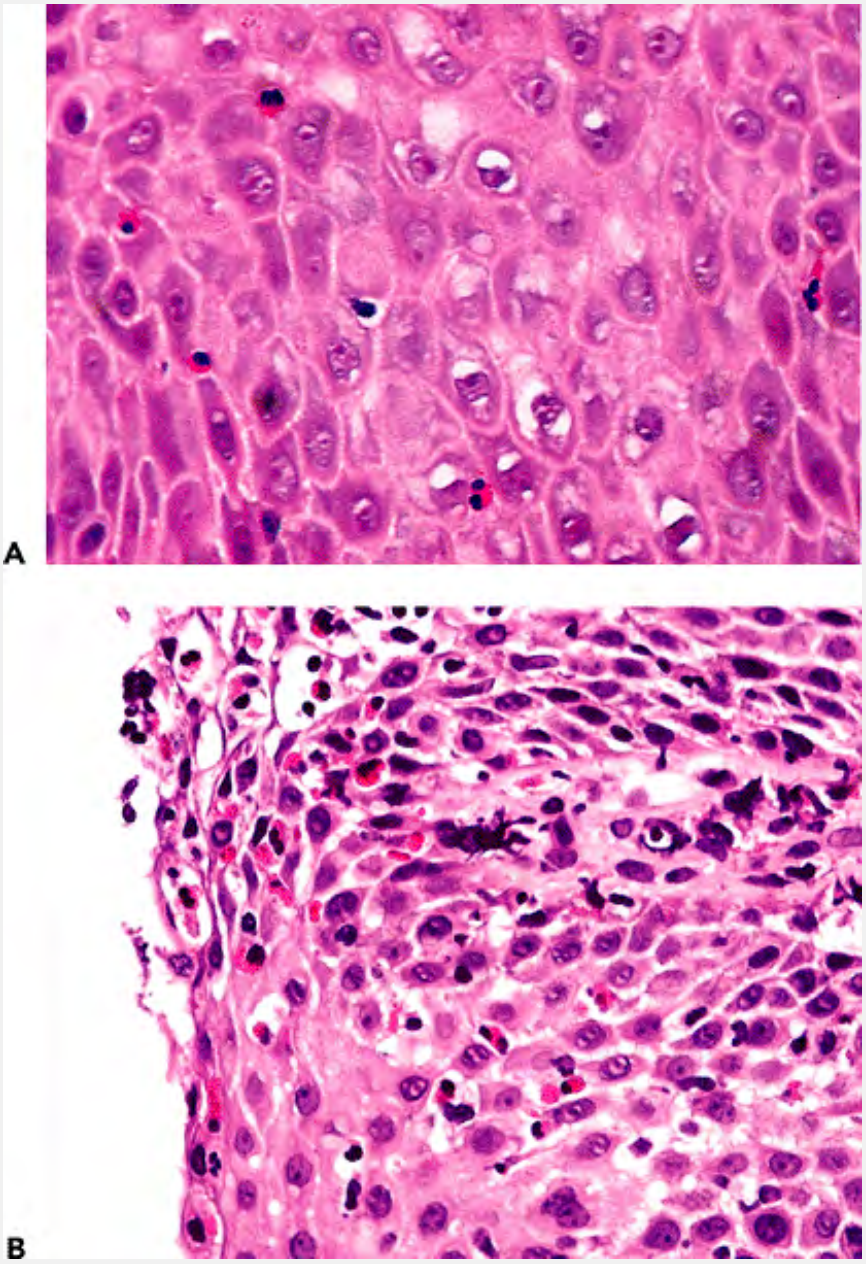

Figure 22.28 Eosinophilic esophagitis. A. Reflux esophagitis. Intraepithelial eosinophils are present between the epithelial cells. B. Allergic esophagitis (feline esophagus). There is marked basal cell hyperplasia, spongiosis with dilated intercellular spaces, and numerous eosinophils.

The presence of IENs obviously implies acute esophagitis and correlates with the presence of erosion or ulceration, albeit of any cause, but is less sensitive for mild GERD. When present, IENs are frequently, but not always, accompanied by the other histologic features of esophagitis. In biopsies, the absence of other features may simply reperesent sampling problems. The use of DIS, IEEs, and IENs as histologic criteria of GERD has the advantage that localization and orientation of the biopsy is not important.

Vascular changes such as dilated capillaries and extravasated red blood cells in the lamina propria should not be considered as criteria for GERD (60,61), although some have been impressed by its usefulness (134). Increased vascularization in the lamina propria, thought of as indicative of RASH is not considered a diagnostic criterion (133). The presence of intraepithelial mononuclear cells (squiggle cells) is associated with GERD but rarely used as the sole criterion (83,135,136).

In the assessment of biopsy tissues for RASH, well-oriented biopsy specimens of full epithelial thickness are necessary. Quite often biopsy samples are taken with small pinch forceps, resulting in a specimen that is small, superficial, and difficult to orient. If endoscopy is being performed to obtain a tissue diagnosis, an appropriate endoscope with large-particle grasp forceps should be used. Changes of GERD may have a patchy distribution; thus, multiple biopsies are recommended. It is important to avoid the use of picric acid containing dyes and fixatives (such as Bouin's solution) because this interferes with the staining of the eosinophil granules, thus preventing their recognition.

Inflammatory Changes on the Cardiac Side of the Z Line

Because of the increasing use of biopsy samples immediately on the squamous side of the Z line to detect inflammatory cells, some biopsy samples inevitably contained cardiac mucosa immediately distal to the Z line. Some of these specimens contained an excess of chronic and sometimes acute inflammatory changes, which were not only unaccompanied by inflammatory changes elsewhere in the stomach, as might be expected with *Helicobacter pylori* gastritis, but inflammation appeared to be completely limited to the gastric cardia and therefore was appropriately termed gastric carditis (114). However, it appears to be a more sensitive marker for GERD than inflammatory changes in the squamous mucosa, as judged by correlation with 24-hour pH studies (57,114,137,138), the proviso being that *Helicobacter* infection (gastritis) is not present as this also causes carditis (139,140,141).

Adenocarcinomas of the Gastroesophageal Region

Adenocarcinomas arising in the gastroesophageal region may have their origin from the gastric cardia, from Barrett's mucosa, or theoretically from the gastric cardiac-type mucosa present in the distal 2 cm of the esophagus. Gastric cardiac adenocarcinomas can be defined macroscopically as those occurring at or below the gastroesophageal junction, with the bulk of the tumor found in the gastric cardia and not involving the body or distal stomach (142). The presence of premalignant changes in the adjacent cardiac epithelium, such as a villous adenoma or dysplasia, would be confirmatory. Adenocarcinoma arising from Barrett's esophagus are predominantly located in the esophagus and are usually associated

with demonstrable Barrett's mucosa histologically. Those arising from the gastric epithelium of the distal 2 cm of the esophagus can be classified with those of the gastric cardia unless associated with Barrett's mucosa. Occasionally, an adenocarcinoma may involve both the lower esophagus and gastric cardia equally, with obliteration of the landmarks of the gastroesophageal junction and any premalignant mucosa. In these cases, identification of the site of origin may be impossible; however, from a practical viewpoint, this distinction may not be important because their clinical behaviors are similar (142,143,144).

Stomach

David A. Owen

Embryology and Postnatal Development

The stomach develops as a fusiform dilatation of the foregut caudal to the esophagus. This occurs first when the embryo is 7 mm in length. Initially, it is attached to the back of the abdomen by the dorsal mesogastrium and to the septum transversum (diaphragm) by the ventral mesogastrium. As the stomach enlarges, the dorsal mesogastrium becomes the greater omentum and the ventral mesogastrium becomes the lesser omentum.

The stomach is derived from endoderm, and early glandular differentiation of the mucosal lining occurs first at the 80-mm stage of fetal development. Enzyme and acid production first occur at the fourth month of fetal life and are well established by the time of birth. The newborn stomach is fully developed and similar to that of the adult.

Gross Morphologic Features

The stomach is a flattened J-shaped organ located in the left upper quadrant of the abdomen. At its upper end, it joins the esophagus several centimeters below the level of the diaphragm. At its distal

end, it merges with the duodenum, just to the right of the midline. The stomach is extremely distensible, and its size varies, depending on the volume of food present.

For the purposes of gross description, the stomach can be divided into four regions: cardia, fundus, corpus (or body), and antrum (1,2) (Figure 23.1). The superomedial margin is termed the lesser curvature, and the inferolateral margin is termed the greater curvature. The cardia is found just distal to the lower end of the esophagus. It is a small and ill-defined area, extending 1 to 3 cm from the gastroesophageal junction. The fundus is that portion of the stomach that lies above the gastroesophageal junction, just below the left

hemidiaphragm. The antrum comprises the distal third of the stomach, proximal to the pyloric sphincter (pylorus), with the remainder of the stomach referred to as the corpus. The junction between the antrum and corpus is poorly demarcated. By external examination, it comprises the portion of stomach distal to the incisura, a notch on the lesser curvature (1). Internally, the gastric mucosa is usually thrown into coarse folds called rugae. These are prominent when the stomach is empty but flattened out when the organ is distended. The rugae are most prominent in the corpus and fundus because this is where the major dilatation to accommodate food occurs. The antrum is characterized by mucosa that is flatter and more firmly anchored to the underlying submucosa (Figure 23.2).

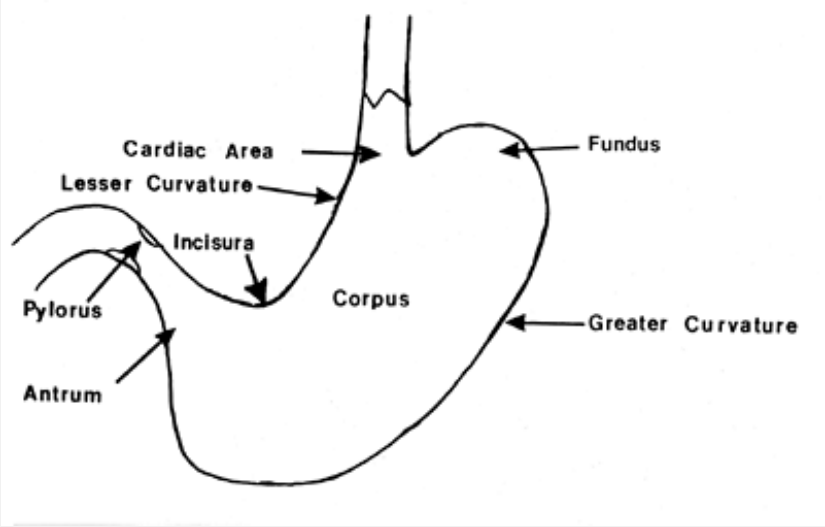

Figure 23.1 Gross anatomical zones of the stomach.

The wall of the stomach has four layers: mucosa, submucosa, muscularis propria, and subserosa. Apart from the mucosa, these layers are structurally similar to the bowel wall elsewhere in the gastrointestinal tract. When viewed close up, the surface of the mucosa is dissected by thin shallow grooves termed areae gastricae (3). These are structurally fixed and do not flatten out when the stomach is distended. They are best seen when the mucosa is viewed *en face* with a hand lens. *Areae gastricae* may be demonstrated radiologically via double-contrast barium examination but also can be recognized on histologic sectionsâ€”particularly from gastrectomy specimens, where they appear as shallow depressions on an otherwise monotonously smooth surface (Figure 23.3).

Blood Supply

Five arteries supply blood to the stomach. The left gastric artery arises directly from the celiac axis and supplies the cardiac region.

The right gastric artery (which supplies the lesser curve) and the right gastroepiploic artery (which supplies the greater curve) arise from the hepatic artery. The left gastroepiploic and the short gastric arteries arise from the splenic artery and also supply the greater curvature. All these vessels anastomose freely, both on the subserosal layer of the stomach and in the muscularis propria, with extensive true plexus formation present within the submucosa. This richness of blood supply explains why it is so

unusual to see gastric infarcts. The mucosal arteries are derived from this submucosal plexus but are end arteries and supply an area of mucosa that is largely independent of the adjacent mucosal arteries (4).

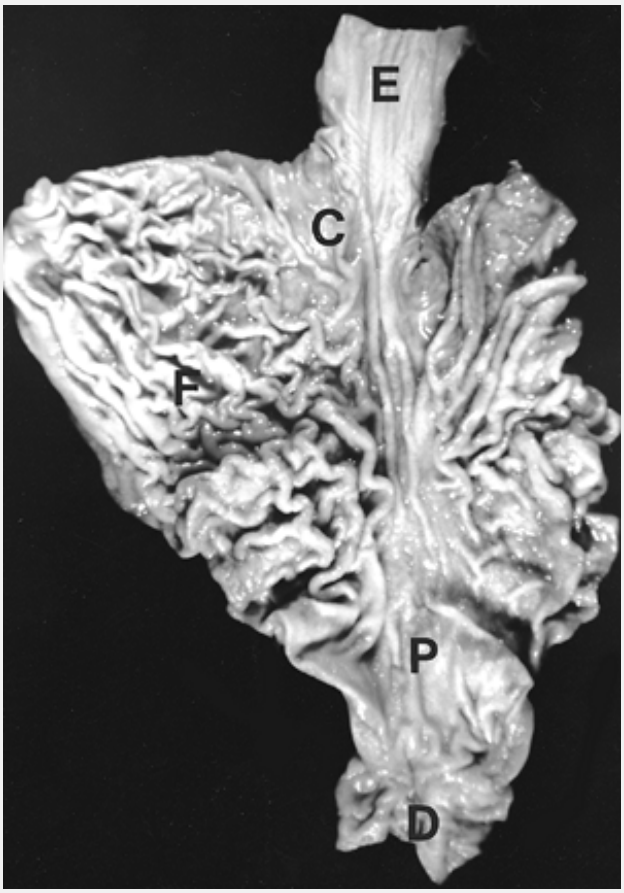

Figure 23.2 Mucosal zones of the stomach. The cardiac mucosa (*C*) is present distal to the lower end of the esophagus (*E*). The pyloric mucosa (*P*) occupies a triangular zone proximal to the duodenum (*D*). Elsewhere, the fundic mucosa (*F*) shows prominent rugal folds.

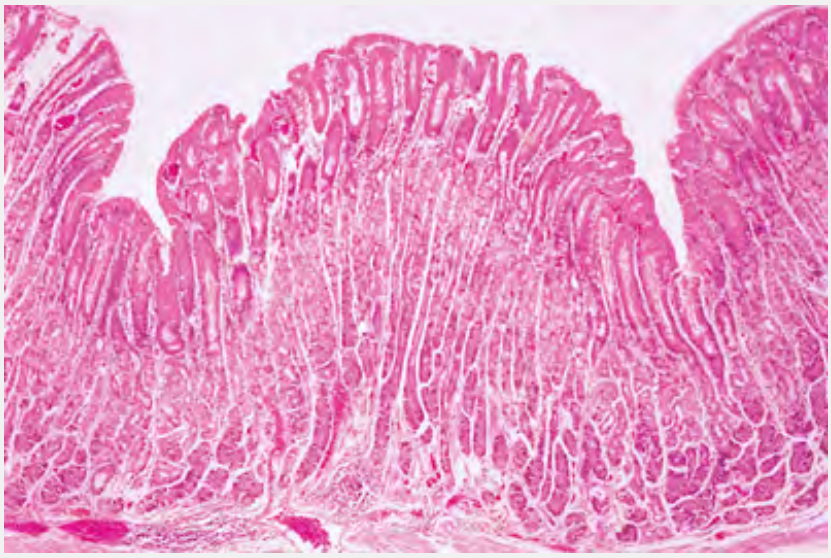

Figure 23.3 Low-power view of the gastric fundal mucosa. The grooves in the mucosa are fixed anatomical features called areae gastricae.

Nerve Supply

The sympathetic nerve supply to the stomach is derived from the celiac plexus via nerves that follow the gastric and gastroepiploic arteries. Branches also are received from the left and right phrenic nerves. The parasympathetic supply is the vagus nerve via the main anterior and posterior trunks that lie adjacent to the esophagogastric junction. Shortly after entering the abdomen, the

anterior vagus nerve gives off a hepatic branch, and the posterior vagus nerve gives off a celiac branch. Therefore, truncal vagotomy above these branches results in denervation of not only the stomach but the entire intestinal tract. Sectioning below these nerves results only in gastric denervation. A highly selective vagotomy (gastric corpus denervation) is achieved by sectioning lateral branches as the two main gastric nerves pass along the lesser curvature, with preservation of the terminal portion of the vagi that supply the antrum. No true nerve plexuses occur on either subserosal layer of the stomach but instead are concentrated in Meissner's plexus in the submucosa and Auerbach's plexus between the circular and longitudinal fibers of the muscularis propria.

Lymphatics

Recent studies (5,6) have disproved the former view that lymphatic channels are present at all levels of the lamina propria. By using careful ultrastructural techniques, lymphatics have been demonstrated to be limited to the portion of the lamina propria immediately superficial to the muscularis mucosae. From there, efferents penetrate the muscle and communicate with larger lymphatic channels running in the submucosa. This arrangement implies that an early gastric cancer may have lymphatic metastases, even though the primary tumor is entirely superficial to the muscularis mucosae.

The lymphatic trunks of the stomach generally follow the main arteries and veins. Four areas of drainage can be identified, each with its own group of nodes. The largest area comprises the lower end of the esophagus and most of the lesser curvature, which drains along the left gastric artery to the left gastric nodes. From the immediate region of the pylorus, on the lesser curvature, drainage is to the right gastric and hepatic nodes. The proximal portion of the greater curvature drains to pancreaticosplenic nodes

in the hilum of the spleen, and the distal portion of the greater curvature drains to the right gastroepiploic nodes in the greater omentum and to pyloric nodes at the head of the pancreas. Efferents from all four groups ultimately pass to celiac nodes around the main celiac axis.

General Histologic Features

Histologically, the mucosa has a similar pattern throughout the stomach. It consists of a superficial layer containing foveolae (pits), which represent invaginations of the surface epithelium, and a deep layer consisting of coiled glands that empty into the base of the foveolae (Figure 23.4). The glandular layer differs in structure and function in different zones of the stomach that correspond roughly, but not precisely, to the gross anatomic regions (Figure 23.1).

Adjacent to the gastroesophageal junction is the cardiac mucosa, where the glands are mucus secreting. Extending proximally from the pylorus is the pyloric mucosa (sometimes called the antral mucosa), where the glands are also mucus secreting. This zone is triangular, extending much further (5â€“7 cm) proximally along the lesser curvature than it does along the greater curvature (3â€“4 cm). The pyloric mucosal zone is not identical to the antral region, although some accounts use these terms interchangeably. Also, contrary to what is implied in some descriptions, the incisura has no fixed relationship to the proximal margin of the pyloric mucosal zone. Elsewhere within the stomach (corpus and fundus), the mucosa is exclusively fundic in type, where the glands are specialized to secrete acid and pepsin.

Histologic transition between pyloric and fundal mucosa is gradual rather than abrupt, with intervening junctional mucosae (1â€“2 cm in width) having a mixed histologic appearance. A broad mucosal transition zone is also present at the pylorus, where gastric and duodenal mucosae merge. However, at the lower end of the

normal esophagus, the change from nonkeratinizing squamous epithelium to columnar epithelium is abrupt, both grossly and microscopically. The position of this squamocolumnar junction is variable and does not always coincide with the

strict anatomic esophagogastric junction, that is, the point where the tubular esophagus becomes the saccular stomach. In some individuals the mucosal junction is located 0.5 to 2.5 cm proximal to the anatomic junction and often is serrated, rather than being a regular circumferential line (Z line) (2).

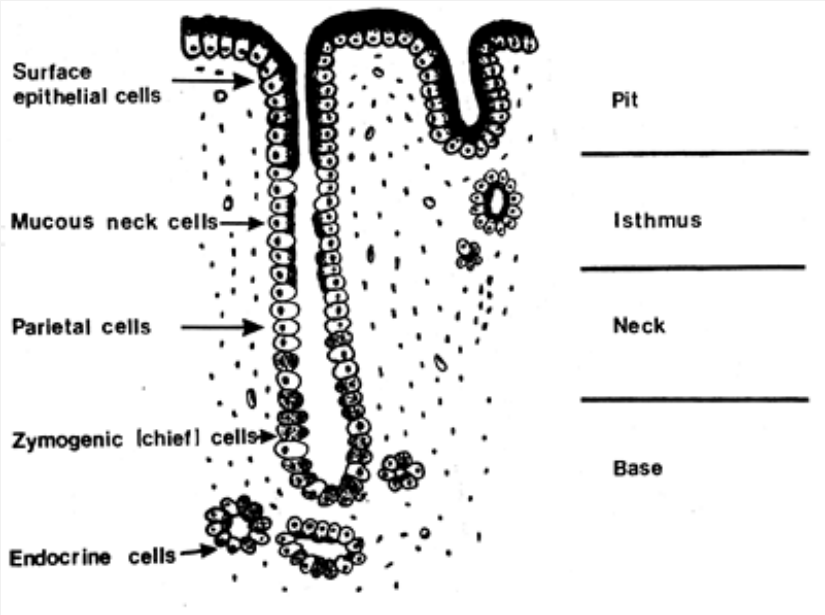

Figure 23.4 Diagrammatic representation of gastric fundal mucosa. Zymogenic (chief) cells are seen mainly in the basal portion of the glands and parietal cells mainly in the isthmic portion. The neck portion contains zymogenic cells, parietal cells, and mucous neck cells. A small number of endocrine cells are present in the basal zone.

Surface Epithelium

Histologically, the gastric mucosa is covered by tall, columnar, mucus-secreting cells with intervening foveolae that are lined by a similar epithelium (Figure 23.5). The surface and foveolar lining cells are similar throughout all the mucosal zones of the stomach. The gastric glands empty into the base of the foveolae. Separating the foveolae and the glands is the lamina propria. In the cardiac and pyloric mucosal zones, the foveolae are wider than in other areas, sometimes giving the mucosa a slightly villous appearance (Figure 23.6).

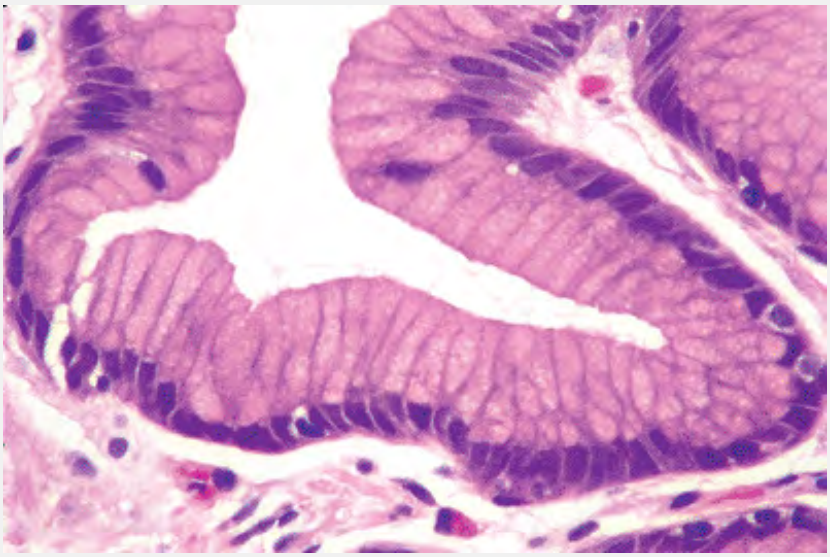

Figure 23.5 Gastric surface epithelium with each cell having a mucous globule in the superficial cytoplasm. Intraepithelial lymphocytes are present. These are surrounded by a clear halo (formalin fixation artifact).

The cells of the surface epithelium and foveolae are tall and columnar with basally situated nuclei and superficial cytoplasm that is almost entirely filled with mucus (Figure 23.7). The nuclei

have an even distribution of chromatin, with single inconspicuous nucleoli. On hematoxylin and eosin (H&E)â€“stained sections, the appearance of the mucus varies, depending on the staining routine and type of stain used. For example, with alcoholic eosin, the mucus appears as a single vacuole that is clear or lightly eosinophilic. With aqueous eosin, the mucus is more heavily eosinophilic and is seen to be present in numerous, small, closely aggregated

vacuoles. Histochemically, the foveolar mucus is all neutral, periodic acid- Schiff (PAS)â€“positive, but Alcian blue-negative at pH 2.5 and lower (7).

Figure 23.6 Gastric pyloric mucosa. Note that the glands are loosely packed and occupy about half the mucosal thickness. The surface epithelium appears slightly villous.

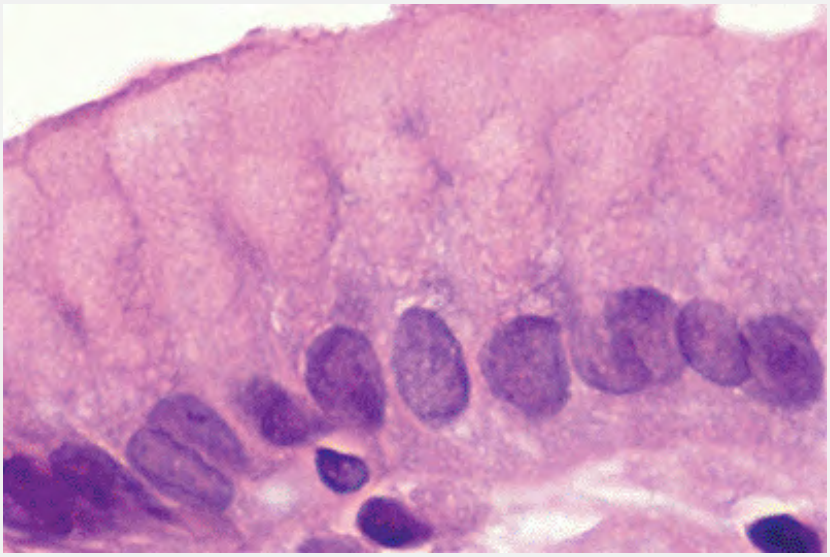

Figure 23.7 Gastric surface epithelium showing cytoplasmic mucus present in multiple small vacuoles.

Cardiac and Pyloric Mucosa

In the cardiac and pyloric zone, the foveolae occupy approximately one-half of the mucosal thickness (Figure 23.6). Both the cardiac and pyloric glands are mucus secreting and are loosely packed with abundant intervening lamina propria (Figure 23.8). Occasional cystic glands may be found in the cardiac mucosa but usually are not encountered in the pyloric mucosa. The cells of the mucus glands have ill-defined borders and a bubbly cytoplasm that is different from the foveolar and surface epithelium. They resemble Brunner's glands of the duodenum. Isolated parietal cells are not infrequently found either singly or in small groups, particularly in the pyloric mucosa and especially at the junctional zone, where it meets the fundic mucosa (1). However, it is uncommon for zymogenic (chief) cells to be present outside of the fundic mucosa and junctional area. The pyloric glands secrete neutral mucin only.

The cardiac glands secrete predominantly neutral mucin with small amounts of sialomucin (7).

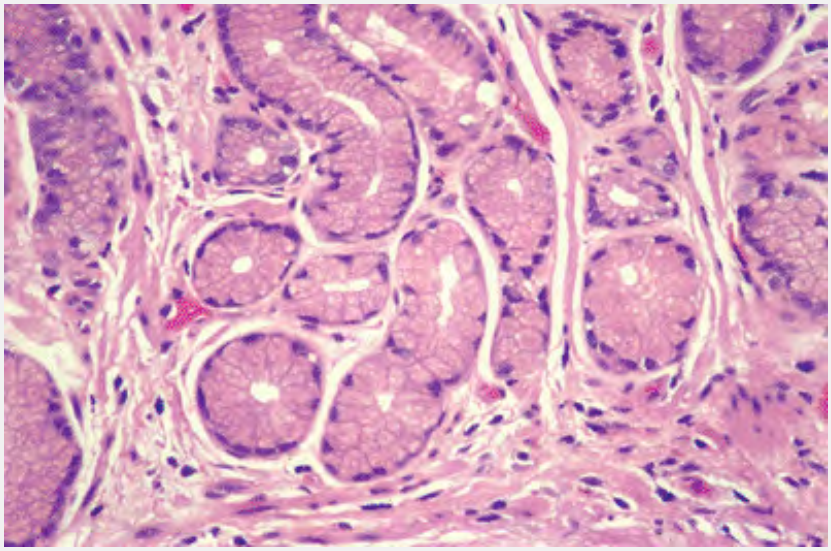

Figure 23.8 Pyloric glands containing cells with a bubbly, foamy appearance.

The extent of the cardiac mucosa and even its existence as a component of the normal gastroesophageal junction has been disputed. Chandrasoma and his associates (8) studied the gastroesophageal region in unselected adult autopsies. They found that when one histologic section was taken through this region only 27% of cases had a zone of pure cardiac mucosa, 44% of cases had a zone of cardiofundic mucosa (glands containing a mixture of mucus-secreting cells and parietal cells), and 29% of cases had only pure fundic mucosa. When the entire gastroesophageal junction from a selected group of adult autopsies was examined, all cases had cardiofundic mucosa present, but only 44% had a zone of pure cardiac mucosa. They also found that the zones of pure cardiac mucosa and cardiofundic mucosae were incomplete so that in some sections the esophageal squamous

epithelium was present immediately adjacent to pure fundic mucosa. The average length of the cardiac and cardiofundic mucosa was 5 mm, and it never extended beyond 15 mm from the lower margin of the squamous esophageal epithelium. Other investigators have obtained similar results (9). In contrast, Kilgore and associates (10) and Zhou and associates (11) examined autopsy material from fetuses, infants, and young children. They found that pure cardiac mucosa was present in every case and measured 1.0 to 4.0 mm in length (average 1.8 mm). In 38% of cases, there was an abrupt transition from cardiac to fundic glands; and, in the remainder of cases, an additional zone of cardiofundic mucosa was present that generally measured less than 1.0 mm in length. In all instances where cardiofundic mucosa was present, it was in addition to a zone of pure cardiac mucosa. These findings suggest that pure cardiac mucosa and cardiofundic mucosa are normal findings but that the extent of the mucus-secreting mucosa is less than was previously thought. Cardiac mucosal abnormalities may occur when there is gastroesophageal reflux or when the stomach is infected by *Helicobacter pylori.* The changes may include inflammatory nuclear atypia, intestinal metaplasia, and the presence of hybrid mucosa (12). Hybrid mucosa is multilayered, with squamous cells at the base of the mucosa and columnar epithelium on the surface. With the development of these inflammatory changes, it may be difficult or even impossible to distinguish between damaged cardiac mucosa and glandular metaplasia of esophageal squamous epithelium (Barrett's esophagus). Reference to specialized pathology texts is required (13). This distinction has a practical importance because Barrett's esophagus carries a higher potential for malignant change than does metaplastic cardiac mucosa (14).

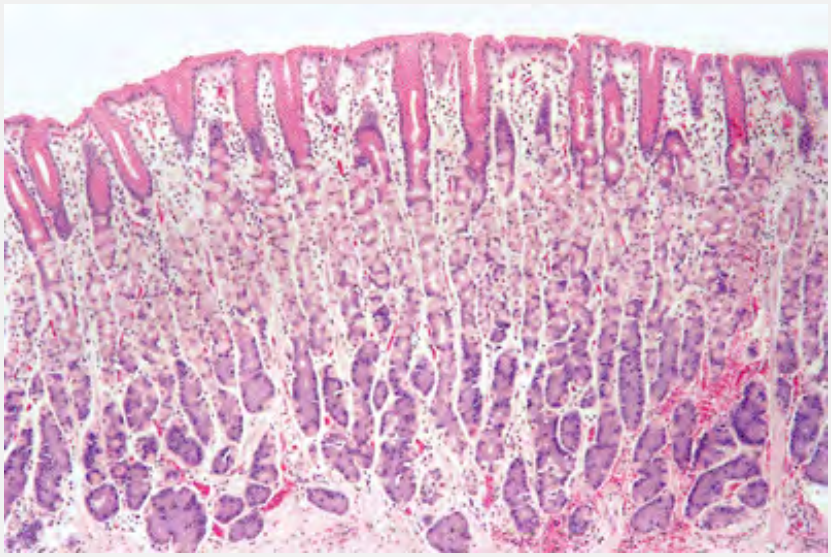

Figure 23.9 Gastric fundic mucosa. Note the short foveolae and the tightly packed glands. Purplish zymogenic cells predominate at the base, and pinkish parietal cells predominate in the upper part of the glands.

Fundic Gland Mucosa

The fundic (or oxyntic) gland mucosa has foveolae that occupy less than one-quarter of the mucosal thickness. In contrast to the cardiac and pyloric mucosa, the glands are tightly packed and are straight rather than coiled (Figure 23.9). For descriptive purposes, they can be divided into three portions: base, neck, and isthmus. The basal portion consists mainly of zymogenic cells (pepsinogen secreting). These are cuboidal and have a basally situated nucleus, which typically contains one or more small nucleoli and cytoplasm that usually stains pale blue-gray with some variation, depending on the type of hematoxylin used (Figure 23.10). The isthmic portion of the glands contains predominantly parietal cells (acid-

and intrinsic factor-secreting). These are roughly triangular, with their base along the basement membrane. The nuclei are centrally placed with evenly distributed chromatin, and the cytoplasm stains a deep pink on well-differentiated H&E sections (Figure 23.10). The neck portion of the fundic glands contains a mixture of zymogenic and parietal cells, together with a third type, mucous neck cells (Figure 23.11). These are difficult to recognize on an H&E stain but are easily identified using a PAS stain, where they are seen to resemble the mucus-secreting cells of the cardiac and pyloric glands. These cells produce neutral and acidic mucin, especially sialomucin, which stains positively with Alcian blue at pH 2.5 (15). Mucous neck cells are found in lesser numbers in the isthmic portion of the glands, and occasional parietal cells can be encountered in the basal portion of the glands. Mucous neck cells are also present in the pyloric mucosa.

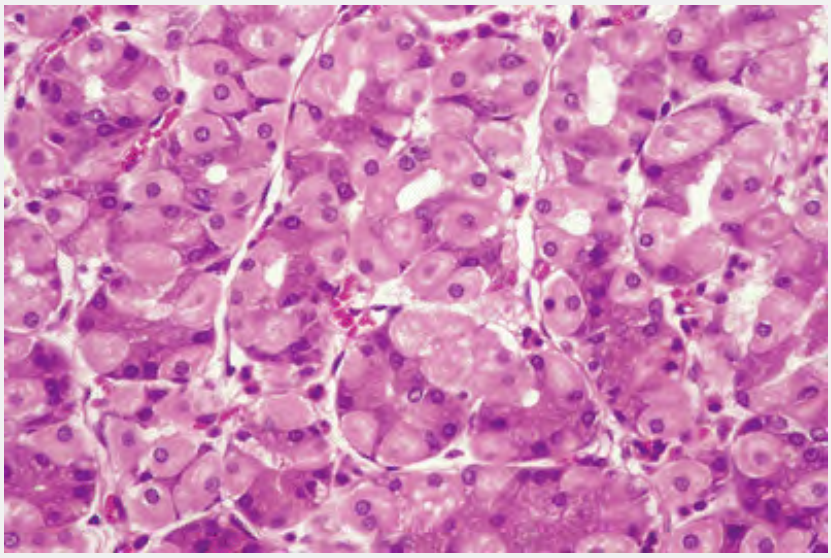

Figure 23.10 Fundic glands, showing parietal cell cytoplasm staining light pink and zymogenic cell cytoplasm staining purplish (H&E).

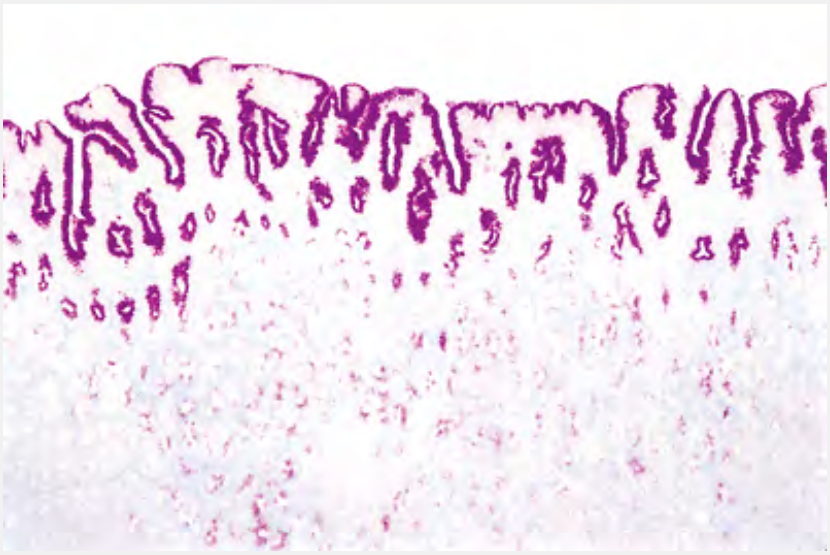

Figure 23.11 Fundic mucosa. The surface and foveolar lining epithelium is intensely positive. Paler staining mucus neck cells are present within the glands (PAS).

Studies indicate that the mucous neck cells located in glands from all areas of the stomach have proliferation and mucosal regeneration as their major functions. These undifferentiated cells act as stem cells and may migrate upward to renew foveolar and surface epithelium or downward to renew zymogenic, parietal, or neuroendocrine cells (16). It has been estimated that, in humans, the gastric surface epithelium is normally replaced every four to eight days. The parietal and zymogenic cells turn over much more slowly, likely every one to three years.

Endocrine Cells

The stomach contains a wide variety of hormone-producing cells. In the antrum, about 50% of the whole endocrine cell population are G cells (gastrin-producing), 30% are enterochromaffin (EC) cells (serotonin-producing), and 15% are D cells (somatostatin-

producing). In the fundic mucosa, however, a major portion of the endocrine cells are enterochromaffin-like (ECL) and secrete histamine. Small numbers of X cells (secretion product unknown) and EC cells are also present. In the fundic mucosa, the cells secreting these

hormones are mostly located in the glands, particularly toward the base. In the pyloric mucosa, they are most common in the neck region just below the foveolae. Within these neuroendocrine cells, the hormones are present as cytoplasmic granules located between the nucleus and basement membrane; but, because the granules are generally inconspicuous on H&E sections, special techniques are required for their demonstration (Figure 23.12). Hormones from the endocrine cells either enter the blood or modulate other locally situated cells (paracrine effect).

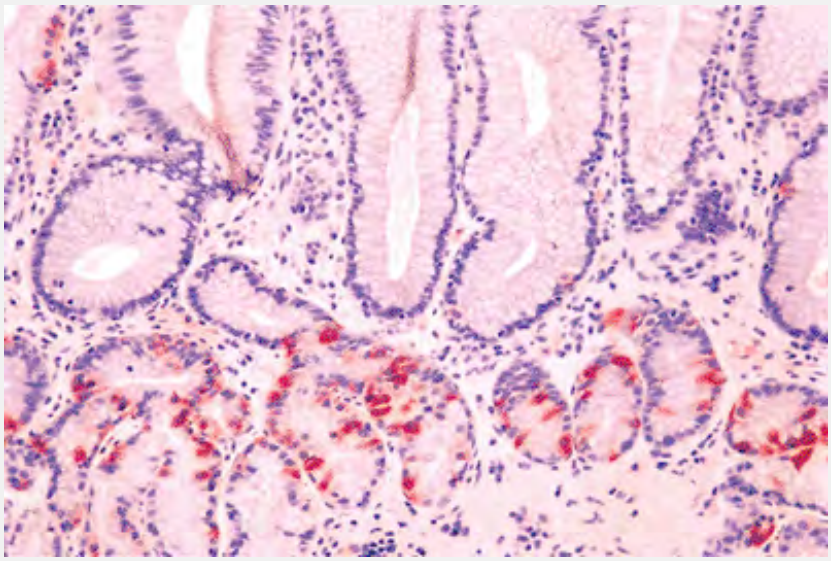

Figure 23.12 Endocrine cells in gastric antral glands. The granules are located between the nucleus and the basement membrane (immunostain for chromogranin).

The EC cells and some of the ECL cells have argentaffin granules, which can be stained by Fontana, Masson, or the diazo technique. Other cells are argyrophilic but not argentaffinic and may be stained by the Grimelius technique (17). Silver stains have now been replaced by more sensitive immunologic techniques (synaptophysin and chromogranin) (18). Individual hormones, for example gastrin and somatostatin, may be demonstrated by specific antibodies. In addition to the presence of hormones in epithelial cells, some hormones also are found in neurons and nerve endings present in the stomach wall and mucosa. It is generally believed that vasoactive intestinal peptide is predominant in neural tissue and that catecholamines, bombesin, substance P, enkephalins, and possibly gastrin are also found at these sites. When hyperplasia of G cells occurs, it is generally linear. Overgrowth of ECL cells in the fundic mucosa occurs secondary to hypergastrinemia, arising as a consequence of pernicious anemia. This has been divided into five growth patterns: pseudohyperplasia, hyperplasia, dysplasia, microinfiltration, and neoplasia (19).

Lamina Propria

The epithelial cells of the surface, foveolae, and glands all rest on a basement membrane, which is similar to that seen elsewhere in the intestinal tract. Within the mucosa is a well-developed lamina propria that provides structural support, consisting of a fine meshwork of reticulin with occasional collagen and elastic fibers that are condensed underneath the basement membrane (Figure 23.13). The lamina propria is more abundant in the superficial portion of the mucosa between the pits, especially in the pyloric mucosa. It contains numerous cell types, including fibroblasts, histiocytes, plasma cells, and lymphocytes. It is also normal to find occasional polymorphs and mast cells. As mentioned, the lamina propria also contains capillaries, arterioles, and nonmyelinated nerve fibers. A few fibers of smooth muscle extend

upward from the muscularis mucosa into the lamina propria, occasionally reaching the superficial portion of the mucosa, especially in the distal antrum.

The lymphoid tissue of the stomach has not been studied as extensively as that of the small bowel. The isolated lymphocytes and plasma cells in the lamina propria are predominantly of B-cell lineage and IgA secreting. Intraepithelial lymphocytes are present in the stomach but are much less frequent than in the small bowel. They are commonly surrounded by a clear halo, which represents a formalin fixation artifact. These lymphocytes, as well as small numbers of lamina propria lymphocytes, are of T-cell origin.

Recently it has been shown that small numbers of primary lymphoid follicles (aggregates of small lymphocytes) can be found in the normal stomach (20). However, secondary lymphoid follicles (follicles with germinal centers) are found only in gastritis, usually secondary to infection with *Helicobacter pylori.*

Submucosa

The submucosa is located between the muscularis mucosae and the muscularis propria and also forms the cores of the gastric rugae. It consists of loose connective tissue, in which many elastic fibers are found. The autonomic nerve plexus of Meissner is found in the submucosa, as are plexuses of veins, arteries, and lymphatics.

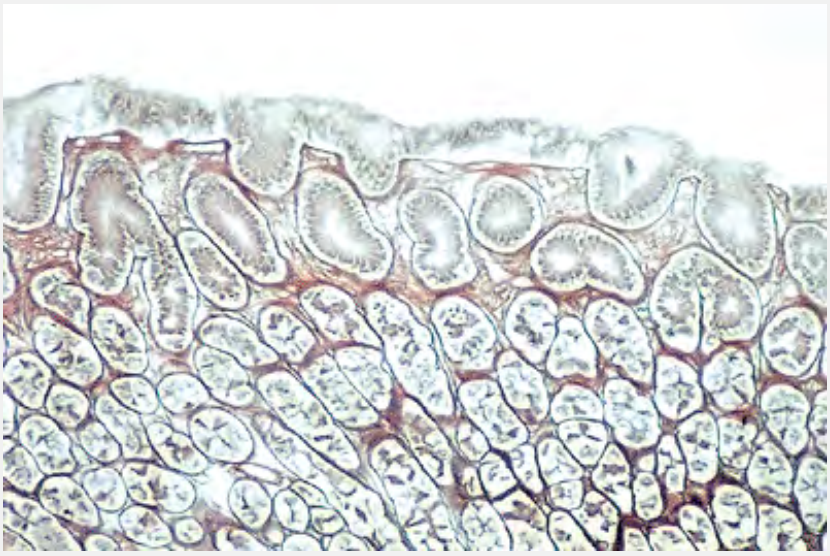

Figure 23.13 Normal gastric fundic mucosa (reticulin).

Muscular Components

In classical anatomy texts (21,22), the main muscle mass of the stomach is referred to as the muscularis externa. In North America, however, the alternative name, muscularis propria, is widely used and preferred. This is because the term *muscularis externa* is ambiguous, and it is sometimes not clear whether it refers to the whole of the main muscle mass or only its external layer.

Three layers of fibers can be recognized in the muscularis propria: outer longitudinal, inner circular, and innermost oblique. The external fibers are continuous with the longitudinal muscle of the esophagus. The inner circular layer is aggregated into a definite sphincter mass at the pylorus, where it is sharply separated from the circular fibers of the duodenum by a connective tissue septum. The oblique muscular fibers are an incomplete layer present

interior to the circular fibers and are most obvious in the cardiac area. Evidence for the presence of a circular sphincter at the cardia is controversial (23). Histologic examination is not conclusive; and, although radiologic techniques show arrest of swallowed food at this level, this may be due to external compression from the adjacent crura of the diaphragm.

The muscularis mucosae consist of two layers, the inner circular and outer longitudinal, together with some elastic fibers. Thin bundles of smooth muscle also penetrate into the lamina propria, where they terminate in the basement membrane of the epithelium. This is most obvious in the antral area.

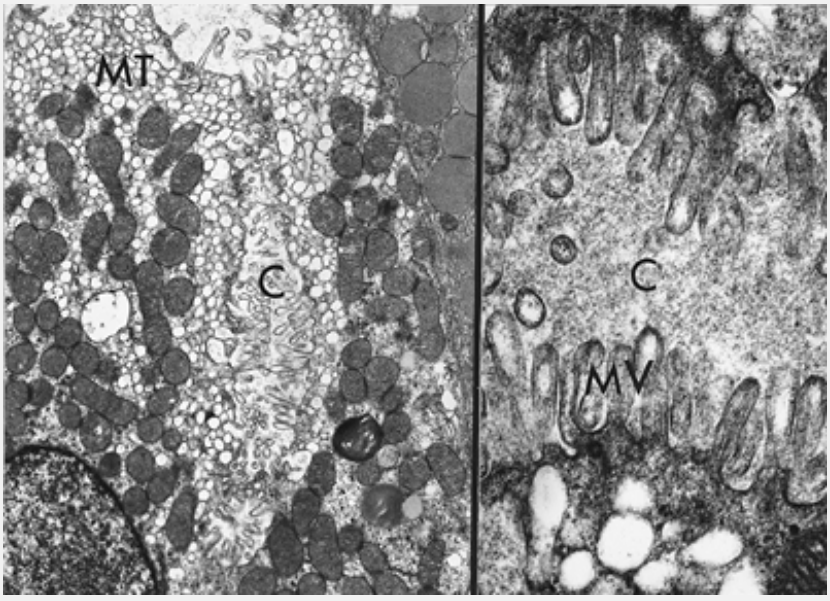

Figure 23.14 Ultrastructural appearances of the parietal cell canaliculus (*C*). Note the fingerlike microvilli (*MV*) and the microtubular invaginations (*MT*). (Original magnifications: *left,* Ã—9000; *right,* Ã—41,000.)

Ultrastructure

The surface and foveolar lining epithelial cells are ultrastructurally similar. They are characterized by multiple, rounded, electron-dense mucous vacuoles in the superficial cytoplasm and stubby microvilli projecting from the luminal surface. The basal cytoplasm contains moderate amounts of rough endoplasmic reticulum and some mitochondria. Adjacent epithelial cells are joined by tight junctions (zona occludens) at their luminal aspect and by adherence junctions along the rest of the cell interfaces. These tight junctions are considered to play an important role in maintaining mucosal integrity and the gastric mucosal barrier.

Parietal cells are unique ultrastructurally (Figure 23.14) (24). In the unstimulated state, the cytoplasm contains an apical crescent-shaped canaliculus lined by stubby microvilli (Figure 23.14). Between the microvilli are elongated membrane invaginations termed microtubules. Upon stimulation, the microtubules disappear, to be replaced by a dense meshwork of intracellular canaliculi (25). The canalicular system is considered essential for the formation of hydrochloric acid. This is achieved by active transport of hydrogen ions across the canalicular membrane. Because this process has high energy requirements, most of the remainder of the parietal cell cytoplasm is occupied by mitochondria.

The zymogenic cells are similar to protein-secreting exocrine cells elsewhere in the body. They have rough-surfaced

vesicles in the superficial cytoplasm and abundant rough endoplasmic reticulum in the remainder of the cell.

Gastric Function

The function of the stomach is to act as a reservoir and mixer of food and to initiate the digestive process. Gastric secretion of acid,

pepsin, and electrolytes is partly under nervous control by the vagus and partly under the control of gastrin, produced by G cells in the antrum. Gastrin release from the G cells may occur either as a result of distention of the antrum or by direct stimulation from ingested food, particularly amino acids and peptides. Hydrochloric acid is produced by the active transport of hydrogen ions across the cell membrane. High concentrations of hydrochloric acid are achieved so that most ingested microorganisms are killed and the contents of the stomach are normally sterile.

Gastric mucus is secreted in two forms: a soluble fraction produced by the gastric glands and an insoluble form produced by the surface and foveolar lining cells. Biochemically, the mucus is a complex glycoprotein consisting of a protein core with branched carbohydrate side chains. Histochemically, gastric mucin is almost entirely neutral, although the mucous neck cells may secrete small amounts of sulfomucin and sialomucin (15). By immunohistochemistry, mucins MUC5AC and MUC6 are detected in the normal stomach (26). The exact physiologic role of gastric mucin is not determined. Clearly, the soluble mucin plays a role in lubrication. The insoluble fraction acts as a surface layer, forming a barrier that, together with bicarbonate secreted by the superficial epithelial cells, prevents back diffusion of acid and gastric autodigestion. The actual structural barrier is formed by the continuous layer of luminal mucosal cells and the tight junctions between adjacent cells. This process is likely modulated by prostaglandins which promote mucosal blood flow.

Special Techniques and Procedures

Relatively few special techniques are applicable to routine diagnosis. Mucin stains are the most widely used, and the combined PAS/Alcian blue is the most versatile. This stains neutral mucin magenta, acid mucin light blue, and combinations purple. The combined stain is preferred over a straight PAS because the

mucus in some gastric carcinomas is PAS-negative. A mucicarmine stain is not recommended because it does not permit identification of the mucin type and is also negative with some types of acid mucin. Sialomucin and sulphomucin may be distinguished by a combined high iron diamine and Alcian blue stain, which stains sulphomucin black and sialomucin light blue. At the present time, however, this distinction is of limited diagnostic utility.

Usually there is no difficulty in distinguishing zymogenic and parietal cells on a good H&E stain (Figure 23.10). If necessary, special stains, such as a Maxwell stain (27), can aid this distinction. Parietal cells can be recognized and quantified by use of a human milk fat globulin antibody (28).

At the present time, the use of cytokeratin 7 and cytokeratin 20 immunostains to distinguish gastric cardiac mucosa from the mucosa of Barrett's esophagus is controversial. Different results have been obtained by different observers, so this methodology cannot be recommended for routine use (13).

Age Changes

Many older adults have a reduced gastric acid output. Histologically, this is characterized by a reduction in the area of fundic mucosa with expansion of the zone of pyloric mucosa. This results in proximal displacement of the pylorofundic junction, a change termed pyloric (or pseudopyloric) metaplasia. Recently it has become recognized that hypochlorhydria of the elderly is not simply the result of aging but is secondary to chronic gastritis (29).

Artifacts

A variety of artifacts may occur in gastric biopsy specimens (Figure 23.15). Most of these artifacts relate to rough handling of the specimen, either at the time the biopsy sample is taken or

when it is removed from the forceps. Crushing is common and can result in compression of the lamina propria, leading to a false impression of an inflammatory infiltrate. Crush artifact also produces telescoping of the foveolar lining cells. Stretching of the mucosa results in separation of the pits and glands, leading to the impression of edema. Hemorrhage into the lamina propria is also common in gastric biopsy samples and has to be distinguished from hemorrhagic gastritis. This can be difficult in small biopsy samples, but usually the microscopic appearances of hemorrhagic gastritis are characteristic. They include superficial epithelial damage and erosions.

Differential Diagnosis

One of the problems for pathologists examining gastric biopsy samples is determining whether the specimen is normal or shows minor degrees of gastritis. It is therefore

appropriate to review briefly certain aspects of the classification and diagnosis. Specific types of gastritis, for example, acute hemorrhagic gastritis or granulomatous gastritis, are usually so distinct that confusion with a normal stomach is unlikely (30). On the other hand, *Helicobacter pylori* gastritis may be patchy and may be associated with atrophy. In the early stage of *H. pylori* gastritis (chronic superficial gastritis), an infiltrate of inflammatory cells is observed in the superficial portion of the mucosa, particularly in the lamina propria between the gastric pits (Figure 23.16). Later, the inflammation spreads deeply to involve the whole thickness of the mucosa and is accompanied by atrophy of gastric glands (chronic atrophic gastritis). Ultimately, the inflammation may burn itself out and all glands are destroyed, leaving only a thinned mucosa containing foveolar structures (gastric atrophy) (30).

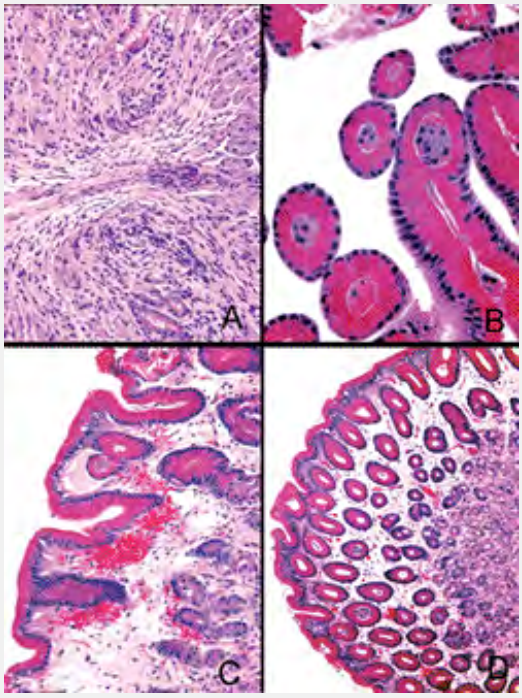

Figure 23.15 Biopsy artifacts: crushing, producing an apparent lamina propria infiltrate (A); crushing, resulting in displacement (telescoping) of cells into pit lumen (B); biopsy-induced hemorrhage (C); and stretching, producing an appearance of superficial edema (D).

The superficial gastric lamina propria normally contains some chronic inflammatory cells. It is often a matter of judgment whether these are considered normal or increased in number because there is no simple satisfactory method of objective measurement. In actual practice, it may be even more difficult to evaluate these cells because the gastric biopsy samples obtained by endoscopists are frequently distorted by crushing or stretching. In assessing possible minor

degrees of inflammation, therefore, study should also be made of the superficial and foveolar lining epithelium, where a number of

useful diagnostic features may be identified, depending on the degree of activity of the inflammation. The earliest changes seen are a reduction in the mucin content of the cytoplasm, an increase in nuclear size, and the presence of one or more prominent nucleoli (Figure 23.17). At the base of the foveolae, there may be increased numbers of mitoses, reflecting a more rapid cell turnover. These findings are features of epithelial damage and regeneration and are common to all forms of gastritis and to reactive gastropathy (chemical gastritis). In severe active *H. pylori*-related inflammation, the epithelium and the lamina propria are infiltrated by acute inflammatory cells (Figure 23.18) and organisms may be seen on the mucosal surface (Figure 23.19). Optimum recognition of organisms is enhanced by using special stains (Giemsa, methylene blue, immunohistochemical stains).

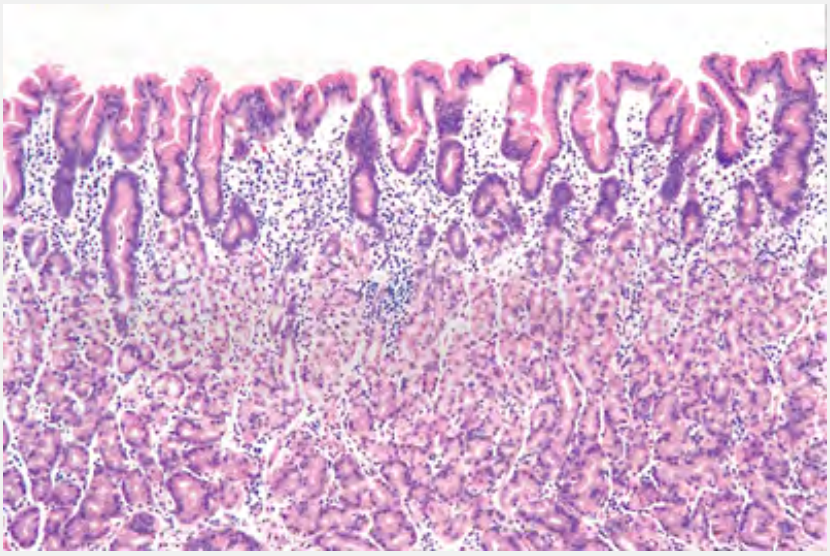

Figure 23.16 Mild chronic superficial gastritis with chronic inflammatory cells present in the superficial lamina propria in excess of normal. This is a borderline biopsy sample and illustrates the least number of cells acceptable for a diagnosis of gastritis.

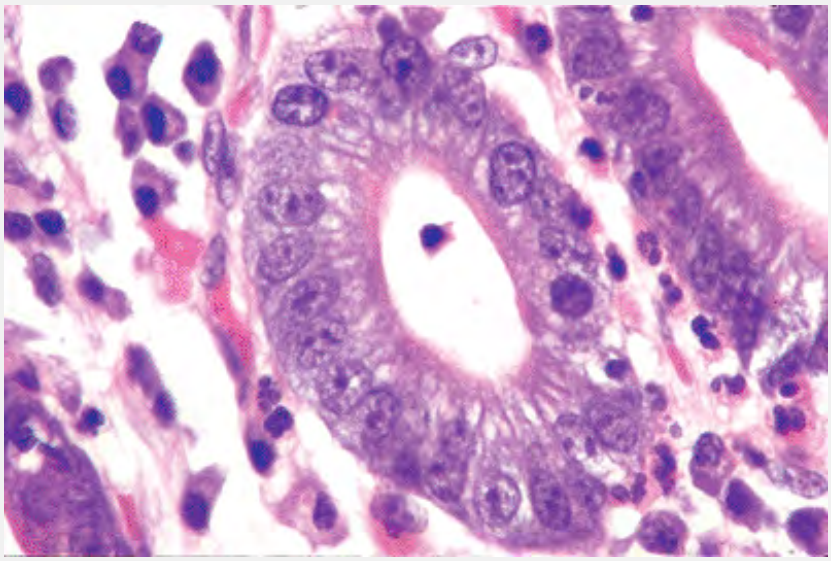

Figure 23.17 Gastritis showing cytoplasmic mucin loss with enlarged nuclei that contain prominent nucleoli.

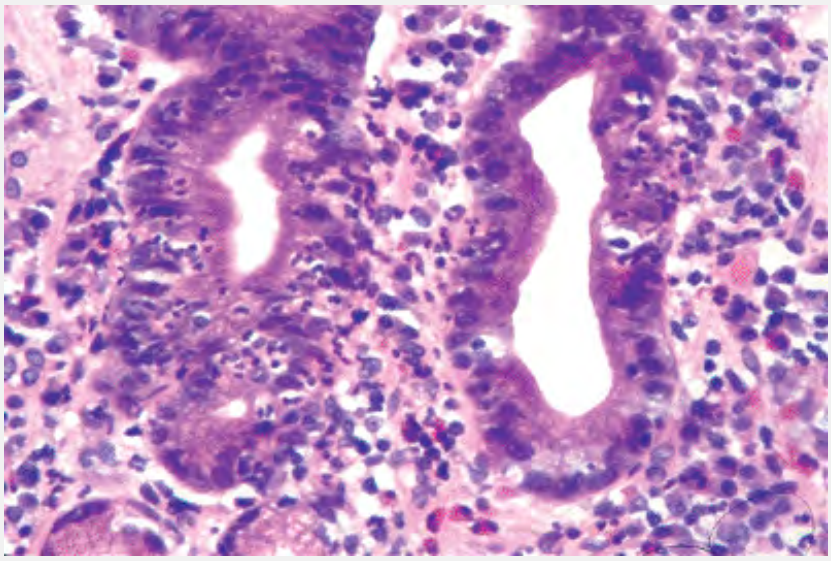

Figure 23.18 Gastric pits infiltrated by neutrophils in a case of *Helicobacter pylori* gastritis.

Where gastritis has been present for some time, there may be atrophy of the mucosal glands, which can be accompanied by an increase in inflammatory cells in the deeper layers of the mucosa. On an H&E section, this is seen as a separation of the glands with increased intervening lamina propria. However, minor degrees of atrophy may be difficult to distinguish, particularly if there is biopsy artifact. In these instances, a reticulin stain can be useful in confirming atrophy by demonstrating coarse condensation of fibers in the lamina propria (Figure 23.20).

Reactive gastropathy occurs when there is increased exfoliation of cells from the mucosal surface. Chemical agents, especially refluxed bile and nonsteroidal anti-inflammatory drugs, are common causes. The gastric surface and foveolar epitheium show regenerative changes as described above, but the mucosa is not infltrated by inflammatory cells. The more severe examples of reactive gastropathy may be characterized by a â€œcork screwâ€• appearance of the foveolae.

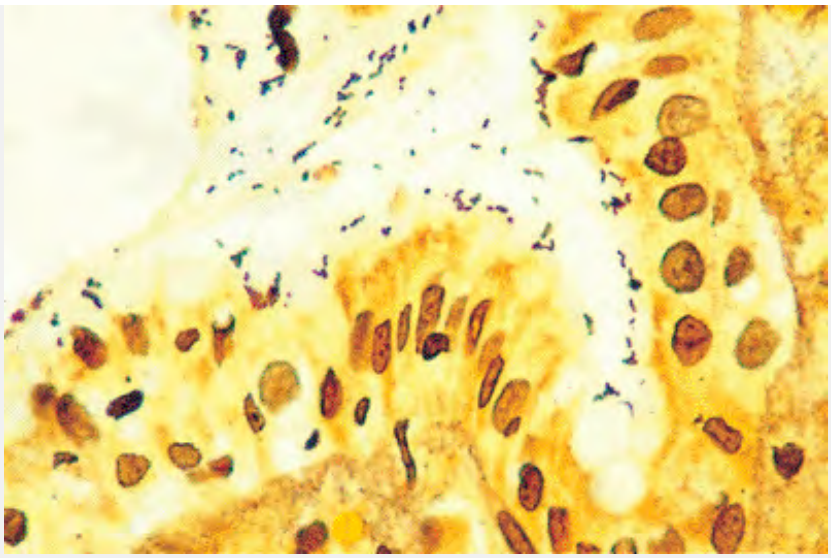

Figure 23.19 *Helicobacter pylori* organisms present in the mucous layer on the gastric mucosal surface.

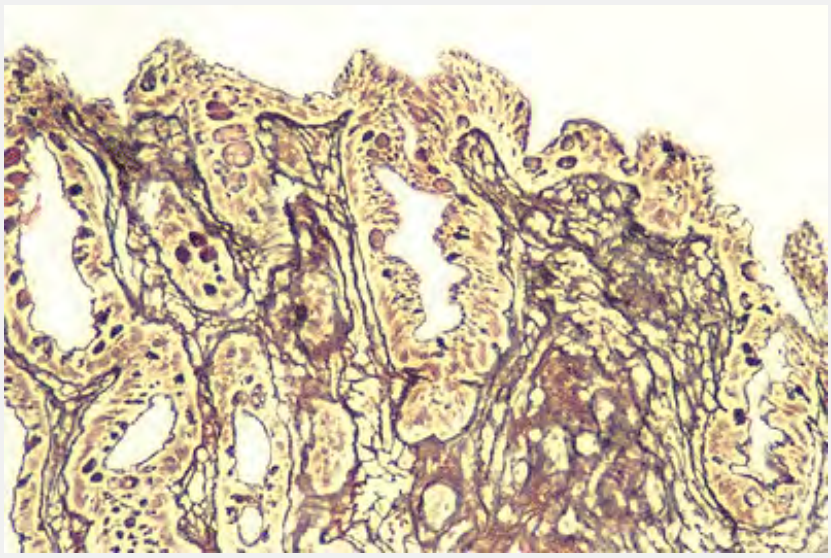

Figure 23.20 Coarse condensation of mucosal fibers in atrophic gastritis (reticulin).

Metaplasia

There are two major types of metaplasia that are seen in the stomach: intestinal metaplasia (IM) and pyloric (pseudopyloric) metaplasia. Both are thought to be the result of chronic gastritis, and consequently both are more frequently encountered in elderly individuals; neither type is considered symptomatic.

In pyloric metaplasia, there is a replacement of the specialized acid- and enzyme-secreting cells of the fundic glands by mucus-secreting glands of the type present in normal pyloric mucosa. This change occurs in the zone of fundic mucosa adjacent to the histologic fundopyloric junction, and what were typical fundic glands now come to resemble typical pyloric glands. Therefore, in persons with extensive pyloric metaplasia, the fundic gland area of the stomach contracts, the pyloric gland area expands, and the junctional zone is moved proximally toward the cardia (30). Unless the site of biopsy is known with accuracy, pyloric metaplasia cannot be diagnosed on routine H&E sections. However, although the fundic glands lose zymogenic and parietal cells, they still retain pepsinogen I activity. This can be demonstrated by immunohistochemical methods (31).

In IM, there is a change in the cells of the surface and pit epithelium so that morphologically and histochemically they come to resemble the cells of either the small or large bowel; IM may be complete (type I) or incomplete (type II) (32,33). In complete small bowel IM, the gastric mucosa changes to resemble normal small bowel epithelium, characterized by fully developed goblet cells and enterocytes with a brush border (Figure 23.21). In advanced cases, the contour of the mucosa changes with the development of villi and crypts. Paneth's cells may be present in the base of the crypts. In incomplete metaplasia, recognizable absorptive cells are not seen. The epithelium consists of a mixture

of intestinal-type goblet cells and columnar mucus-secreting cells, morphologically resembling those of the normal gastric epithelium.

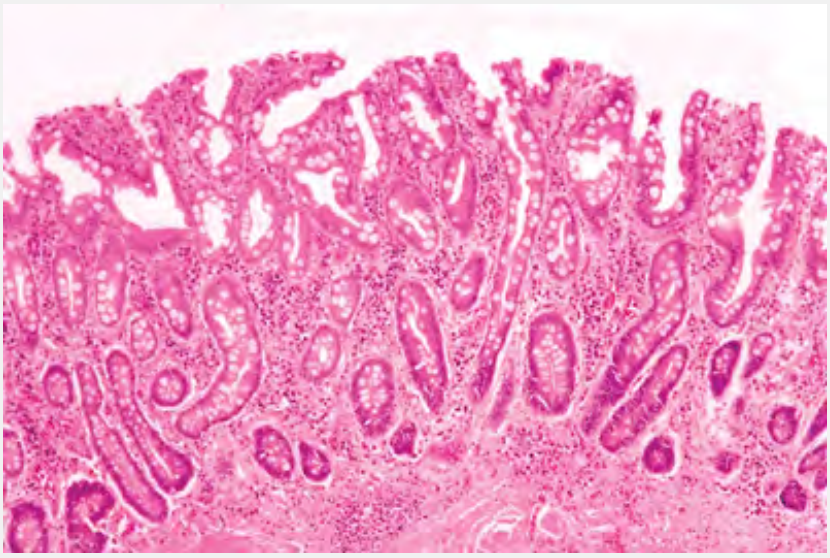

Figure 23.21 Complete intestinal metaplasia (IM).

Histochemical changes detected in the mucus production of the various types of IM are interesting and complex (15,32). In the normal stomach, mucus secreted by the columnar cells is neutral in type, recognized histochemically as PAS-positive and Alcian blue-negative. In complete IM, the enterocyte cytoplasm, apart from the brush border, is mucin-negative, but the goblet cells secrete either sialomucin (an acid mucin that is PAS-positive, Alcian blue-positive at pH 2.5 but Alcian blue-negative at pH 0.5) or sulfomucin (a strongly acidic mucin that is weakly PAS-positive and Alcian blue-positive at pH 2.5 and at pH 0.5) (Figure 23.22). In incomplete small bowel metaplasia, sialomucin is present in the columnar cells; and, in incomplete large bowel metaplasia (also called type III metaplasia) (34), the columnar cells contain sulfomucin (Figure 23.23). Sulfomucin may be recognized separately from sialomucin because it stains positively with high

iron diamine (33). The details of

these methods are well described in standard textbooks of histochemistry (34).

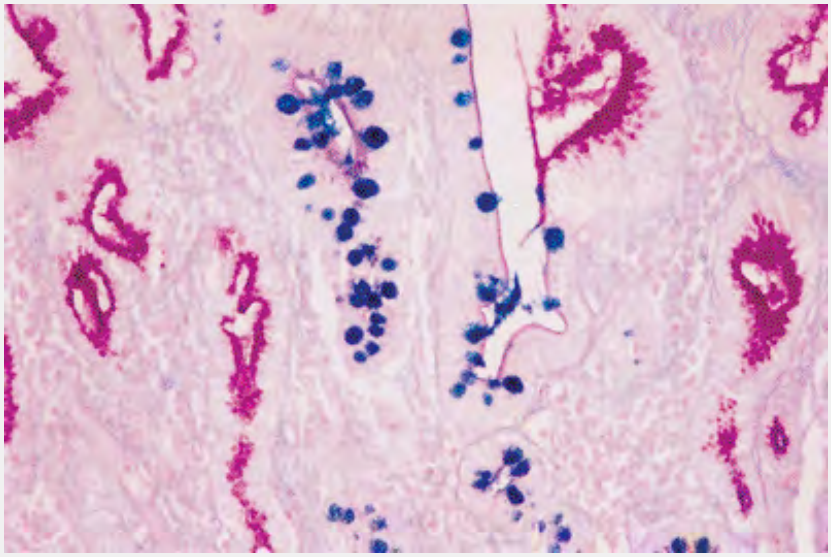

Figure 23.22 Complete intestinal metaplasia (PAS/Alcian blue).

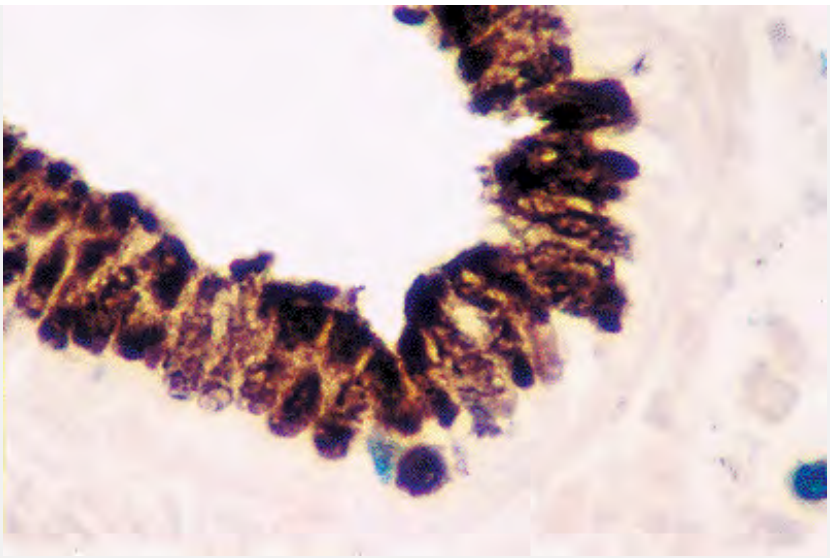

Figure 23.23 Incomplete large bowel metaplasia. The pit contains columnar cells with cytoplasmic sulphomucin (high iron diamine and Alcian blue).

Minor degrees of gastric IM are relatively common in persons in North America and elsewhere. The variants described above rarely exist as a pure entity, and mixtures of the various types within the same gastric foveola are encountered frequently. However, IM should never be considered normal and almost always reflects some degree of gastric damage, usually from chronic gastritis.

Less commonly encountered forms of metaplasia include subnuclear vacuolation (35) and ciliated metaplasia (36). These changes all involve the pyloric mucus glands. Subnuclear vacuolation is not strictly a metaplastic change because it does not simulate the appearance of any other type of normal cells and probably represents a degenerative change secondary to gastritis or duodenal reflux. The vacuoles are clear on H&E sections and indent the nucleus. Ultrastructurally, they consist of a membrane-lined space derived either from endoplasmic reticulum or Golgi and probably contain nonglycoconjugated mucus core protein (37).

Ciliated cells are found at the base of antral glands where there is superficial IM (36). The cause and significance of this change is not known.

Pancreatic acinar metaplasia (38) may be present in up to 1.2% of gastric biopsy samples or 13% of gastrectomy specimens. The cells, which are indistinguishable from normal acinar cells, also produce lipase and trypsinogen. Seventy-five percent of cases are positive for amylase. Cells are present in nests and variably sized lobules scattered among the cardiac and fundic mucosae.

Specimen Handling

Gastric mucosa is delicate and should be handled with care. Tissue should be gently removed from the biopsy forceps and oriented before being placed flat on a supportive mesh, such as filter paper or gelfoam. A variety of fixatives are suitable, depending on personal preferences, although routine formalin is suitable for most purposes. Sections are cut in ribbons, usually at two or three levels.

For the best results, it is suggested that gastrectomy specimens be opened and pinned out on a cork board or wax platform before being immersed in formalin and fixed overnight. If sections are taken directly from a fresh specimen, they almost invariably curl up, resulting in irregular orientation of the final slide.

Small Intestine

Terry L. Gramlich
Robert E. Petras

Gross Anatomy and Surgical Perspective

The small intestine, located within the abdominal cavity, is a multiply coiled tubular organ that extends from the gastric pylorus to the junction of the cecum and ascending colon. Its average length in the human adult is 6 to 7 m (1). Three subdivisionsâ€”the duodenum, jejunum, and ileumâ€”are defined and characterized by various anatomic relationships. The duodenum is the most proximal portion of the small intestine; it measures about 12 inches (20â€“25 cm) in length and extends from the pylorus to the duodenojejunal flexure. The duodenum, excluding the most proximal several centimeters, is a fixed, retroperitoneal structure that forms a C- or U-shape around the head of the pancreas (2). Four subdivisions of the duodenum have been described: (a) the first portion, also known as the duodenal cap or bulb, is the most proximal and superior segment; (b) the descending or second portion, into which the common bile duct and major and minor pancreatic ducts empty into their respective

papillae; (c) the horizontal or third portion; and (d) the ascending or fourth portion, which veers forward at the level of the second lumbar vertebra, just left of midline, to become continuous with the remainder of the small bowel (1,2).

The origin of the jejunum is marked by a strip of fibromuscular tissue, the so-called ligament of Treitz, which anchors the terminal duodenum and duodenojejunal flexure to the posterior abdominal wall (3). Distal to the ligament of Treitz, the remainder of the small bowel is arbitrarily subdivided into the jejunum (the proximal two-fifths) and the ileum (the distal three-fifths, terminating at the ileocecal junction within the right iliac fossa) (1).

Although a discrete point demarcating jejunum from ileum does not exist, several relatively distinctive features become gradually more apparent from proximal to distal; these features help surgeons isolate specific segments of the small bowel. For example, the proximal jejunum has a thicker wall

and is about twice the diameter of distal ileum. In addition, jejunal segments have more prominent permanent circular folds (plicae circulares) that can be palpated externally at surgery (1,4). The quantity of mesenteric adipose tissue is greater in the ileum, thus imparting a dense opaque appearance that contrasts with the less fatty, translucent mesentery of the jejunum (4). Finally, most of the jejunum lies within the upper abdominal cavity, whereas most of the ileum lies within the lower abdominal cavity and pelvis.

The arterial vascular supply of the small bowel originates from two major aortic axes: the celiac and superior mesenteric trunks (5). The duodenum is supplied by branches and interanastomosing arcades of both trunks, and its blood supply is intimately associated with that of the pancreatic head (1). The jejunum and ileum receive their blood from more distal branches of the superior mesenteric artery (5). The lymphatic and venous drainage systems

follow the arterial supply and flow into regional lymphatics and lymph nodes or the portal venous system, respectively.

Sympathetic neural input to the small bowel is carried by the celiac and superior mesenteric plexuses, whereas the parasympathetic supply is derived from distal branches of the vagus nerve; these both closely follow the arterial paths into the bowel wall.

Physiology

The small intestine has several functional roles, the most important of which is the processing and absorption of ingested nutrients. Pancreatic enzymes act on the larger ingested carbohydrates and proteins to produce more appropriately sized molecules for further digestion. The brush border created by the numerous apical microvilli on absorptive epithelial cells offers an array of peptidases and carbohydrases, which act as key enzymes in additional nutrient breakdown and processing (6). The resulting smaller molecules are subsequently absorbed across the epithelial layer, and most pass into the portal venous system for eventual systemic distribution.

Fat digestion differs somewhat in that pancreatic lipase and bile act intraluminally to create free fatty acids and monoglycerides that migrate via direct diffusion through the lipid-soluble plasma membrane of enterocytes without surface processing or active transport (7). Most undergo intracytoplasmic resynthesis with directed packaging into chylomicrons and are released into regional lymphatic vessels. Water and electrolytes, vitamins, minerals, and various drugs also are absorbed at points along the mucosa of the small bowel. Therefore, the structural integrity of this viscus is critical to the maintenance of nutritional status, as well as in appropriate drug handling.

The small intestine also functions to propel and segmentally mix

both newly accepted gastric contents and the residual material left after initial digestive efforts. Although a number of factors influence gut motility, the most basic contractile activity is initiated at the level of the individual smooth muscle cells within the wall (8). Important functional differences exist, based on whether an individual is feeding or fasting. With feeding, a distended bowel segment initiates peristalsis, a forward propulsive motion that is mediated through the enteric nervous system; the intrinsic neurons of the myenteric plexus of Auerbach are most important in this regard (8,9). In contrast, during fasting or between meals, a slow yet continually recurring set of contractions attempts to clear the enteric lumen of any residual debris. The hormone motilin is believed to be important in the generation of these migratory motor complexes (9). Other endocrine influences, as well as the autonomic and central nervous systems, play a modulatory role in these intrinsic activities.

Advances in the burgeoning field of endocrine gut physiology and immunohistology have disclosed a variety of hormones within individual cells lining the small intestinal mucosa (10). Although the precise physiologic role of most of these cells and their secretory products remains to be determined, some are thought to exert a modulatory effect on gut motility or to influence the function of nearby epithelial cells (9,11).

The gut in general and the small bowel in particular have a crucial function in mucosal immunity. The mucosa/gut-associated lymphoid tissues, which are discussed in detail later in this chapter, are important in the local defense against mucosally encountered microorganisms and generate the initial immunologic responses to these various agents (12). Additionally, these tissues are the breeding ground for various reactive and neoplastic pathologic conditions.

Histology

Although regional histologic differences exist within the small intestine, the general microscopic structure is similar throughout its length. The wall of the small bowel can be divided into four basic layers: mucosa, submucosa, muscularis externa or propria, and serosa.

Mucosa

Mucosal Architecture and Design

Because the principal function of the small intestine is absorption of ingested nutrients, the mucosa, which is the layer in contact with luminal contents, is specifically designed for this purpose. Several architectural adaptations augment the otherwise limited surface area of the small intestine (13). One of these, the grossly evident permanent circular folds (plicae circulares), courses perpendicular to the longitudinal axis of the bowel (13,14) (Figure 24.1). These mucosa-covered folds contain submucosal cores and

traverse nearly the entire circumference of the bowel lumen before overlapping with adjacent permanent folds. In addition to enhancing surface area, they act as partial barriers that attenuate the forward flow of intraluminal contents, thus increasing the time of contact with absorptive surfaces.

Figure 24.1 A single plica, or permanent circular fold, with its submucosal core and mucosal surface. The absorptive surface area is further augmented by intraluminal mucosal projections (villi).

The mucosa is composed of an epithelial component, a lamina propria, and a muscularis mucosae. The surface epithelium and lamina propria form intraluminal projections called villi. These microscopic fingerlike and leaflike projections cover the entire luminal surface of the small bowel and are the most important morphologic modification responsible for enhancing surface area (13,15,16) (Figures 24.2,24.3). Each villous surface is covered by a single layer of epithelium consisting of various cell types. Beneath this epithelial layer lies a core of lamina propria that contains a centrally located, blind-ended lymphatic channel (lacteal), an arteriovenous capillary network, and an abundant migratory cell population (17,18,19) (Figure 24.4).

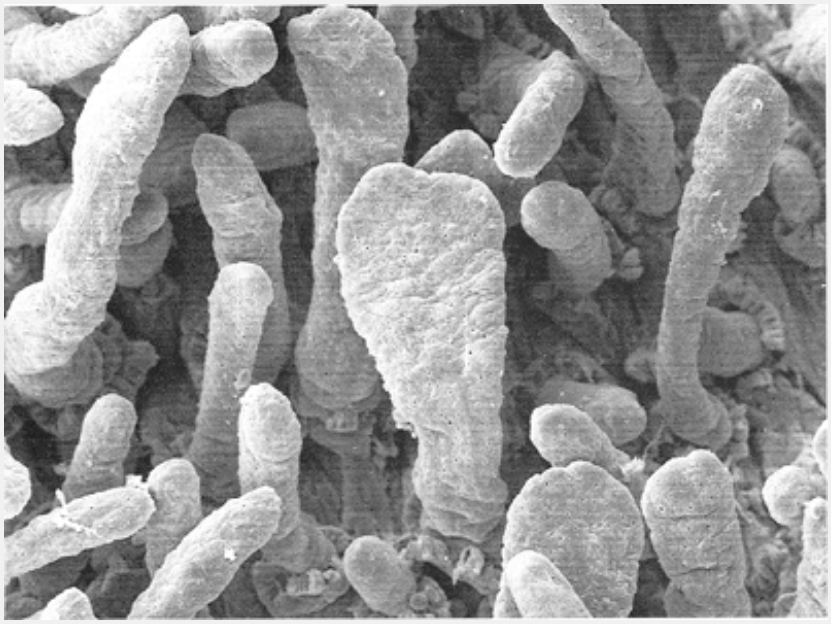

Figure 24.2 Scanning electron micrograph of small intestinal mucosa discloses the fingerlike and leaflike appearance of villi. Fingerlike villi predominate in the more distal segments of small bowel (jejunum and ileum), whereas leaflike villi are more common in the duodenum. Mixed populations, as in this micrograph, are considered normal.

In the intervening regions and beneath the villi lie the crypts of LieberkÃ¼hn. These tubular intestinal glands open between the villi and extend down to the muscularis mucosae (Figure 24.3). The crypts are depressions of the surface epithelium, whereas the villi are extensions above it. However, these mucosal compartments are contiguous in that the lamina propria forming the villous cores also surrounds the crypts. The ratio of villous length to crypt length in normal small bowel varies from about 3:1 to 5:1 (13) (Figure 24.3). The crypts and surrounding lamina propria lie upon the muscularis mucosae, a thin fibromuscular layer that separates the mucosa from the underlying submucosa.

Mucosal Components and Their Composition

Epithelium

The mucosal epithelium is divided into the villous and crypt compartments. Although similar in appearance, the cell types differ somewhat, and their basic functions are distinct. Common to both, however, is a basic polarity of cellular organization, with nuclei aligned side by side, typically in a basal location within each cell.

Figure 24.3 Normal jejunal villi. These villi are long and slender mucosal projections with a core of lamina propria covered by a luminal epithelial layer. A single row of intestinal glands (crypts) is found at the base of the mucosa. These crypts lie between adjacent villi and are surrounded by the same lamina propria that forms the villous cores.

Villous Epithelium.

The absorptive cell is the major villous epithelial cell type encountered. It is tall, columnar, with a basally situated round-to-oval nucleus and an eosinophilic cytoplasm (Figure 24.5). The apical surface contains a brush border that appears densely eosinophilic, stains positive with periodic acid-Schiff (PAS), and is composed of microvilli and the glycocalyx, or fuzzy coat (Figures 24.5,24.6). Microvilli, which are best seen on ultrastructural examination, are evenly spaced surface projections that also augment the mucosal surface area of the small intestine (20) (Figure 24.7). Multiple filamentous structures emanating from and contiguous with their surface comprise the glycocalyx (17). The microvillous membraneâ€“glycocalyx complex houses important enzymesâ€”peptidases and disaccharidasesâ€”that function in terminal digestive processes. This layer probably also acts as a barrier to microorganisms and other foreign matter (21). Components forming the glycocalyx are continually

synthesized within the absorptive cell and transported to the surface to replace the preexisting coat in a dynamic fashion (17,21,22). Although its functional capacities are uncertain, absence of the glycocalyx of the small bowel mucosa was the sole detectable histologic abnormality found in some children with allergic enteropathy (i.e., cow's milk allergy) (21).

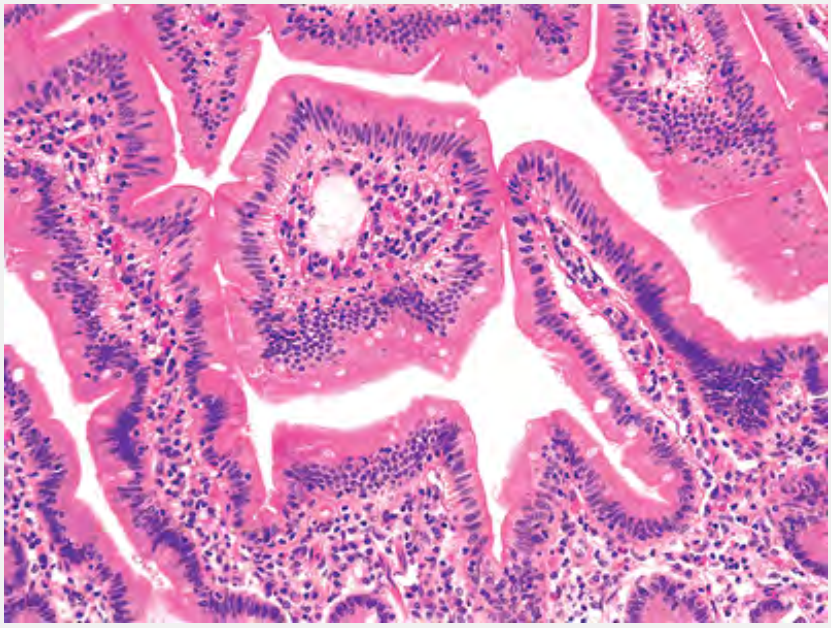

Figure 24.4 The duodenal villous surface is covered by a single layer of tall columnar epithelial cells. The underlying lamina propria core contains lymphoid and plasma cells and a connective tissue framework, including a lymphatic vessel (lacteal) and a subepithelial capillary network.

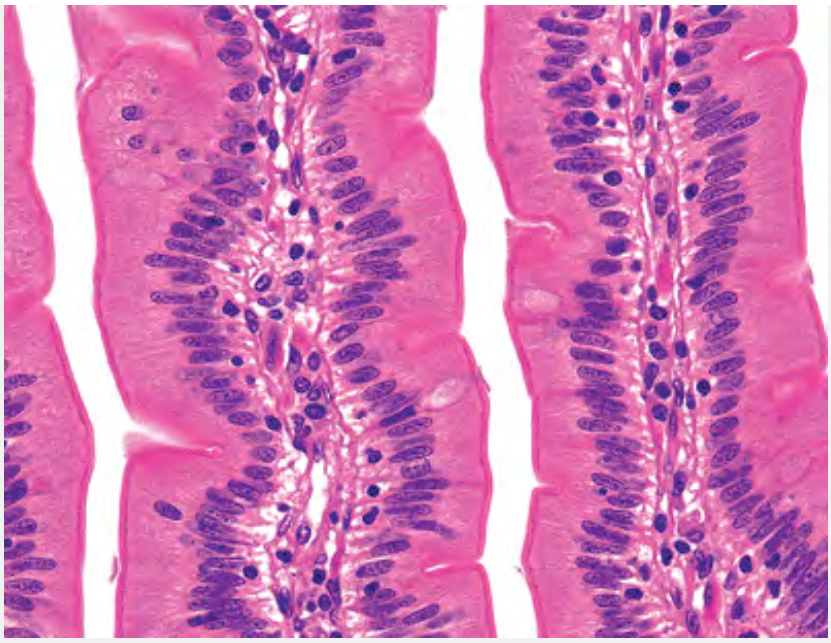

Figure 24.5 High-magnification view of a jejunal villi disclosing the general features of villous morphology. Both columnar absorptive cells and goblet cells (with apical clear vacuole) cover the villous surfaces; each cell type has a basally situated oval-to-round nucleus. Microvilli (brush border) are seen extending from the columnar absorptive cell surface. Note the intraepithelial lymphocytes scattered among and between the epithelial cells.

Figure 24.6 Periodic acid-Schiff (PAS) stain highlights the microvillous membraneâ€“glycocalyx complex along the apical surface of the absorptive cells. The thin subepithelial basement membrane that separates the lamina propria from the epithelial compartment also stains with PAS but to a lesser degree. The neutral subgroup of mucins contained within the goblet cells are PAS-positive as well.

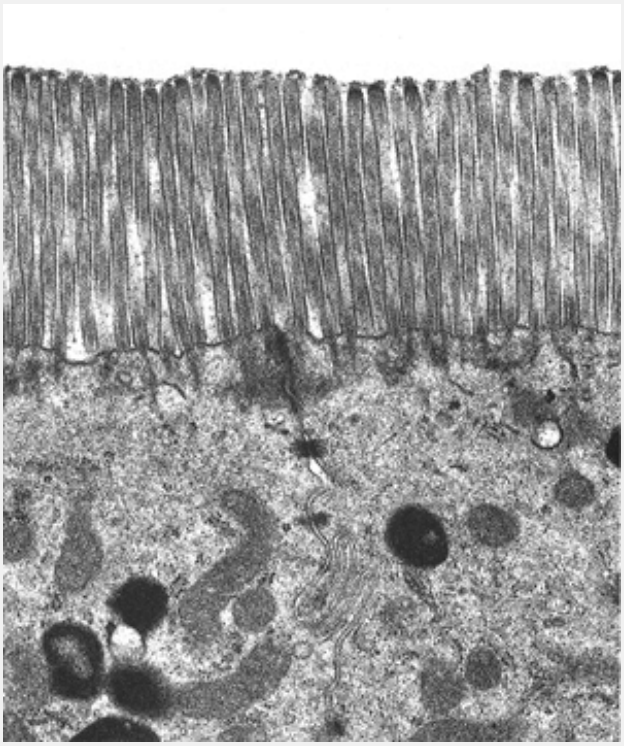

Figure 24.7 Transmission electron micrograph of microvilli emanating from the absorptive columnar cell surfaces. The glycocalyx component is the filamentous layer overlying the microvilli, but most of this has been artifactually removed during processing.

Interspersed among the absorptive cells are goblet cells, which have a characteristic apical mucin droplet and an attenuated, basally situated, bland nucleus (Figure 24.5). They contain both neutral and acid mucin and function as secretory cells, sustaining a moist viscid environment within the lumen (20). In a combined Alcian blue/PAS stain, the droplets appear blue-purple (Figure 24.8). The acid mucins of the small intestine are primarily sialomucins, in contrast to the colonic goblet cell, which contains predominantly acid sulfomucins (23,24). The number of goblet cells increases with distal progression along the small bowel (20).

Scattered endocrine cells are present within the villous epithelium, but they are more abundant within the crypts. Intraepithelial lymphocytes are scattered among and lie between individual epithelial cells, usually just above the basement membrane; normally there is about one lymphocyte for every five epithelial cells (25,26) (Figure 24.5). Intraepithelial lymphocytes mark as T cells (Figure 24.9), and most are of the T-suppressor/cytotoxic (CD8-positive) variety (27,28,29). An increase in the number of intraepithelial lymphocytes is characteristic of several disorders, including gluten-sensitive enteropathy (celiac sprue), tropical sprue, and giardiasis (30,31).

Crypt Epithelium.

The crypt epithelium primarily functions in epithelial cell renewal (20); and, as a consequence of this regenerative function, mitoses are seen frequently within the crypts (normal range: 1â€“12 mitoses/crypt) (32). Goblet cells and columnar cells, some of which are undifferentiated or stem cells, are conspicuous. The four major epithelial cell types of the mucosa (absorptive, goblet, endocrine, and Paneth's cells) arise from this stem cell (33). Differentiation and maturation occur in about five to six days as the cells migrate from the crypt depths to the villous tips, where they are subsequently sloughed into the lumen (20,33); however, the Paneth's cell remains within the crypt base (34). It is thought that apoptosis probably functions as a regulator of cell migration toward the villous surface; however, it is not certain whether this form of programmed cell death is responsible for epithelial cell sloughing from the villous tip (35). Morphologically, cells undergoing apoptosis show nuclear condensation and cell shrinkage with subsequent detachment from adjacent epithelium. In addition,

the cell disintegrates into so-called apoptotic bodies and is phagocytosed by local histiocytes (35).

Figure 24.8 Alcian blue/PAS combination stain showing characteristic blue-purple apical mucin droplet of intestinal goblet cells. The heterogeneous composition (neutral and acid mucins) allows both stains to be incorporated into the droplet, imparting this distinctive color.

Endocrine cells are relatively abundant in the crypts, occurring as single cells or in discontinuous groupings along the intestinal tract (10). They are of two morphologic types. The â€œopenâ€• type have a pyramidal shape that tapers toward the glandular lumen with which they communicate, whereas â€œclosedâ€• cells are spindle-shaped and have no luminal connection (10). The former are the most frequent type found in the small bowel. Some endocrine cells disclose eosinophilic basal (infranuclear) granules on hematoxylin and eosin (H&E) staining so that they are easily

identified on routine preparations (Figure 24.10); however, not all enteroendocrine cells have such a quality, and their identification remains elusive unless special methods are used. Silver (argyrophilic, argentaffinic) preparations or immunocytochemical techniques are useful for visualization in these cases. The disadvantage of silver stains is that no information can be gleaned with respect to endocrine cell type or hormonal composition, and some cells do not reduce silver preparations (10). Immunocytochemistry is, therefore, the best method for definitive evaluation. Antibody preparations to chromogranin and neuron-specific enolase have been shown to be useful nonspecific markers for endocrine cells (36) (Figure 24.11). Precise identification of endocrine chemical content requires specific monoclonal or polyclonal antibody preparations. Although most often used in experimental settings, specific hormonal content immunostaining also may have diagnostic value in studying neuroendocrine tumors (37). Electron microscopy

also can be used to identify cytoplasmic neurosecretory granules.

Figure 24.9 Small intestinal mucosa immunostained for UCHL1 (CD45 RO), a panâ€“T-lymphocyte marker. The positive red-brown reaction highlights both the intraepithelial and lamina propria T cells. Although CD8-positive T-suppressor/cytotoxic lymphocytes predominate within the epithelium, lamina propria T cells usually mark for CD4, the T-helper/inducer subset.

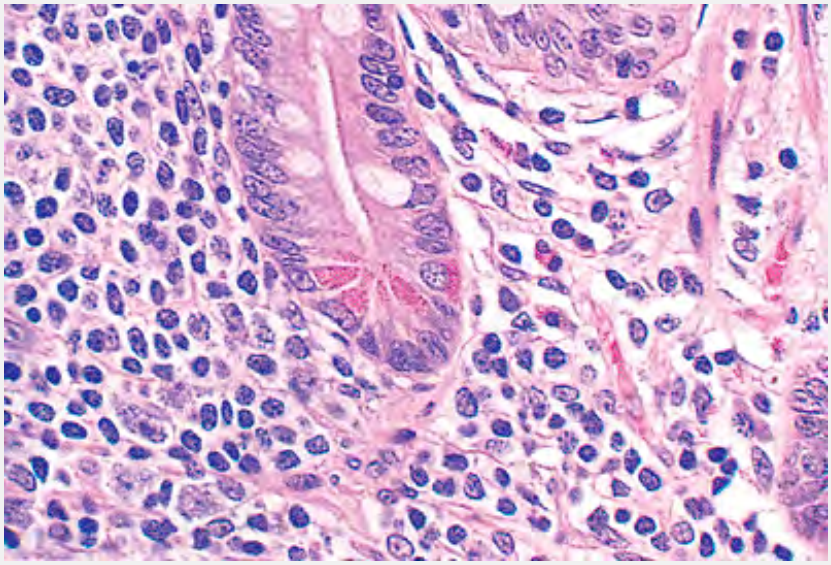

Figure 24.10 A single crypt surrounded by normal cellular lamina propria with abundant migratory cells. Both absorptive columnar and goblet cells are seen lining the crypt. In addition, an endocrine cell (infranuclear eosinophilic granules) and several Paneth's cells (supranuclear granules) are clearly evident.

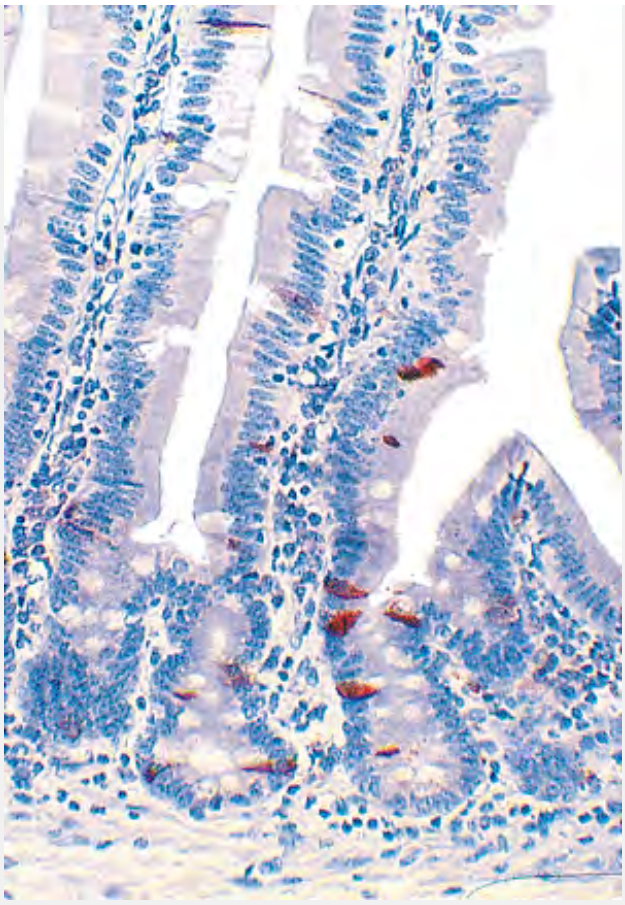

Figure 24.11 Immunostain for chromogranin shows numerous endocrine cells within the crypts and several scattered along the villous surface.

At least 16 distinct types of endocrine cell have been described along the gut (38) and have a characteristic regional distribution and composition. Individual cells containing cholecystokinin, secretin, gastric inhibitory polypeptide, and motilin populate more proximal segments of the small bowel, whereas enteroglucagon-, substance Pâ€“, and neurotensin-storing cells are seen in greater frequency in the ileum (38,39). Serotonin- and somatostatin-containing cells are not as regionalized and are found throughout the gastrointestinal tract (38). Some of these endocrine cells are

known to play key roles in daily gastrointestinal activity. For example, secretin and cholecystokinin are released in response to various foodstuffs and modulate pancreatic secretion and gallbladder function, respectively (39). Most other gut endocrine cells are still of uncertain or unknown physiologic significance (11,39).

The Paneth's cells, normally found only in the crypt, comprise most of the base of individual crypts throughout the entire small intestine (40). They also are encountered to a lesser degree in the appendix, cecum, and ascending colon (41). Paneth's cells have a pyramidal shape with their apices pointing toward the lumen. Their cytoplasm contains characteristic supranuclear, intensely eosinophilic granules that are easily visualized in H&Eâ€“stained sections (Figure 24.10). Interestingly, fixatives containing picric acid (e.g., Hollande's, Bouin's) mask the eosinophilic staining of these granules, often disclosing only unstained cytoplasmic vacuoles (40) (Figure 24.12). Their round nuclei often contain a prominent nucleolus (20,29). The exact function of Paneth's cells is still uncertain, but they are known to contain lysozyme, defensins (Figure 24.13), and immunoglobulin, and they are capable of phagocytic activity.

These features suggest that they play a role in regulating the intestinal microbial flora (41,42,43).

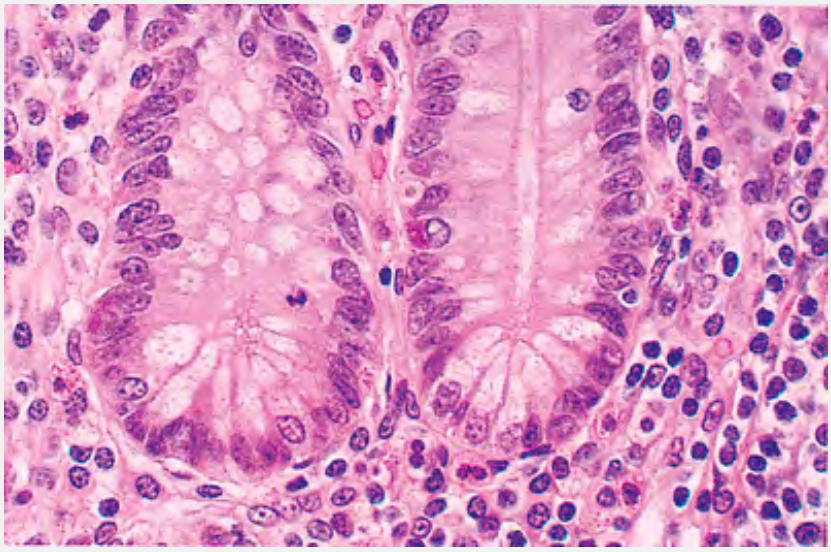

Figure 24.12 Although Hollande's and other picric acidâ€“containing fixatives are superior preservers of cytomorphologic detail, the characteristic supranuclear eosinophilic granules of Paneth's cells are not as easily visualized when compared with the appearance in 4% formaldehyde solution (see Figure 24.10). Clear vacuoles replace the distinct eosinophilic granules within the Paneth's cells (along the crypt bases). Note that the single endocrine cell in this crypt maintains its infranuclear granular staining quality.

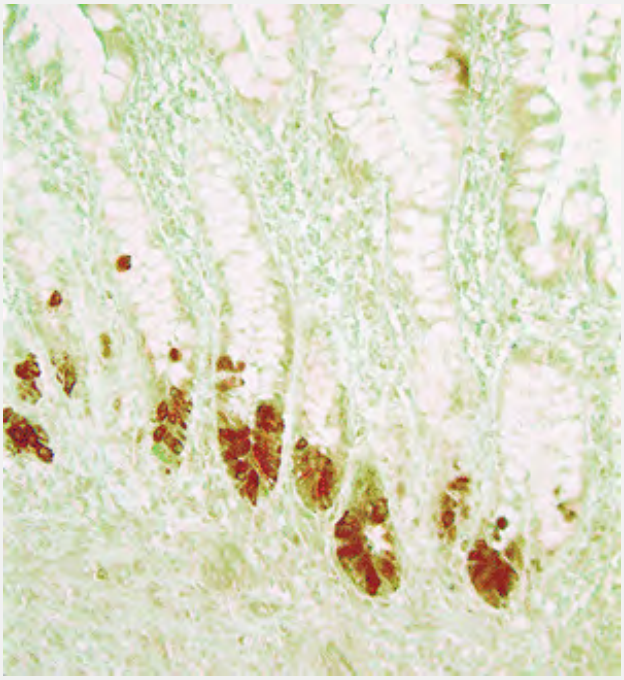

Figure 24.13 Immunostain for defensin HD5 highlights Paneth's cells at the base of the crypts.

The crypt epithelium also contains intraepithelial lymphocytes that are predominantly T-suppressor/cytotoxic (CD8-positive) cells (44). Other inflammatory cell types, such as the neutrophil or the plasma cell, are not normally present within either the crypt or villous epithelial compartments; their presence would indicate a pathologic state (31,45).

Immunostaining Patterns of the Epithelium.

Carcinoembryonic antigen (CEA) is present on the apical surfaces of cells covering the villi and lining the crypts, and it has been shown to localize to the glycocalyx surface component (46). Additionally, the mucin droplets of goblet cells contain an abundance of CEA and consequently mark intensely with polyclonal anti-CEA. However, no intracytoplasmic immunostaining for CEA is

evident in the normal small bowel (46).

Human leukocyte antigen (HLA)-DRâ€“like antigens have been shown to be present in a scattered, focal distribution on the apices of small intestinal columnar-shaped cells (47). Immunostaining with antiâ€“HLA-DR discloses a diminishing intensity of reactivity from the villous surfaces to the crypt bases. Immune-related cells such as lymphocytes (mostly B cells) and macrophages along with the walls of capillaries in the lamina propria also show immunoreactivity for HLA-DR (47).

Lamina Propria

The lamina propria, the intermediate layer of the mucosa, functions both structurally and immunologically. It rests upon the muscularis mucosae, surrounds the crypts, and extends upward as the cores of the intestinal villi. The crypt epithelium and villous epithelium rest upon the lamina propria and are separated from it by a distinct basement membrane recognized as a slender eosinophilic, PAS-positive band at their interface (Figures 24.4,24.5,24.6). This subepithelial basement membrane is a continuous structure composed of an ultrastructurally apparent basal lamina and a deeper network of collagenous/reticular fibers and ground substance (17). Interweaving collagen bundles and other connective tissue fibers, fibroblasts, mature fibrocytes, and smooth muscle cells comprise the framework of the lamina propria (45), whereas blood capillaries, lymphatics, and nerves course through this layer on their various routes to and from all portions of the bowel wall.

The most conspicuous feature of the lamina propria is its abundant immunocompetent and migratory cell component (Figures 24.10, 24.12). Five types of immunocompetent or inflammatory cells are normally encountered in the lamina propria: plasma cells, lymphocytes, eosinophils, histiocytes, and mast cells. Neutrophils are not usually encountered in the lamina propria, or for that

matter anywhere in the small bowel wall, with the exception of those confined to vascular lumina.

Plasma cells are the most abundant cellular lamina propria constituent; most contain cytoplasmic immunoglobulin (Ig)A but some contain IgM (Figure 24.14). In contrast to extraintestinal sites (e.g., peripheral lymph nodes) (30,48), IgG-secreting plasma cells are scant. Lymphocytes, both B and T cells, are also common. The predominant subset of T cells within the lamina propria is the T-lymphocytes with the helper/inducer immunophenotype (CD4 positive) (27,48,49) (Figure 24.9). Lymphocytes are found throughout the lamina propria but often form more dense infiltrates just above the muscularis mucosae (45). Moreover, lymphoid aggregates and nodules, many with germinal centers, are scattered along the small bowel and are found in increasing concentration distally. These lymphoid aggregates are based in the lamina propria, but they often extend to some degree into the underlying submucosa.

Histiocytes or macrophages are also seen in the lamina propria but in fewer numbers than lymphocytes or plasma cells. Most are located along the superiormost aspect of the lamina propria near the tips of the villi (28). They function in T-cell regulation as antigen presenters and phagocytes (30).

Exaggerated expression of this latter function can be seen pathologically in disseminated *Mycobacterium avium-intracellulare* complex infection and in Whipple's disease, where the lamina propria becomes filled with macrophages engorged with microorganisms (30,50,51,52).

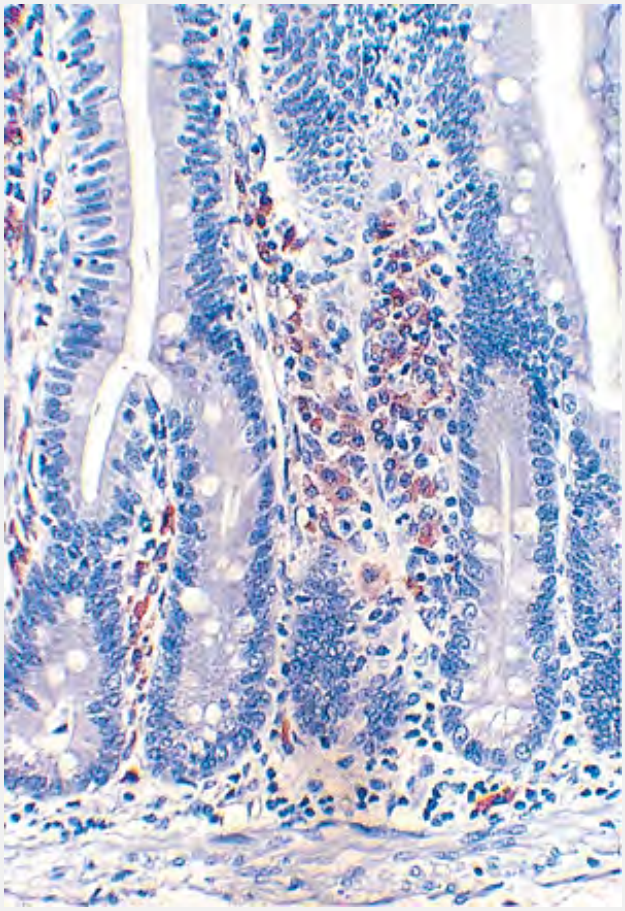

Figure 24.14 Numerous IgA-containing plasma cells (red-brown cytoplasmic staining) within the lamina propria of normal small intestine, immunostained for Î±-heavy chain. Note that, in contrast to T cells (see Figure 24.9), the plasma cells localize to the lamina propria and are not normally found in the epithelium.

The only granulocytes normally found in the lamina propria are eosinophils and mast cells. Eosinophilic leukocytes usually are conspicuous, but their role in the normal bowel is uncertain (53). The numbers of eosinophils in the lamina propria increase under various conditions, including those comprising the eosinophilic gastroenteropathies (54,55,56,57,58). Mast cells are relatively

abundant in the small intestinal lamina propria, as compared with other body sites (30), but in absolute numbers appear to decrease with distal progression along the small bowel (59). Their function in the gastrointestinal tract in normal and disease states is unknown. Increased numbers of mast cells can be found in inflammatory bowel disease and in the specimens of some individuals with eosinophilic gastroenteropathy (57,60). According to some investigators, a specimen disclosing more than eight mast cells per high-magnification field should suggest the diagnosis of systemic mast cell disease (61). Mast cells can be seen on H&Eâ€“stained sections, but they are more easily visualized with special techniques such as toluidine blue, sulfated Alcian blue, or Giemsa stains. Rarely, subepithelial (lamina propria) endocrine cells may be found in the small bowel; however, these are much more prominent in the vermiform appendix (62). Occasionally, in apparently healthy individuals and in certain disease states (e.g., Crohn's disease), ganglion cells are found in the lamina propria of the small bowel. These could potentially be confused with cytomegalovirus infectionâ€“induced cellular changes.

Muscularis Mucosae

The muscularis mucosae, which is the outermost layer or limit of the mucosa, is a slender band of tissue composed of elastic fibers and smooth muscle arranged in an outer longitudinal and inner circular layer (Figure 24.15). However, these layers are usually not well delineated on routine light microscopy. Tufts of smooth muscle radiate from the muscularis mucosae into the lamina propria and extend into the villi. The muscularis mucosae provides an important structural foundation for the mucosa, and its absence in some biopsy specimens can cause a loss of villous orientation, an artifact that may interfere with optimal evaluation (53).

Submucosa

Between the muscularis mucosae and muscularis externa is the submucosa, a loose, paucicellular layer composed of a regular, honeycomb-like arrangement (at the ultrastructural level) of collagenous and elastic fibers and related fibroblasts. The submucosa also may contain scattered, rather inconspicuous migratory cells (e.g., histiocytes, lymphoid and plasma cells, and mast cells) and adipose tissue (63). Its histologic appearance and principal role in maintaining the structural integrity of the small bowel are similar throughout the gastrointestinal tract (63). The submucosa is a major focus of vascular routing and related distribution of regional blood and lymphatic flow. Relatively large caliber arterioles, venules, and lymphatic vessels form extensive individual plexuses and networks within this layer (5,19) (Figure 24.16). From this â€œvascular center,â€• numerous penetrating capillary vessels supply and drain most of the mucosa and muscularis externa (5,19). Lymphatic vessels may be distinguished from blood vessels by the thinner wall of the former and the lack of luminal erythrocytes. However, certain immunohistologic patterns and electron microscopic characteristics are more helpful for definitive identification (18,64,65). Specifically, the endothelial cells of blood capillaries immunostain for PAL-E and factor VIIIâ€“related antigen, whereas lymphatic capillary endothelia typically lack these antigenic sites and remain unstained with such antibody preparations (64,65). In addition, blood capillaries as seen by ultrastructural analysis have a continuous basal lamina, endothelial fenestrations, and ensheathing pericytes. However, lymphatic capillaries have a discontinuous basal

lamina and lack both fenestrations and surrounding pericytes (17,18). Although small lymphatic vessels are a conspicuous submucosal component, prominent dilated lymphatic structures in this layer, as well as in the mucosa, can be seen in pathologic states such as intestinal lymphangiectasia or Crohn's disease (31,66).

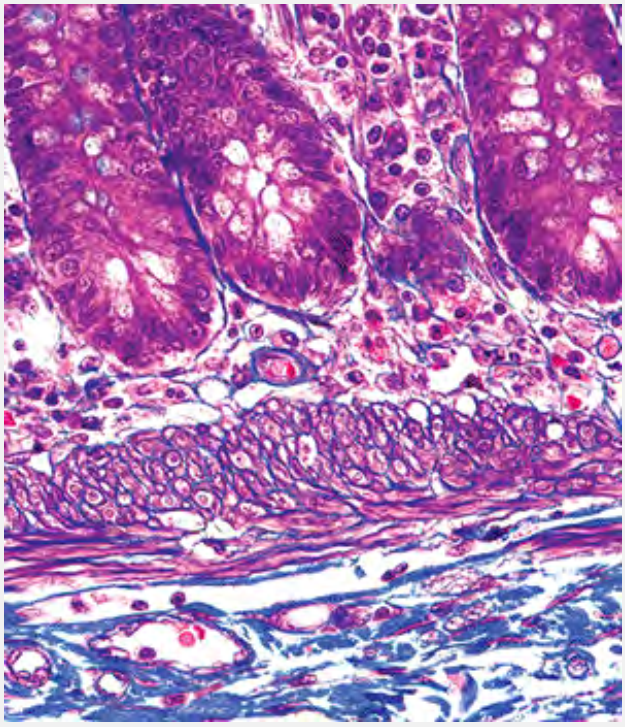

Figure 24.15 High-magnification photomicrograph disclosing inner circular and outer longitudinal smooth muscle bands of the muscularis mucosae; this layering is often inconspicuous on hematoxylin and eosin preparations, where the muscularis mucosae appears as a thin eosinophilic strip between the lamina propria and underlying submucosa (Masson's trichrome).

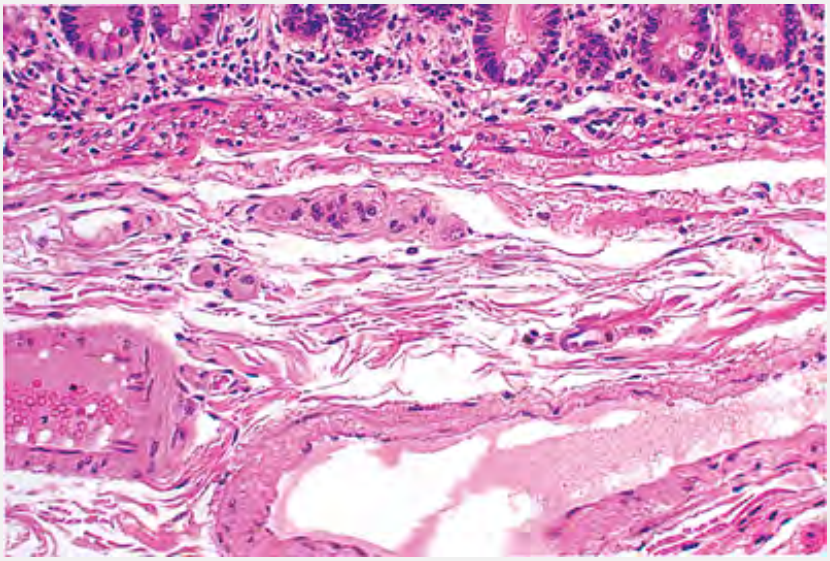

Figure 24.16 Normal submucosa separated from overlying mucosa by the eosinophilic-staining muscularis mucosae. The submucosa is paucicellular, disclosing fibrocollagenous tissue and a prominent vascular component. Note the ganglion cells of Meissner's plexus just beneath the muscularis mucosae.

Neural structures are also prominent in the submucosa. The submucosal Meissner's plexus forms one of the two major integrative centers of the enteric nervous system. It consists of a network of ganglia that interconnect through neural processes (67). The ganglia contain compact aggregates of neurons (ganglion cells) routinely identified on H&E preparations by their characteristic large oval shape, abundant pink cytoplasm, vesicular nucleus, and single prominent, often eosinophilic nucleolus (Figure 24.16). Abundant S-100â€“positive Schwann cells, glial-like cells, and neural processes are also present in Meissner's plexus. The entire plexus, including the ganglia, contains no connective tissue elements or vascular structures in the normal state (67,68,69,70). The plexus is also normally devoid of inflammatory cells; therefore, if these are seen, an injury pattern specific to the

neural plexus (such as an inflammatory neuropathy) should be considered, as long as primary inflammatory bowel disease can be excluded (69). Neural interconnections exist between Meissner's plexus and the myenteric plexus of Auerbach (discussed below), as well as with extrinsic (autonomic) neural processes.

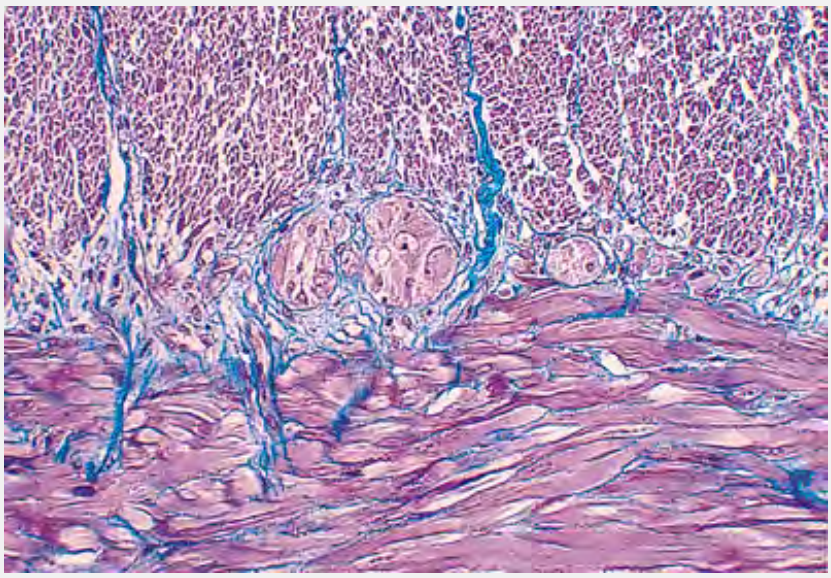

Figure 24.17 Masson's trichrome stain clearly delineates the inner circular (*above*) from the outer longitudinal (*below*) smooth muscle bands of the muscularis externa. The prominent muscular component (*red*) is partitioned into bundles of varying size by delicate collagenous fibers (*blue*). Note the ganglia of the myenteric plexus of Auerbach, characteristically located between the two muscle bands. Fibrous tissue is minimal within the muscularis externa and is also not normally part of the plexus.

Muscularis Externa

The muscularis externa (or muscularis propria) is the thick outer

smooth muscle layer that surrounds the submucosa. It is covered externally by subserosal connective tissue and, in most places, by a serosa. Its two distinct muscular layers, oriented perpendicular to each other, are arranged as an outer longitudinally running muscle fiber layer and an inner circular muscle band (Figure 24.17). Blood vessels, lymphatics, and nerves course through the muscularis externa and slender collagenous septa surround groups of smooth muscle cells, creating characteristic bundles and packets of muscle (Figure 24.17). However, fibrous tissue in this layer is minimal in the normal small bowel (69) so even slight fibrous alterations or collagen deposition may be significant. Moreover, the fact that only a few disease entities (including ischemia, irradiation, familial visceral

myopathy, scleroderma, and mycobacterial infection) are associated with fibrosis of the muscularis propria aids in narrowing a broad differential diagnosis (31).

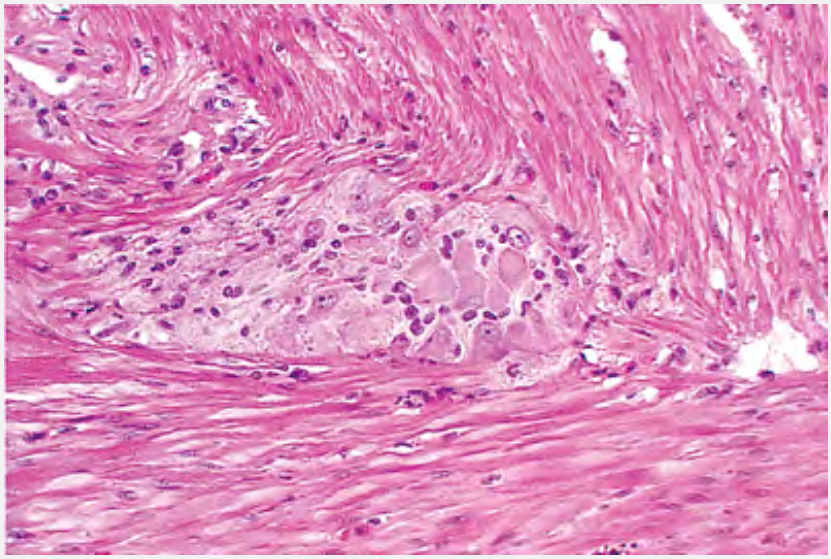

Figure 24.18 A single ganglion of the myenteric plexus of Auerbach located at the interface of the inner (*above*) and outer (*below*) smooth muscle layers of the muscularis externa.

Ganglion cells (neuronal cell bodies) are evident and characterized by a polygonal shape, abundant pink cytoplasm, and an eccentric nucleus; spindled neural projections and Schwann cells are also intermixed.

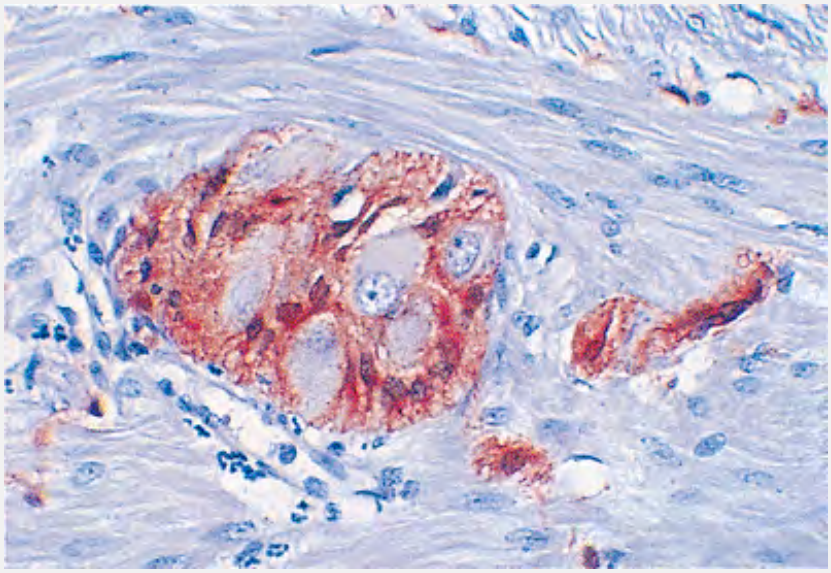

Figure 24.19 This S-100 immunostain highlights the otherwise inconspicuous spindled Schwann cell component of the ganglion. It also marks the Schwann cells accompanying the neural projections that interconnect these ganglia to one another within the plexus system. Note that the ganglion cells show no such immunoreactivity.

The myenteric plexus of Auerbach, the other major neural plexus of the enteric nervous system, lies between the outer longitudinal and inner circular muscle layers (Figures 24.17,24.18,24.19). Auerbach's plexus is similar in composition to the submucosal plexus, although it typically has larger ganglia, a greater number of neurons, and a more compact plexus network (68,69). As a

consequence of these features, it is best to evaluate the myenteric plexus for specific disease processes involving the enteric nervous system, such as the various visceral neuropathies. Because routine processing allows only a small portion of the plexus to be visualized and because many of these conditions cause no detectable changes on routine H&E-stained sections, special preparations of thicker, larger, and silver-stained sections cut *en face* are currently necessary to diagnose many of these disorders (69). Finally, although of lesser importance, a deep muscular, subserous plexus and several mucosal plexuses are also present within the small bowel (68). Interstitial cells of Cajal (ICC) are located in relation to the myenteric plexus of Auerbach and in septa between circular muscle lamellae (Figure 24.20). These â€œpacemaker cellsâ€• are felt to play a role in intestinal motility (71).

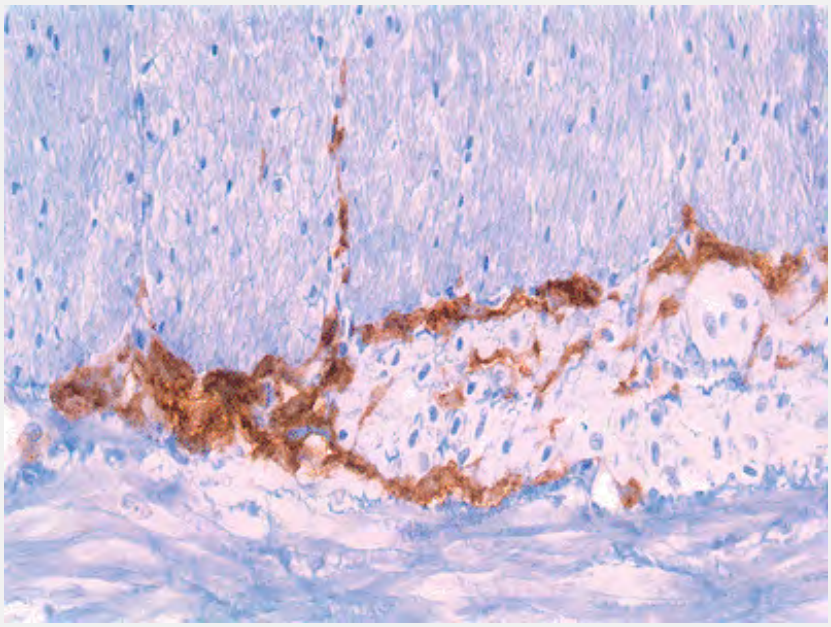

Figure 24.20 The CD117 (c-kit) immunostain shows interstitial cells of Cajal surrounding the myenteric plexus of Auerbach.

Figure 24.21 The subserosal region contains a delicate fibrocollagenous network, blood vessels, lymphatics, and nerves. The serosa consists of a thin fibrous layer (*blue* and *bottom*) covered by a single layer of mesothelial cells; however, the mesothelium is often denuded in surgical specimens. A portion of the outer layer of the muscularis externa is also present in this field (*top*). (Masson's trichrome.)

Serosa and Subserosal Region

The serosa is the covering that envelops most of the external surface of the small bowel. Its outermost layer consists of a single row of cuboidal mesothelial cells, under which lies a thin band of loose connective tissue. A subserosal zone of connective tissue lying between this mesothelial covering and the muscularis externa also contains ramifying branches of blood vessels, lymphatics, and nerves (Figure 24.21).

Distinctive Regional Characteristics of the Small Bowel

Duodenum

The duodenum exhibits several distinctive histologic features, many related to its proximal location in direct continuity with the pylorus. The gastroduodenal junction,

although well-delineated grossly, is poorly demarcated histologically (72) (Figures 24.22,24.23). A gradual transition in epithelial types occurs, with three distinct subtypes in the duodenum (73): (a) an antral-type mucosal epithelium that is identical to the pyloric mucosa; (b) a â€œusual small intestinal typeâ€• (jejunal type) characterized by villi covered by absorptive cells and interspersed goblet cells; and (c) a transitional type (Figure 24.23), in which the same villus is covered by epithelium having features of both antral-type and usual small intestinal-type epithelia. In the region of the gastroduodenal junction, irregular undulating slips of antral-type mucosa extend about 1 to 2 mm into the anatomic duodenum, which then abuts a 2- to 3-mm segment of transitional-type epithelium (73). Distal to this, only the usual small intestinal-type mucosa is found (73). The transitional type epithelium occurring in more distal aspects of the duodenum and in the rest of the small intestine is termed gastric metaplasia (31).

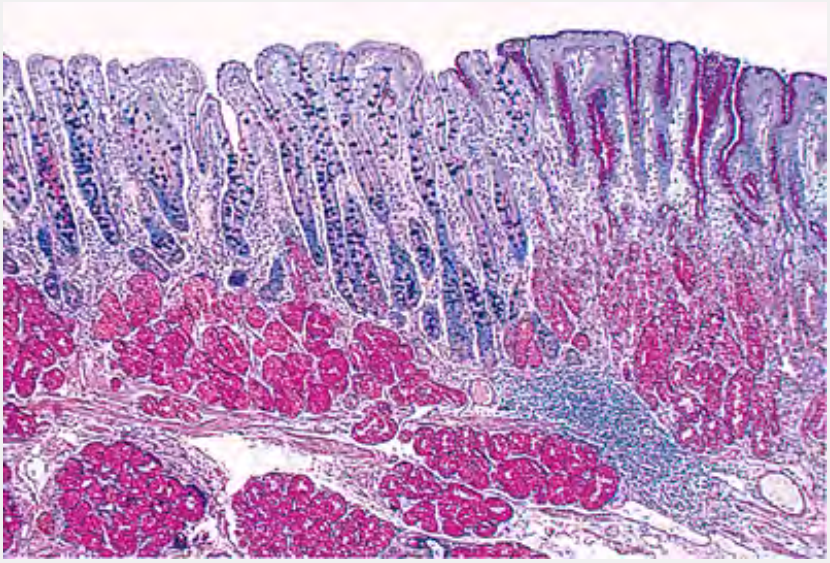

Figure 24.22 Gastroduodenal junction. Note the transition from PAS-positive (*red*) gastric foveolar epithelium and underlying pyloric glands (*right*) to a villous mucosal architecture of the duodenum (*left*) lined predominantly by Alcian blue/PAS-positive (*blue-purple*) goblet cells and absorptive cells. Note that both pyloric (*right*) and Brunner's glands (*left*) are composed predominantly of cells containing only neutral, PAS-positive mucin. Brunner's glands, however, are predominantly submucosal in location, while pyloric glands are an intramucosal structure. (Alcian blue/PAS.)

Although the duodenal mucosa may demonstrate long villi with a villous-to-crypt length ratio on the order of 3:1 to 5:1, more commonly, particularly in the first portion (the duodenal cap or bulb), the villi are shorter and broader with occasional branching extensions (74) (Figure 24.24). They often have a leaflike shape with few fingerlike forms when viewed under a scanning electron or dissecting microscope (20,74,75) (Figure 24.25). Also, the number of mononuclear cells within the lamina propria is increased in the duodenum when compared with the rest of the proximal

small intestine (74,75). This varied constellation of findings is considered normal and is probably a consequence of the effect of acidic gastric contents on this most proximal intestinal site (40,75).

Figure 24.23 Several villi within the confines of the gastroduodenal junction disclosing both â€œusual small intestinal-typeâ€• epithelium and antral-type, PAS-positive, foveolar epithelium. This transitional-type epithelium is a characteristic hybrid found in this region. At more distal small intestinal sites, this transitional type epithelium is termed gastric metaplasia. (Alcian blue/PAS.)

The submucosa of the gastrointestinal tract lacks glands except at

two sites: the esophagus and the duodenum. The submucosal Brunner's glands are the type localized to the duodenum. Indeed, these glands are typically used by the pathologist to identify histologically a segment of small

intestine as duodenum. Brunner's glands, which begin just distal to the gastroduodenal junction, are most concentrated in this region and gradually decrease in quantity along the duodenum (76). Beyond the entrance of the ampulla of Vater, only scattered groups can be found. In rare instances, Brunner's glands extend beyond the duodenojejunal flexure for a short distance (77,78,79).

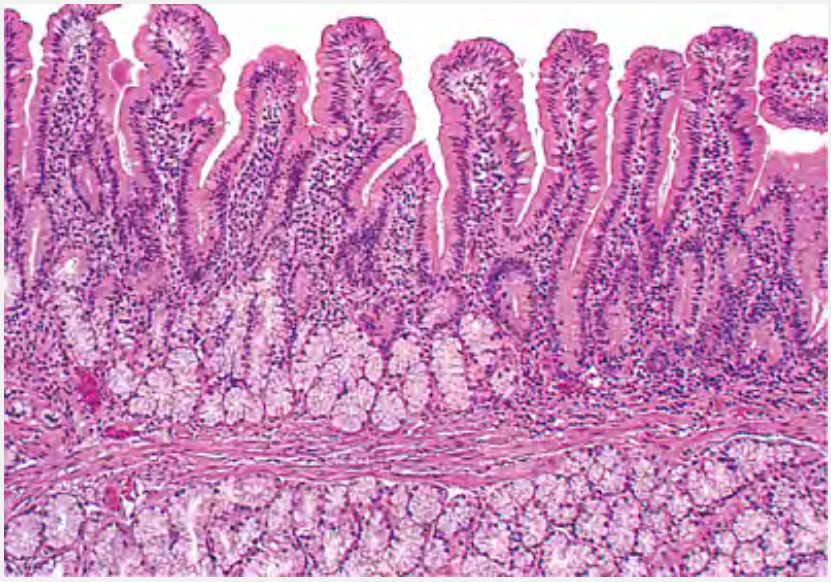

Figure 24.24 Short, slightly broader villi predominate in the duodenum. The underlying submucosal Brunner's glands are a distinctive feature of this portion of small bowel. Note that a fair portion of Brunner's glands normally occurs above the muscularis mucosae.

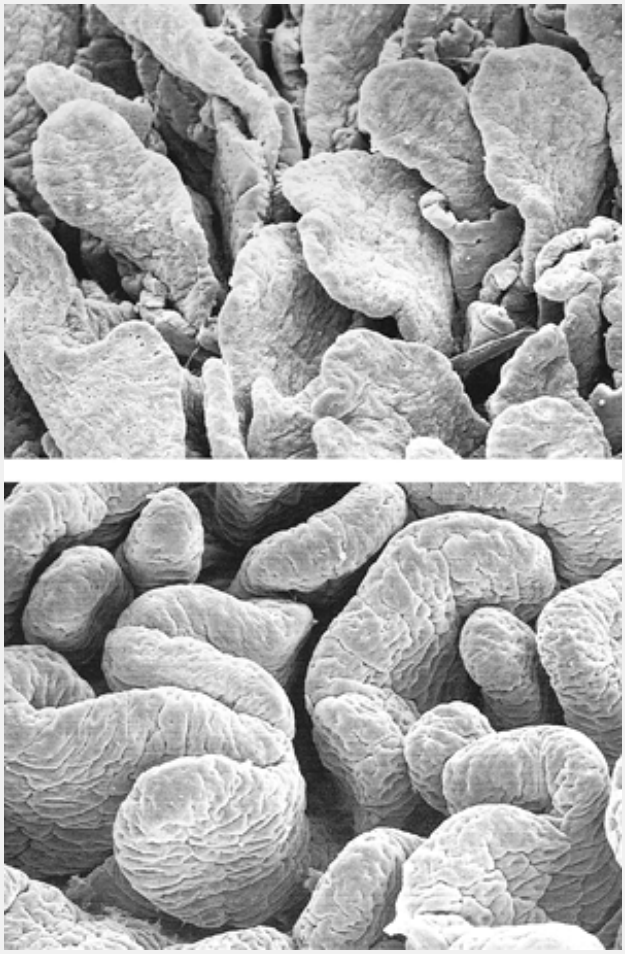

Figure 24.25 Two views of duodenal mucosa using scanning electron microscopy: leaflike (A) and ridged-shaped (B) villi predominate in these normal duodenal specimens.

Brunner's glands are lobular collections of tubuloalveolar glands predominantly located within the submucosa; however, they often extend through the muscularis mucosae into the deep portions of mucosa beneath the crypts of LieberkÃ¼hn (Figures 24.24, 24.26). On average, about one third of the gland population resides within the mucosa (77). Brunner's glands are lined by cuboidal-to-columnar cells with pale, uniform cytoplasm and an oval, basally situated nucleus. Their cytoplasm contains neutral

mucins that are PAS positive and diastase resistant (Figure 24.22). Occasionally, mucous cells with apically concentrated mucin and perinuclear vacuolization or clearing are seen. Although opinions vary, these changes are thought to represent the secretory phase of the gland (i.e., recently fed state) (80,81). The glands empty by way of ducts lined by a similar epithelium, which are often seen passing through slips of muscularis mucosae (Figure 24.26). These ducts drain into the crypts at varying levels (79). Brunner's glands and their ducts can be distinguished from surrounding crypts by the absence of goblet cells and by their diffuse cytoplasmic PAS positivity (79).

Although most of the lining epithelial cells of the Brunner's glands are of the mucous type, scattered

endocrine cells are present as well. Many can be detected on routine H&E-stained sections because of their basal eosinophilic granulated cytoplasm (82). By using immunohistologic methods, some have been shown to contain somatostatin, gastrin, and peptide YY (83). However, the ducts that drain Brunner's glands are devoid of endocrine cells (83).

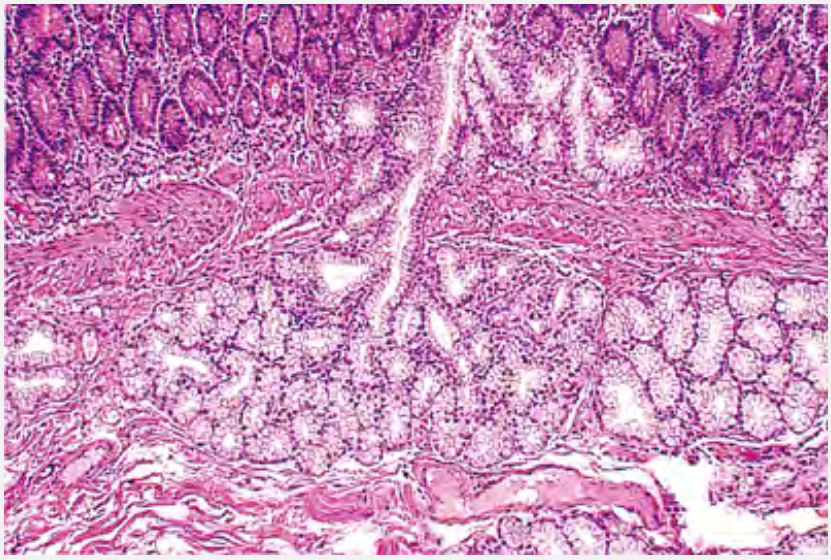

Figure 24.26 Submucosal Brunner's gland lobule with draining duct extending through muscularis mucosae. Note the stark contrast between the crypt epithelium and that of the Brunner's glands and their ducts.

Peptidergic neural fibers, predominantly those with immunoreactivity for vasoactive intestinal peptide and substance P, course within and between individual Brunner's glands. These neuroendocrine substances are probably important in local regulation of acinar secretion, although this function has been verified only for vasoactive intestinal peptide (83). The function of Brunner's glands has not been fully elucidated, but their mucus is felt to be of prime importance for protection of the duodenal mucosa from the potentially damaging effects of the delivered acidic gastric contents (78).

Hyperplasia of Brunner's glands exists in three forms: (a) diffuse glandular proliferation, imparting a coarse nodularity to most of the duodenum; (b) isolated discrete nodules in the proximal duodenum; and (c) a solitary nodule, often designated as an â€œadenomaâ€• of Brunner's glands (77,84,85). All three types are typically composed of an increased quantity of normal-appearing Brunner's glands, accompanied by variable proportions of smooth muscle (Figure 24.27). The distinction between adenoma and hyperplasia is arbitrary, and no substantial evidence exists to suggest that any of these proliferations are truly neoplastic (84). Moreover, carcinoma arising from a population of Brunner's glands has yet to be convincingly documented (31). Nodules or polypoid structures composed of collections of these submucosal glands in the duodenum are probably best termed Brunner's gland nodules (31).

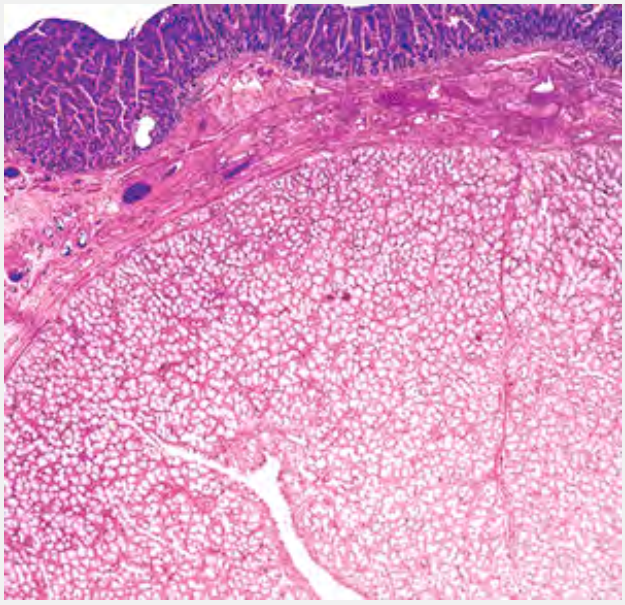

Figure 24.27 Brunner's gland nodule disclosing abundant normal-appearing submucosal glands of Brunner intermixed with smooth muscle, underlying an unremarkable duodenal mucosal villous surface.

Pseudomelanosis duodeni, or brown-black pigment, located primarily within lamina propria macrophages, rarely may be observed in the proximal duodenum (86) (Figure 24.28). Lipomelanin, ceroid, iron, sulfide, and hemosiderin have been identified in these deposits. Most reported patients were hypertensive and also suffered from upper gastrointestinal bleeding, chronic renal failure, or diabetes mellitus (86).

Jejunum

The jejunum is the least distinctive segment of the small bowel; and, as such, its histologic features are most similar to those described for the small bowel in general. However, a characteristic feature is the prominent development of the plicae circulares, or

permanent circular folds, also termed valves of Kerckring and valvulae conniventes (Figure 24.1). These folds are tallest and most numerous (i.e., closely spaced) in this portion of the small bowel (20). Histologically, the jejunal villi are tall with a villous-to-crypt ratio on the order of 3:1 to 5:1. The vast majority of jejunal villi are slender and fingerlike (Figures 24.2,24.3), in contrast to the slightly shorter villi of the ileum and to the leaflike, occasionally branched and blunted villi of the proximal duodenum (20,40). These morphologic transitions are gradual, particularly in the mobile small intestine, where the separation between jejunum and ileum is arbitrarily defined.

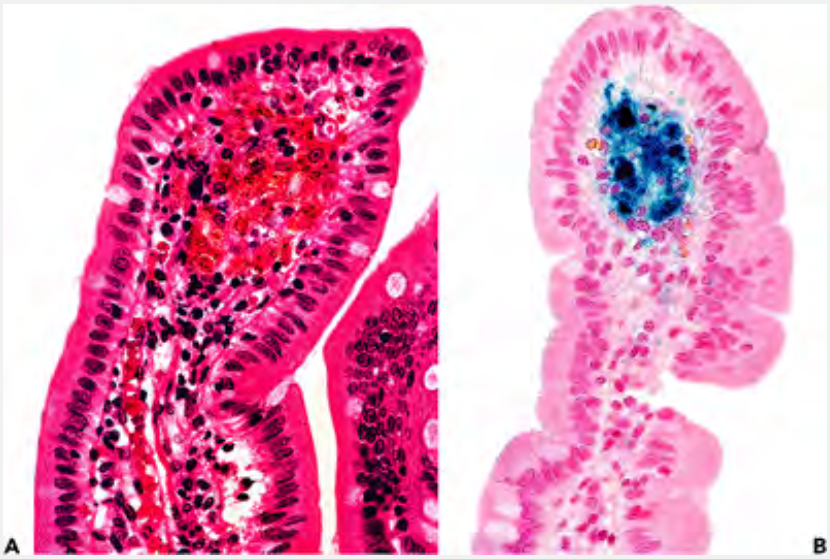

Figure 24.28 A. Macrophages containing granular brown-black pigment within the lamina propria of the duodenum, a characteristic of pseudomelanosis duodeni. B. Prussian blue stain disclosing the prominent iron content of the pigment.

Ileum

The ileum has a number of distinctive features, including its unique junction with the large intestine. The ileum protrudes approximately 2 to 3 cm into the large intestine at the junction of the cecum and ascending colon. This nipplelike extension of the terminal ileum is encircled by large bowel mucosa and has been likened to the relationship of the uterine cervix with the vagina (87). A muscular sphincter at this site, along with external ligamentous support, is responsible for modifying its function in order to prevent reflux and to allow forward passage of ileal contents (87,88). Histologically, the mucosal transition demonstrates a gradual loss of villi occurring at variable lengths along the short intracecal ileal segment; the ileal mucosa blends rather imperceptively with the mucosa of the large bowel (Figure 24.29). The ileocecal region normally can contain abundant fat within its submucosa, diffusely distributed and proportional to adipose content in the rest of the abdominal cavity (89) (Figure 24.29). In fact, on rare occasion, a distinct mass of fat is evident. This benign entity, so-called lipohyperplasia of the ileocecal region, reportedly can cause variable symptoms, including abdominal pain and lower gastrointestinal bleeding (89).

The distinctive mucosal characteristics of the ileum, when compared with both jejunum and duodenum, include shorter and fewer plicae circulares and an increased proportion of goblet cells within the epithelium (Figure 24.30). The villi are typically shorter than at more proximal sites and have a predominantly fingerlike shape (20). These features become gradually more apparent along the length of the small intestine and are most evident in the distal ileum. With distal progression, lymphoid nodules that can be found anywhere in the small intestine gradually increase in quantity (20). In addition, specialized clusters of lymphoid aggregates, or Peyer's patches, are most prominent in the ileum.

Peyer's patches are located along the antimesenteric border of the small bowel. They consist of varying numbers of lymphoid follicles, ranging from 5 to over 900, and have been shown to be present

during fetal life (90). Until puberty, they increase in size and number and subsequently regress steadily thereafter; nonetheless, Peyer's patches are invariably present even into extreme old age (90). In children, these patches can be grossly visualized near the

ileocecal junction (91); although on the whole, they cannot be seen with the naked eye (92). Moreover, hyperplastic Peyer's patches (or focal lymphoid hyperplasia) may be found in the terminal ileum during childhood and have been linked to more than one-third of the cases of idiopathic intussusception occurring in the ileocecal region in this age group (93,94,95).

Figure 24.29 Transition from villous mucosal surface of ileum (*left*) to flat mucosa of large intestine (*right*) at the ileocecal junction. Note the prominent submucosal adipose tissue characteristic of this region.

Figure 24.30 Characteristic ileal mucosa with slender relatively short villi (compare with jejunal villi in Figure 24.3) lined by abundant goblet cells with a lesser number of absorptive columnar cells.

Peyer's patches are basically specialized groups of lymphoid follicles that occupy the mucosa and a variable portion of the submucosa. Structurally, four distinct compartments exist: follicle, dome, follicle-associated epithelium, and interfollicular regions (30,96) (Figure 24.31). Most lymphoid follicles within a Peyer's patch contain a germinal center that is populated by numerous surface IgA-positive B cells, with occasional CD4-positive T cells and macrophages (30,92) (Figures 24.31,24.32). However, the surrounding mantle zone contains a population of small B cells (predominantly surface IgD- and IgM-positive). The dome is the area between the follicle and the overlying surface epithelium; this region contains a heterogeneous population of cells, including B cells of all immunoglobulin isotypes (except IgD), macrophages, and plasma cells (92). The specialized or follicle-associated epithelium overlying lymphoid aggregates is distinct from

surrounding villous epithelial surfaces. It characteristically has fewer goblet cells and contains membranous cells, or M cells, interspersed among the usual columnar absorptive cells (30,97) (Figure 24.32). The M cell is a specialized columnar epithelial cell that transports luminal antigens to adjacent extracellular spaces, thus allowing access to immunocompetent cells. These cells play a key role in mucosally based immunity, antigen tolerance, and probably in certain immunopathologic disease states (97). Morphologically, M cells have an attenuated brush border with diminished alkaline phosphatase staining intensity (96,98), a thin strip of apical cytoplasm, and a basally situated round nucleus. The M cell's cytoplasm is often deformed by several lymphocytes (97). However, definitive M-cell characterization rests upon the identification of specific ultrastructural features (96,97). The follicle-associated epithelium also has a distinctive migratory cell composition because the intraepithelial lymphocyte population is more abundant and has a greater proportion of CD4-positive (T-helper/inducer) cells than does the usual villous epithelium (approximately 40% versus 6%) (96). Last, the fourth component of the Peyer's patch is called the interfollicular region. As in the lymph node, it is predominantly a T-cell zone with CD4-positive T-lymphocytes outnumbering CD8-positive lymphocytes by a 7:1 margin (92).

Plasma cells are a scant component of Peyer's patches, in contrast to the surrounding lamina propria, but they may frequently be found in the dome compartment. Peyer's patches are believed to be important in the generation of the mucosal immune response, in part by supplying the lamina propria with immunocompetent surface IgA-positive B cells

that become functional secretory plasma cells (30,91,92,97).

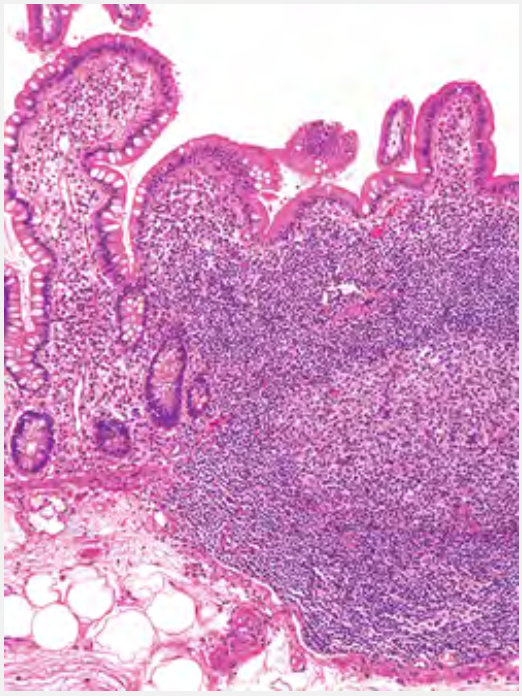

Figure 24.31 Confluent lamina propria lymphoid aggregates of a Peyer's patch. This organized lymphoid tissue typically extends into the underlying submucosa. The four components of the Peyer's patch are seen and include lymphoid nodules with germinal centers, an overlying flattened follicle-associated epithelium, and an intervening pale-staining dome region. The abundant lymphoid population between the follicles is the T-cellâ€“rich interfollicular zone.

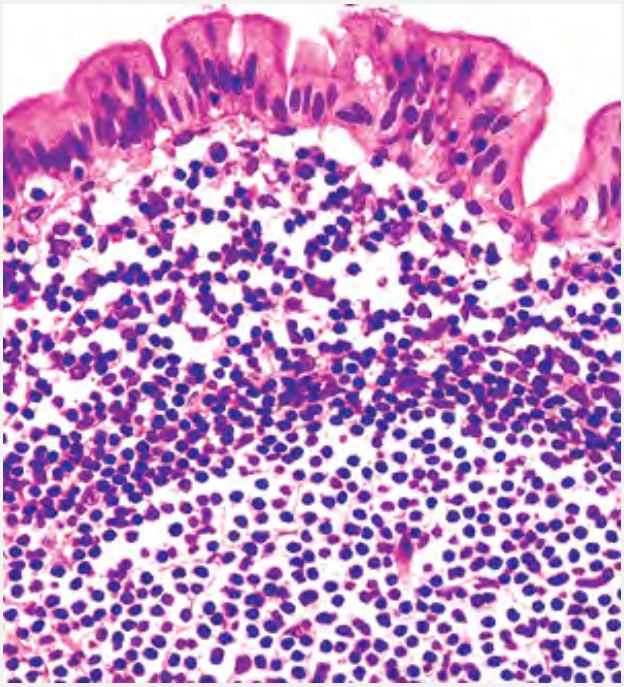

Figure 24.32 High magnification of surface epithelium above a lymphoid nodule within a Peyer's patch. The polymorphous germinal center (*below*) is surrounded by monotonous, small round lymphocytes that comprise the nodule's mantle zone. Above this lies the dome region with lymphocytes, plasma cells, and macrophages. The follicle-associated epithelium characteristically has few, if any, goblet cells; ultrastructurally, most of these cells would be identified as M cells.

Irregularly distributed, granular brown-black pigment can commonly be found in the deep portions of Peyer's patches in adults (99) (Figure 24.33). Although its origin is controversial, atmospheric or dietary sources are most probable (99,100). Accumulating principally within macrophages, this pigment has been shown by x-ray spectroscopy to contain a distinct mineral composition that includes silicates, aluminum, and titanium

(99,100). The pigment is inert and has no known clinicopathologic significance.

A final distinctive feature often seen in the ileum is Meckel's diverticulum; it is the most common intestinal congenital anomaly and is found in 1 to 2% of the general population (31). Meckel's diverticulum is an antimesenteric outpouching of the terminal ileum usually located approximately 20 cm from the ileocecal junction. It represents the persistence of the omphalomesenteric duct. Although Meckel's diverticulum is usually an incidental finding, it can cause lower gastrointestinal bleeding or small bowel obstruction (101,102). Histologically, small intestinal mucosa alone lines the diverticulum in about 50 to 70% of cases. Ectopic gastric or pancreatic tissues are found in the remainder, typically encountered at the distal most aspect (102).

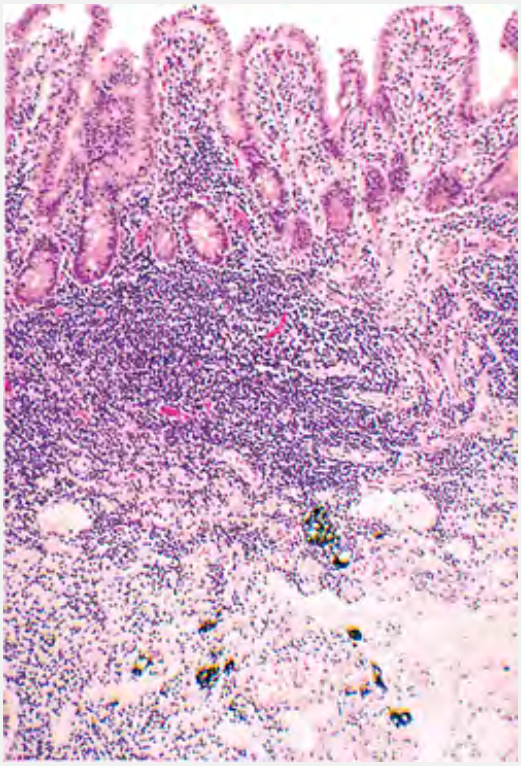

Figure 24.33 Dense brown-black granular pigment within the

depths of a Peyer's patch of ileum. The pigment is typically confined to macrophages.

Special Considerations

Geographic, Age-Related, and Dietary Factors

Because geographic and local environmental factors can affect small bowel morphology, historical data about the residence or recent travel of an individual are essential to evaluate histologic material accurately. Specimens from individuals residing in, or visiting at length, certain less developed tropical locations such as Africa, southern India, and Thailand show a distinctly different villous appearance from those of individuals who live in temperate climate zones (45,103,104,105,106). The morphologic alterations seen in individuals from such tropical areas include leaflike villi predominating over fingerlike forms in jejunal segments examined via biopsy and an increased number of lamina propria mononuclear cells (107). This difference in the villous population is reflected histologically as stubby villi with a pyramidal shape (i.e., a broader base than apex) and occasional branched and fused villous tips (45,103,104). Interestingly, although the villi are shorter, the villous-to-crypt length ratio usually remains constant in all geographic settings (45,104). Such alterations should probably be considered a normal variant because these individuals are typically asymptomatic and otherwise healthy (103).

The cause of these morphologic changes is uncertain, but environmental factors, particularly regional enteric flora, presumably play a role (103). Similar mucosal changes are seen in normal individuals in temperate environments, but only in

proximal portions of the duodenum. Therefore, these particular mucosal alterations must be analyzed in the context of both the patient's residence and the site within the small intestine in order to prevent misinterpretation as a pathologic change, such as tropical sprue.

Aging also modifies small bowel mucosal architecture. Although the literature on humans is limited, it has been shown that specimens from elderly individuals generally have shorter and broader villi than those from younger individuals (108). Moreover, lower animal and human fetuses have been documented as having fingerlike villi exclusively, suggesting that exposure to the environment or aging itself modifies villous architecture (108,109). However, the functional significance of these changes is uncertain (108).

Diet alters villous architecture in laboratory animals. A diet high in fiber results in broad and fused villi, whereas a fiber-free diet seems to prevent the formation of leaflike forms (17). If this finding is valid in humans, it may be one factor related to the presence of stubby, leaflike villi seen in patients in less developed countries where high-fiber diets are common.

Metaplastic and Heterotopic Tissues

Gastric type mucosa is not an unusual finding in the small intestine. A distinction can be made between metaplasia, an acquired alteration, and heterotopia, thought to be congenital in origin. Gastric metaplasia characteristically consists solely of antral-type, PAS-positive, foveolar columnar cells lying along the surface epithelium (Figure 24.23). This change is focal and often in direct continuity with usual columnar absorptive epithelium on the same villus (75). Gastric metaplasia may be encountered in more than 60% of healthy asymptomatic individuals in the duodenal bulb, where it can be regarded as within normal limits (75). More distally, however, it is less commonly seen in the

asymptomatic person but rather frequently is associated with duodenitis or mucosal ulceration (75,110). Scattered chief and parietal cells without any organized arrangement are also associated with this type of metaplasia or with reparative processes (110).

In contrast, gastric heterotopia is usually a grossly evident mucosal polyp that contains all cellular elements encountered in the normal gastric fundic mucosa. Characteristically, mucous foveolar epithelium overlies an organized arrangement of glands lined by chief and parietal cells; this is typically well demarcated from the surrounding usual intestinal villous epithelium. Gastric heterotopia is also fairly common, being reported in up to 2% of the population (111); it may be found anywhere along the gastrointestinal tract (110). Gastric heterotopia is a well-defined entity in the proximal duodenum and usually presents as a mucosal nodule on the anterior wall. Although they are usually of no clinical significance, larger ones may cause obstructive symptoms (111). In contrast, gastric heterotopia distal to the ligament of Treitz is usually symptomatic and often causes intussusception (112). This relationship to clinical symptoms may derive from patient selection bias because asymptomatic gastric heterotopias at a distal site would not be routinely detectable.

Heterotopic pancreas tissue also can be found anywhere along the small intestine but most commonly is found in the duodenum and jejunum (113,114). It can form submucosal, intramural, or serosal nodules and is composed of various admixtures of pancreatic acini, ducts, and islets of Langerhans (113,115) (Figure 24.34). Isolated ductal structures admixed with smooth muscle may be the predominant or exclusive component, and in these instances the alternative term adenomyoma has been used (31,114). Nodules of pancreatic tissue within the small intestine are usually asymptomatic, although larger lesions (greater than 1.5 cm) with prominent mucosal involvement may become clinically significant (114,115). A single case of a combined submucosal pancreatic

heterotopia with overlying gastric type mucosa in the duodenal bulb recently was reported (116).

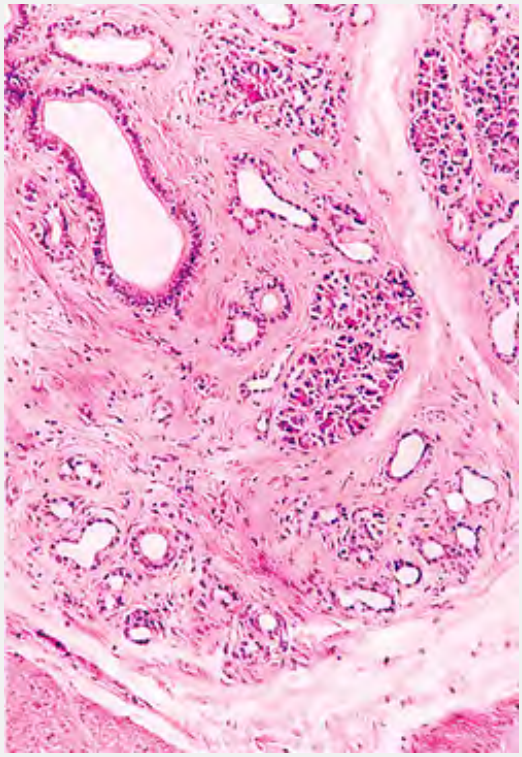

Figure 24.34 Heterotopic pancreas in the duodenum characterized in this instance by variably sized ducts, acini, and abundant smooth muscle.

Lymphoid Proliferations

Lymphoid tissue is a prominent feature of the small bowel. The gut-associated lymphoid system in this region, as in the entire gastrointestinal tract, is compartmentalized into lymphocytes of the epithelium, lamina propria, isolated lymphoid aggregates, and Peyer's patches (117). The normal appearance and immunologic

composition of these distinct lymphoid populations have been detailed earlier in the chapter. All these compartments participate at some level in mucosal immune response, but they also provide the milieu for various hyperplastic and neoplastic immunoproliferations, as well as for certain immunodeficiency states. Some of these disorders have histologic features that deviate only slightly from a normal appearance and from one another. Additionally, some are believed to be preneoplastic.

Lymphoid hyperplasias are divided into two broad categories: focal and diffuse forms (118). Focal lymphoid hyperplasia is a localized, well-circumscribed proliferation of benign lymphoid tissue characterized by a polymorphic infiltrate of lymphocytes within which numerous benign follicles with reactive germinal centers are dispersed. These proliferations often involve only the mucosa and submucosa, but they may extend through the entire wall (118). Focal lymphoid hyperplasia is predominantly found in the terminal ileum of children or adolescents who present either with ileocecal intussusception or with a clinical syndrome mimicking appendicitis (93,95,118).

Diffuse or nodular lymphoid hyperplasia is a distinct entity in which multiple nodules composed of aggregates of benign lymphoid follicles disfigure the mucosa and submucosa along extensive lengths of the small intestine, with or without colonic involvement (118,119,120). It is usually asymptomatic and incidentally encountered (118). However, a distinct clinicopathologic variant exists that is characterized clinically by associated, combined variable immunodeficiency and giardiasis-related diarrhea and histologically by a greatly diminished or absent plasma cell population in the nearby lamina propria (118). Nodular lymphoid hyperplasia, with or without combined variable immunodeficiency, has been associated with an increased risk for the development of various malignancies (e.g., malignant lymphoma, carcinoma) (118,119,120,121).

Differentiation of these benign lymphoid lesions from malignant lymphoma can be problematic. However, recognizing the diagnostic morphologic features of malignant lymphoma, such as the usual cytologic monotony of the lymphoid population, the lack of a reactive follicular architecture, and the presence of mucosal ulceration, should resolve most dilemmas (118,122,123,124). Additionally, because the majority of small bowel malignant lymphomas are of B-cell lineage (124), demonstration of light-chain restriction by immunohistologic techniques or flow cytometric analysis or detection of heavy- or light-chain immunoglobulin gene rearrangements (e.g., monoclonality) by molecular diagnostic methods can aid in certain cases (125,126,127); T-cell receptor gene rearrangement analysis may be necessary in a minority of cases.

Morphologic Changes Associated with Ileal Diversion and Continence-Restoring Procedures

With the increasing number of diversion and continence-restoring procedures being performed after total colectomy, it has become common to see biopsy and revision specimens after such operations. As a consequence, familiarity with the altered yet â€œnormalâ€• morphology within these ileal creations must be appreciated in order to evaluate them optimally. The expected mucosal changes include villous shortening and crypt lengthening (approximate 1:1 to 2:1 ratio), increased numbers of goblet cells and lymphoid follicles, and a denser mononuclear cell infiltrate within the lamina propria (31,128,129). These alterations are similar after either colectomy with conventional ileostomy or after ileoanal anastomosis with ileal reservoir formation (e.g., pouch) (129,130,131). However, ileostomy stomas in particular show additional changes of mucosal prolapse exemplified by fibromuscular obliteration of the lamina propria and superficial

erosions and microhemorrhages (31). Additionally, goblet cell mucin alterations have been seen in nearly 50% of pouches examined, with conversion to predominantly sulfomucins (i.e., colonic epithelial mucin) (131). However, another group of investigators saw no change in goblet cell mucin from the typical small bowel acid sialomucins in ileal segments after either ileoanal anastomosis with pouch formation or conventional ileostomy (129). Nonetheless, all these changes should be interpreted as â€œnormalâ€• because more definitive and specific criteria need to be met to establish persistent, recurrent, or novel disease in these specimens.

Mucosal Biopsy Specimen Evaluation in Suspected Malabsorption

Specimen Procurement and Processing

The usefulness of small bowel mucosal biopsy is unquestioned (132), particularly in the evaluation of malabsorptive states. In the past, up to four biopsy samples were usually obtained from the area of the ligament of Treitz via a suction biopsy device attached to a long tube (133). In recent years, the standard upper endoscope has been used, and comparable specimens have been procured (76,134). Because this technique is performed under direct visualization, many

more biopsy specimens can be obtained. Regardless of the biopsy technique used, the most critical part of the procedure is proper orientation of the specimen. Ideally, specimens are immediately mounted mucosa side up on a solid substance such as filter paper or plastic mesh and then placed into Hollande's or other fixative. After processing, the histotechnologist embeds the tissue perpendicular to the mounting material. Alternatively, biopsy specimens may be placed unmounted into fixative immediately.

The tissue can then be properly oriented after processing at the time of embedding. Because the specimen will naturally curl, some tangential sectioning can be expected. Proper specimen evaluation requires examination of optimally oriented intestinal villi obtained from the central region of the biopsy specimen. Although serial sectioning is advocated by some investigators (107), step-sectioning (threeâ€“seven levels) is a reasonable alternative.

Our standard small bowel biopsy procedure consists of obtaining four to six endoscopic biopsy specimens. One can be used to make a touch preparation that is then fixed in alcohol and stained via the Giemsa technique. The other tissue samples are placed in fixative and routinely processed. Step-section slides are obtained: three are stained with H&E and one with alcizn blue/PAS. The PAS stain is a useful screen for Whipple's disease and *Mycobacterium avium-intracellulare* complex infection. Trichrome stain can be used to confirm collagen deposition seen in ischemia or collagenous sprue. In addition, the iron hematoxylin counterstain used in the trichrome technique makes it easier to identify giardiasis.

Specimen Interpretation and Common Artifacts

With appropriate specimen procurement, the mucosa with muscularis mucosae and a small portion of upper submucosa should be available for histologic examination. These specimens should be evaluated in a systematic fashion, including assessment of (a) villous architecture, (b) surface and crypt epithelia, (c) lamina propria constituents, and (d) submucosal structures (53). A well-oriented specimen is essential for optimal evaluation. However, it must be remembered that villi vary in length and shape, particularly in the proximal duodenum, and that villous apices bend and twist in various planes to create unusual forms; these variations should not be misinterpreted as a villous

abnormality (40,53). Generally, if four normal villi in a row are observed, the villous architecture of the entire specimen is probably normal (53,107). This does not mean that specimens with fewer than four well-aligned normal villi should be considered inadequate because even one normal intestinal villus in a proximal small bowel biopsy specimen rules out unrelated celiac sprue (31). Conversely, identification of four normal villi in a row does not necessarily exclude focal lesions, although it almost always does (107). The pathologist must be wary of certain common artifacts that may lead to erroneous interpretations. Careful attention to certain features (described below) within the various mucosal compartments will aid in their recognition.

Tangential Sectioning

Inappropriate orientation of the specimen, occurring at any point during processing, will lead to various tangential cuts or sections. The mucosa must be sectioned perpendicular to its long axis, or a distorted pattern disclosing apparently short and broad villi and an expanded lamina proprial compartment will be observed. However, several features aid in recognizing an oblique cut: (a) numerous elliptically shaped glands, (b) a multilayered arrangement of the crypts (Figure 24.35), or (c) a multilayered surface epithelium (53) (Figure 24.36). If any of these features are present, the villous architecture must be interpreted with caution.

Brunner's Glandâ€“Related Artifact

Brunner's glands have an inconsistent effect on villous architecture (31). Occasionally, normal length villi can be encountered overlying the Brunner's glands (Figure 24.37), but more commonly the villi appear distorted, short, broad, and stubby (31,40) (Figure 24.24). To minimize the potential effects of this artifact on interpretation, biopsy specimens of the small bowel for evaluation of malabsorptive states are routinely obtained as distally as

possible in

the duodenum or from the proximal jejunum (i.e., near the ligament of Treitz) (76,134). Occasionally, however, more proximal small bowel biopsies are necessary for evaluation of duodenitis or ulcer disease.

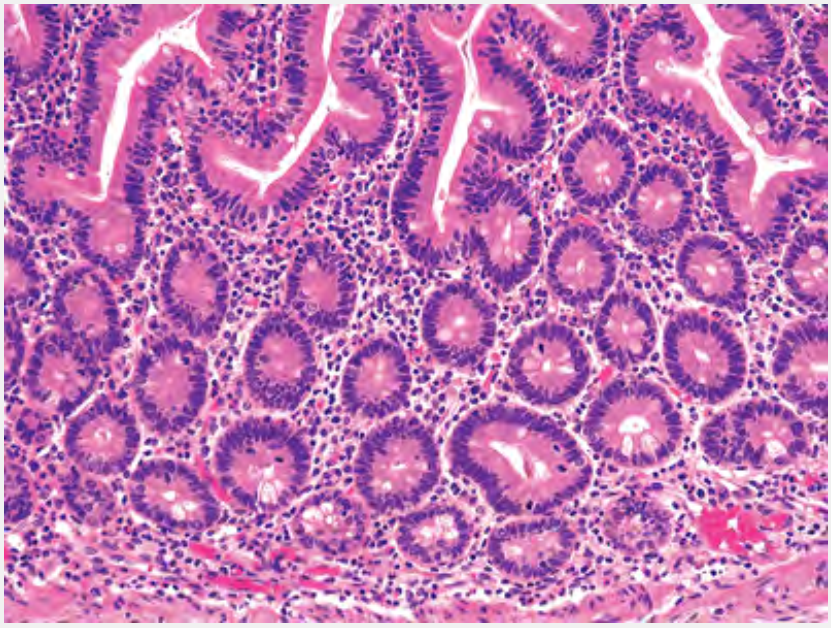

Figure 24.35 Multilayering of crypts indicates a tangential or oblique section of small intestine. The villous architecture overlying the crypts is normal, albeit unusual in appearance; this is also a product of malorientation of the biopsy specimen.

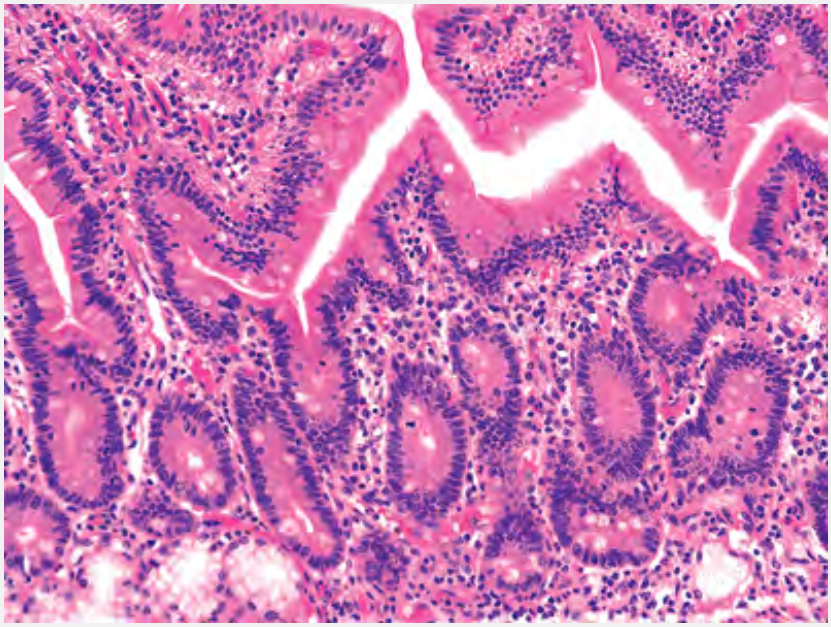

Figure 24.36 Another clue in identifying a tangential cut is multilayering, or â€œstratification,â€• of the surface epithelium (*left portion of central villus*). The normal surface layer is one-cell thick. This broad and short villous appearance is a consequence of malorientation and should be interpreted accordingly.

Lymphoid Aggregateâ€“Related Artifact

Mucosal lymphoid aggregates, or nodules, are scattered along the small bowel and often distort the villous architecture. Villi are usually absent over lymphoid aggregates, and nearby villous forms may be distorted, short, and stubby (53) (Figure 24.31). Therefore, when a lymphoid aggregate is seen below an isolated flat portion of the surface epithelium, it should not be misinterpreted as a severe villous abnormality.

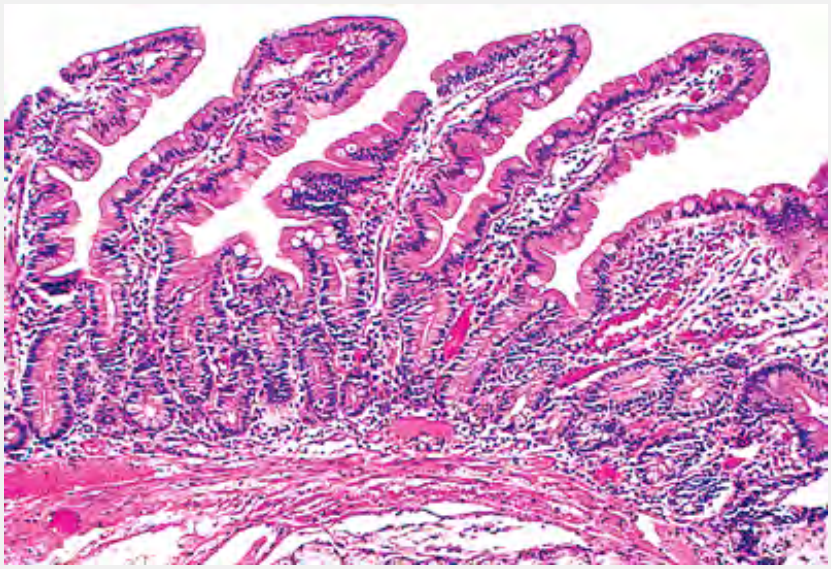

Figure 24.37 Occasionally, long slender villi, similar to those seen in the jejunum, are found overlying Brunner's glands. However, villi associated with Brunner's glands are more commonly shorter and broader (see Figure 24.24).

Figure 24.38 Absence of muscularis mucosae in a small bowel biopsy specimen, resulting in shorter- and broader-appearing villi that are widely spaced.

Absence of Muscularis Mucosae

As mentioned earlier, the muscularis mucosae is an important structural component of the mucosa. In its absence (for instance, in a very superficial mucosal biopsy specimen), the tissues tend to spread laterally, resulting in villi becoming more widely spaced and appearing short and broad (53,135) (Figure 24.38).

Biopsy Traumaâ€“Related Artifacts

As a direct result of the traumatic pinch or suction biopsy procedures, certain alterations of normal mucosa can be seen. Separation of the villous surface epithelium from the underlying lamina propria or focally denuded epithelium are not unusual (53,135). The lack of acute erosive changes (e.g., neutrophilic infiltrate, cellular necrosis) or chronic evidence of ulceration (e.g., granulation tissue, regenerative epithelium) allow this alteration to be recognized as biopsy related. Additionally, focal hemorrhage and scattered polymorphonuclear leukocytes may be observed in the lamina propria as a consequence of the biopsy procedure. Crush or compression artifact can occur at the site of closure of the endoscopic forceps, resulting in a condensation of the lymphoplasmacytic component that can be misinterpreted as increased chronic inflammation (136). Additionally, the connective tissue may be altered in such a way that it appears more tightly packed, mimicking fibrosis or excessive collagen deposition (136).

Fixative-Related Artifacts

Certain fixatives other than formalin (4% formaldehyde solution) can cause interpretive problems. Although Hollande's fixative better preserves cytologic and nuclear detail, several artifacts may interfere with evaluation. The brightly eosinophilic granules of Paneth's cells and sometimes eosinophilic leukocytes seen readily in formalin-fixed tissue are not as well preserved by Hollande's fixative. Additionally, suboptimal clearing of Hollande's fixative from the specimens before paraffin embedding can result in residual minute, round, basophilic structures that resemble yeast forms or parasites (e.g., cryptosporidium, *Giardia lamblia*) (136)

Acknowledgment

We thank James T. McMahon, Ph.D., for the scanning electron micrographs.

Embryology

The gastrointestinal tract is a remarkably complex, three-dimensional, specialized, and vital organ system derived from a simple tubal structure composed of all three germ layers (endoderm, mesoderm, and ectoderm). Early in development, the gut is patterned into four asymmetrical axesâ€”anterior-posterior (AP), dorsoventral (DV), left-right (LR), and radial (RAD), utilizing critical developmental pathways that are directed by reciprocal mesodermal (mesenchymal) to endodermal (epithelial) cell-cell interactions and endodermal to endodermal cell-cell interactions (1 ,2 ,3 ,4 ,5 ,6 ,7,8 ,9). Because gut epithelium is a constitutively developing tissue, constantly differentiating from a stem cell in a progenitor pool throughout adult life, these developmental pathways, axes of development, and cell-cell â€œcross talkâ€• continue to be important in cell differentiation, homeostasis, and apoptosis of the adult intestinal epithelium (8 ,9 ,10 ,11 ,12).

The adult colon displays a morphologic and functional pattern clearly identifiable in three of the four embryonic axes, and interacts with the gut derivatives (thyroid, lung, liver, and pancreas) produced in the fourth embryonic axis (13 ,14).

Development and differentiation along the AP axis gives rise to the foregut, the midgut, and hindgut, resulting in regionally specific differentiation from mouth to anus. The significant variation in patterns of gene expression, physiologic function, disease distribution, and variations in histologic appearance between the right and left colon reflects the combined midgut and hindgut derivation (8 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30). The cecum, appendix, ascending, and proximal portion of the transverse colon (right colon) are derived from the midgut while the distal transverse, descending, sigmoid colon, and rectum (left colon) are derived from the hindgut (13 ,14).

The LR axis is manifested in the colon by characteristic turning and looping of the gut, resulting in portions of colon with varying mesentery and fixation within the abdominal cavity (13).

The fundamental axis maintained in the adult is the radial (crypt to surface) axis. Homeostasis of intestinal epithelium occurs throughout life along this radial axis, with the epithelial and mesenchymal progenitor/proliferative cells being deeper in the radial axis than the differentiated functional cells and the apoptotic cells being luminal (11 ,31 ,32 ,33).

Abnormalities of any of the developmental pathways or along any axis during organogenesis may result in gross morphologic malformations, including diverticula, rotational malformations, stenoses, atresias, duplications, aganglionic segments, imperforate anus, and others (13 ,14 ,34 ,35 ,36 ,37). Perturbations of developmental pathways used for organ homeostasis may result in metaplasias, polyposis syndromes, and malignant transformation (10 ,38 ,39 ,40 ,41 ,42).

Anatomic Considerations

The colon is the terminal 1.0 to 1.5 m segment of the

gastrointestinal tract, following the periphery of the peritoneal cavity, with the rectum extending into the pelvis and concluding at the anal canal (Figure 25.1) (43 ,44). There is considerable anatomic variation in the position of the colon segments, mesenteric coverings, and attachments to the posterior abdominal wall (44 ,45). Nonetheless, consistency of vascular supply, venous drainage, and innervation distinguishing the two primary (right and left) colon segments along the embryologic AP (midgut/hindgut) axis is maintained. The right colon receives its blood supply from the superior mesenteric artery, parasympathetic nervous innervation from the vagus nerve, and sympathetic innervation from the superior mesenteric ganglia. The left colon receives its blood supply from the inferior mesenteric artery, parasympathetic innervation from sacral nerves S2, S3, and S4 through the nervi erigentes; and sympathetic innervation from the inferior mesenteric ganglia. Venous drainage is predominantly portal. The rectum receives blood from the middle and inferior rectal arteries, parasympathetic innervation from the nervi erigentes, and sympathetic innervation through the hypogastric plexus through lumbar spinal segments L1, L2, and L3 (19 ,43 ,44 ,45).

Unique external features of the colon include the teniae coli and haustra, visible through the investing serosa and subserosal tissue. The muscular layers of the large intestine are composed of both longitudinally and circularly arranged fibers. The longitudinal fibers are present circumferentially through the length of the colon but are primarily concentrated into three flat bands called the teniae coli (43 ,44 ,45). Convexities of the circular muscular layer, the haustra, are transient and probably the result of structural and functional properties of the colon.

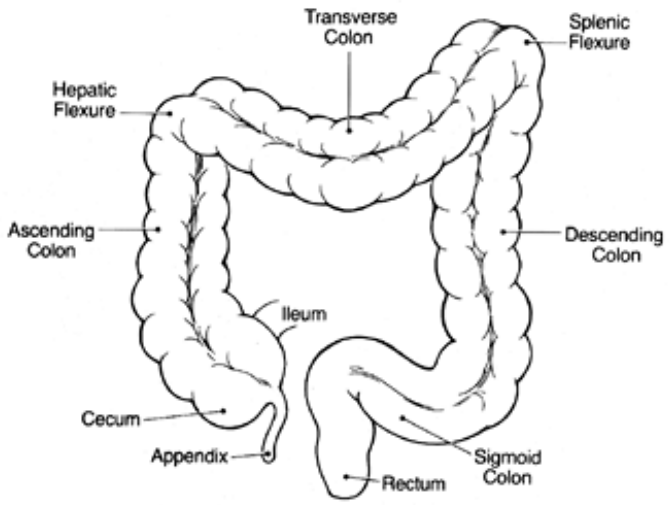

Figure 25.1 Major regions of the colon.

From the luminal perspective, various landmarks are recognized by the endoscopist. The cecum is readily identified by the ileocecal valve, appendiceal orifice, and blind-ended, saclike appearance. The subjacent portal vasculature imparts a blue hue to the mucosa at the hepatic flexure. Orientation of the teniae coli within the transverse colon results in a T-shaped lumen, ending in a slitlike orifice and acute angle of the splenic flexure. Although the descending and sigmoid colon may have thickened mucosal folds and diverticular orifices, calibration marks on the colonoscope are more reliable means of approximating the location within this region.

Function

The basic function of the large bowel is conservation of salt and water and facilitation of orderly disposal of waste materials (30). Considerable advancements have been made recently in characterizing the vast and interrelated colon functions; these further support the concept of two primary, unique colon segments, the right and left colon (15 ,19 ,46). In addition to their distinct embryologic derivation, the right and left colon

display segment-specific arrays of physiologic functions, patterns of motility, commensal bacterial populations, and metabolic intermediate and end products; as well as local and systemic immune functions (15 ,21 ,23 ,24 ,26 ,29 ,30 ,47 ,48 ,49 ,50 ,51). These varied functions are reflected in differing patterns of gene, lectin and surface marker expression, varying disease distributions, and rates of (and sequences involved in) neoplastic transformation (23 ,24 ,28 ,29 ,46). Subtle regional variations of the colonic mucosa, reflecting the segmental nature of the right and left colon, have been well recognized by gastrointestinal pathologists (15 ,20 ,22) and are described in the following sections.

The most well-recognized function of the colon is absorption of water, desiccation, and transient storage of the feces. The cecum receives 1.3 to 1.8 liters of electrolyte-rich ileal effluent daily and is a high-capacity absorptive surface, effectively absorbing 80% of the chylous water (and sodium ions, Na^+) during the prolonged mucosal exposure created by the retrograde peristalsis unique to the cecum (21 ,26 ,27 ,30). Bulk absorption (of water and sodium) occurs via electroneutral sodium chloride (NaCl) transport at the surface and in the superficial portions of the crypts (21 ,30 ,52). Within the left colon, as fecal contents are propagated distally, low-capacity electrogenic absorption via luminal sodium channels, regulated by aldosterone and angiotensin, serve in further absorption of water, as well as preservation of sodium (21 ,30 ,53 ,54), particularly during periods of salt deprivation and/or mucosal injury. An additional mechanism for water absorption unique to the left colon, involving formation of

a hyperosmolar (Na^+) compartment between the colonocytes and pericrypt myofibroblasts, has been observed and may be vital in extracting water from the osmotically dense feces, allowing final compaction and storage with a stool output of 200 to 500 g daily (27 ,55 ,56).

The colon participates in several diverse and integral metabolic processes through absorption, secretion, fermentation, oxidation, and other processes unique to the colonic epithelium or in concert with the colonic commensal bacteria. Rivaling London's East End or New York City in cultural diversity, there are an estimated 400 to 500 microbial species (bacteria, fungi, and a few protozoa) forming complex ecosystems from the terminal ileum to the rectum (49 ,58 ,59 ,60). Bacterial cells outnumber human cells roughly 1000:1, with highest concentration in the cecum and decreasing gradient and varying composition proceeding distally. In the colon of healthy humans, commensal bacteria are required for numerous vital processes: formation of short-chain fatty acids, metabolic intermediates and vitamins; metabolism of proteins and amino acids; detoxification or biotransformation of bile acids, and natural sterols and phytoestrogens, as well as phosphate and oxalate excretion (29 ,49 ,50 ,57 ,58 ,60 ,61). Fermentation of carbohydrates to form short-chain fatty acids, particularly butyrate, serves as a major source of energy for colonocytes, and butyrate plays a crucial role in colonocyte growth and differentiation (51 ,57 ,60 ,62 ,63). Nearly equal to the activity observed in the liver, colonocytes have the capacity to mediate biotransformation of bile salts, drugs, and xenobiotics (49 ,50). Many of these processes are segment-specific to either the right or the left colon.

Colonic commensal bacteria are integral to the health and function not only of the large intestine, but to the host at large through activity in local and systemic immune function and regulation. Locally, the colonic epithelium and commensal flora serve as important barriers to infection via tight junctions and secretion of antimicrobial substances, as well as competition for nutrient substrates (64 ,65 ,66 ,67 ,68).

The intestinal mucosa (terminal ileum through rectum) is the largest immune organ of the body (49 ,58 ,59 ,68 ,69). Lamina propria and lymphoid aggregate plasma cells represent 80% of the

antibody-producing cells within the entire body and produce more antibodies than any other part of the body (49 ,58 ,59 ,69). The process of antigen sampling across specialized regions of the colon results in â€œgut primingâ€• and routinely confers protection from subsequent infection locally and in other mucosal tissues (systemic immunization) (70 ,71 ,72 ,73 ,74 ,75 ,76 ,77). At baseline, the gut immune system is highly activated in response to normal floraâ€”so called physiologic inflammationâ€”in which the intestinal microflora and the intestinal immunologic mechanisms influence each other locally and systemically, forming an interdependent mutualistic ecosystem, the balance of which is required for maintenance of health and prevention of disease (71 ,73 ,74 ,78 ,79).

Light Microscopy

Although regional histologic differences exist within the right and left colon, the overall microscopic structure is similar throughout its length. The colon contains four histologically distinct compartments: (a) mucosa, (b) submucosa, (c) muscularis externa (or muscularis propria), and (d) serosa. The enteric nervous system spans all four compartments with cell bodies (ganglia and plexi) in both the submucosa and muscularis propria extending processes throughout the lamina propria, submucosa, and muscular layers, while receiving and transmitting information through synapses with the central nervous system via parasympathetic and sympathetic autonomic nervous systems.

Mucosa

The luminal colonic mucosa is the most metabolically and immunologically active compartment of the colon, as reflected in its organization and relative complexity. The luminal surface is covered by glycocalyx (glycans, enzymes, lectins, and mucin), facilitating formation of the commensal microbial ecosystem and

serving as an integral barrier function (80 ,81 ,82). Beneath the glycocalyx is polarized columnar epithelium lining millions of regularly spaced crypts that span the depth of the lamina propria. The crypts are aligned perpendicular to and extend to the muscularis mucosae, imparting the well-known â€œrack of test tubesâ€• appearance (Figure 25.2). Some variation in space between crypts is expected in biopsies of normal individuals; however, irregularly oriented or bifurcated crypts are considered

abnormal (see Regional Variation in Histologic Features , below). Variation in the usual pattern of the mucosa is seen at innominate grooves (regularly occurring folds in the mucosa), adjacent to lymphoid follicles, with lymphoglandular complexes and with the normal mucosal folds and ridges created by contraction of the muscularis mucosae (Figures 25.3 ,25.4 ,25.5). Each of these variations must be distinguished from the histologic changes of chronic mucosal injury (inflammatory bowel disease, or IBD) (Table 25.1).

Figure 25.2 Normal colonic mucosa. The histologic section of this endoscopic mucosal biopsy specimen is oriented so the simple columnar surface epithelium facing the lumen is at the top of the figure and the cut surface of the specimen is at the bottom. The

mucosal crypts are lined up in parallel, and their mouths are open to the lumen. The lamina propria consists of the stromal elements investing the crypts and extending from the surface epithelium to the smooth muscle cells of the muscularis mucosae at the bottom.

Figure 25.3 Innominate grooves of colonic mucosa. Multiple crypts open in a â€œmirror imageâ€• across a common crypt lumen at the groove, with the common crypt lumen opening to the colonic lumen. This normal finding is not a true branching of the crypts and should not be misinterpreted as architectural distortion indicative of chronic mucosal injury (i.e., inflammatory bowel disease). The innominate groove common lumen is generally within the superficial one-third of the mucosa.

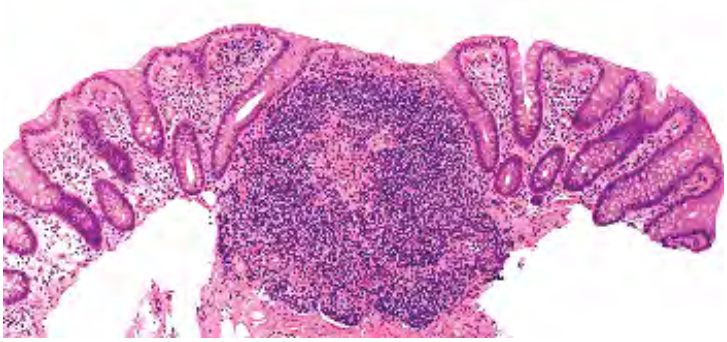

Figure 25.4 Colonic lymphoid aggregate. This lymphoid aggregate splays the adjacent crypts, which appear in a diagonal or near horizontal axis (rather than vertical), and mimics basal lymphoplasmacytosis at the crypt/lymphoid aggregate margin, resembling minor architectural disarray. Goblet cells are absent in the crypt epithelium adjacent to the follicle, while retained on the opposite side of the crypt. These normal features of colonic lymphoid aggregates should not be misinterpreted as architectural distortion indicative of chronic mucosal injury (i.e., inflammatory bowel disease) (see Table 25.2). These aggregates may contain well-formed germinal centers and appear as small polyps endoscopically.

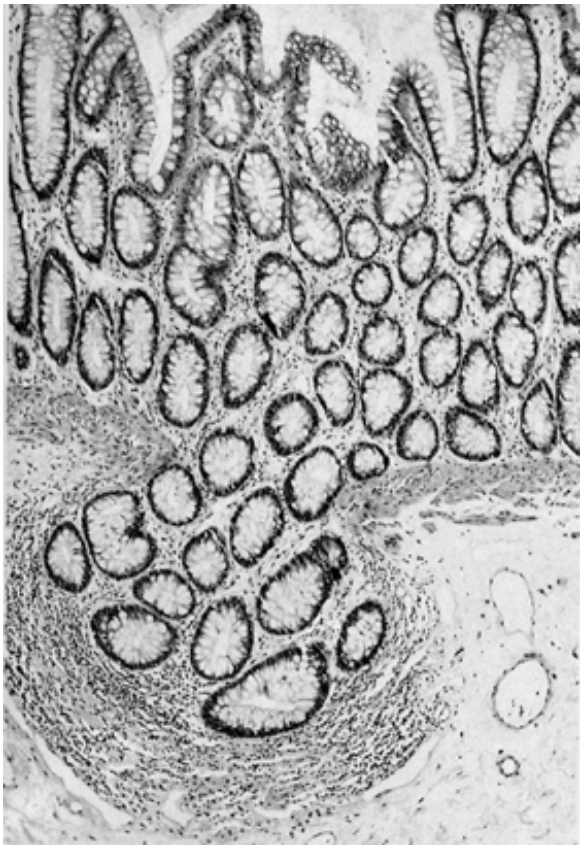

Figure 25.5 Lymphoglandular complex. In this tangential section, crypt epithelium is present within a lymphoid follicle that extends from the mucosa through the muscularis mucosae into the

submucosa.

Advances in immunohistochemistry and development of new antibodies has allowed further classification of cell types, with utility in assessing both normal and pathologic histologic patterns and providing useful adjuncts to standard histochemical stains (Table 25.2) (52 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123).

Regional Variation in Histologic Features

Although the overall mucosal pattern as described above is maintained, the right and left colon display subtle histologic differences in the ratio of surface epithelial colonocytes to goblet cells, thickness of mucus layer, normal presence of Paneth's cells, crypt length, quantity of surface intraepithelial lymphocytes, lamina propria mononuclear cell distribution, and density, as well as lymphoid aggregate density (Figure 25.6). These subtle, but significant, differences make it essential to dissuade our clinical colleagues from the practice of utilizing pooled biopsies simply labeled *colon* . We encourage gastroenterologists and surgeons to uniformly adopt the practice of separately submitting and appropriately labeling biopsy material from the right and left colon, whether for evaluation of diarrhea or classification of polyps, because the range of normal histologic appearance differs significantly (15 ,20 ,22) and neoplastic sequence and progression varies within the right and left colon (19 ,28 ,99).

Mucosa with regular eosinophilic subnuclear material
Collagenous colitis
Accurate Interpretation:

Normal colon, tangentially sectioned.
Assess for other features of microscopic colitis.[1]
Tangential sectioning of the surface epithelium results in the cytoplasm of adjacent enterocytes appearing below the basally aligned nuclei of â€œin planeâ€• enterocytes.
Levels or a trichrome stain.
Normal colon â€”histologic features seen in association with adjacent lymphoid aggregates or follicles:
Focally increased surface intraepithelial lymphocytes with otherwise normal architecture.
Lymphocytic colitis
Accurate Interpretation:
Normal colon
Assess for other features of the microscopic colitides.[1]
Level through the biopsy material to locate the adjacent lymphoid aggregate or lymphoid follicle.
Focal â€œarchitectural distortionâ€• in association with numerous lamina propria mononuclear cells. Other biopsy fragments appear normal.
Nonspecific colitis
IBD: ulcerative colitis (UC), indeterminate colitis (IDC), Crohn's disease
Accurate Interpretation:
Normal colon
Assess for other features of chronic mucosal injury.[2]
Level through the biopsy material to locate the adjacent lymphoid aggregate or lymphoid follicle.
Normal colon â€“ histologic features mimicking chronic colitis (IBD).
Biopsy contains horizontal and unusually oriented crypts.
IBD (either UC or IDC).
Accurate Interpretation:
Normal colon
Biopsy material evulsed without the muscularis mucosae

frequently contains unusually oriented crypts.
Assess crypt morphology only in areas in which the muscularis mucosae is present, â€œtetheringâ€• the crypts.
Examine other tissue fragments; levels when necessary.
Assess for other features of chronic mucosal injury.[2]
Right (or ascending) colon biopsy with numerous lamina propria mononuclear cells
Nonspecific colitis
IBD (either UC or IDC)
Accurate Interpretation:
Normal proximal (right) colon
Ensure site of biopsy
Determine extent of mononuclear expansion, if any. The right colon contains significantly more lamina propria inflammatory cells than the left colon.
Assess for other features of chronic mucosal injury.[2]
Deeply eosinophilic granular cells at the base of crypts in the left colon (Paneth cells?) indicating chronic mucosal injury
Nonspecific colitis
UC, IDC, or Crohn's
Accurate Interpretation:
Normal colon
Assess for other features of chronic mucosal injury.[2]
Endocrine cells have apical (luminal) nuclei and fine basal granules and are normal throughout the colon.
Paneth cells have basal nuclei; coarse luminal granules are normal in the right colon and pathologic in the left.
Bifurcated crypts in sigmoid colon and/or rectum, without other findings
Inactive IBD
Accurate Interpretation:
Normal colon or rectum
One to two bifurcated crypts within the sigmoid colon or rectum is acceptable.

Assess for other features of chronic mucosal injury.[2]
Normal colon â€“ histologic features commonly encountered resulting from bowel preparation effects:
Widely spaced crypts, without other findings
Edema
Nonspecific colitis
Accurate Interpretation:
Normal colon
Water content/edema is not a reproducible finding.
Review clinical history for type of bowel preparation, sodium phosphate enemas frequently cause edema.
Ensure biopsy fragment contains muscularis mucosa.
If other features suggest (i.e., lamina propria pallor [reduced mononuclear cells] and crypt distortion), consider treated IBD.
Basal and/or surface epithelial apoptosis with or without reactive appearing surface enterocytes.
Resolving acute self-limited colitis
Antibiotic associated colitis
Accurate Interpretation:
Normal colon
Review the clinical history to determine bowel preparation used (oral sodium phosphate frequently causes basal apoptosis, while sodium phosphate enemas may cause surface or basal apoptosis bowel preparation effect).
Alert clinical colleagues that sodium phosphate causes bowel preparation effect and is ill advised in the evaluation of diarrhea or GVHD patients.
(*GVHD,* graft-versus-host disease; *IBD,* inflammatory bowel disease; *IDC,* indeterminate colitis; *UC,* ulcerative colitis)
1. Histologic features of microscopic colitis: (a) increased intraepithelial lymphocytes; (b) accompanying damage to surface epithelium (reactive appearance, epithelial sloughing); (c) superficially dense mononuclear inflammatory infiltrate; and with or without (d) thickening or irregularity of the subepithelial

basement membrane collagen table (usually entraps superficial capillaries).
2. Histologic features of chronic mucosal injury (chronic colitis, also known as inflammatory bowel disease, or IBD): (a) mononuclear expansion of lamina propria, displacing crypts and resulting in (b) basal plasmacytosis; (c) crypt architectural distortion (bifurcated or irregularly oriented crypts; crypt â€œdropoutâ€•); and (d) Paneth cell (left colon only) or pyloric metaplasia.

Immunohistochemical Profile

Cell Type	Positive	Negative	Histochemical Stain

Table 25.2 Predominant Immunohistochemical and Histochemical Staining Patterns of many of the Normal Cell Types Present in the Human Colon (51 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123)

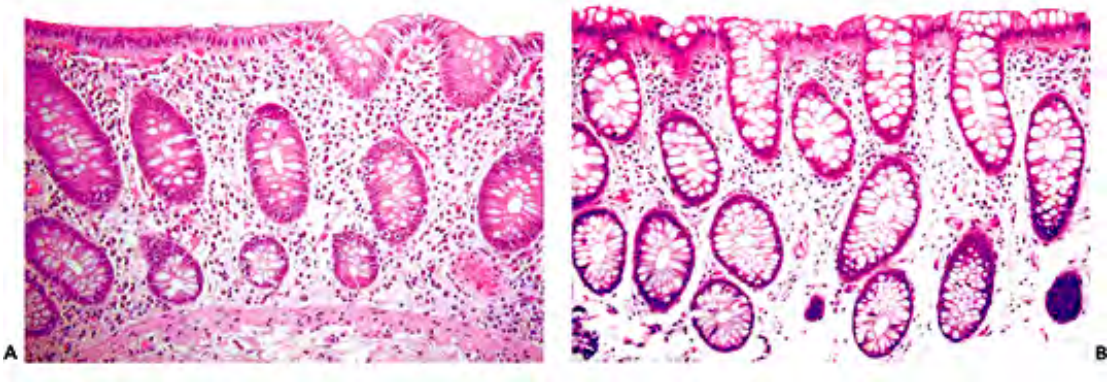

Figure 25.6 Normal mucosa from the cecum (A) and rectum (B). A. The mucosa in the cecum has more absorptive cells and fewer goblet cells compared to the rectum. The lamina propria is more cellular, with greater density of plasma cells, eosinophils, and lymphoid aggregates in the cecum as compared to the rectum. Paneth's cells are normally present, residing at the base of the crypts. B. The rectal mucosa has a higher ratio of goblet cells to absorptive cells, with a less dense lamina propria and more easily identified muciphages. Paneth's cells are not normally seen within the rectum.

Reflecting a dominant function in absorption and antigen processing, the right colon displays a higher colonocyte (absorptive enterocyte + M cell) to goblet cell (roughly 5:1) ratio as compared to the left colon (Figure 25.6). Proceeding distally, an increase in goblet cells are apparent, with a ratio of 3 or 4:1 (colonocyte:goblet cell), facilitating increased formation of gel-type mucin in the descending and sigmoid colon necessary for consolidation and transit of the increasingly formed fecal matter (15 ,26 ,27 ,124). Paneth cells are normally present at the base of crypts within the midgut-derived right colon but are indicative of metaplasia secondary to chronic mucosal injury after the distal one-third of the transverse colon (Figure 25.6).

Surface intraepithelial lymphocytes are seen in greater concentrations in the right colon than the left and can be marked

overlying lymphoid aggregates (20 ,22 ,125 ,126 ,127). Similarly, lamina propria mononuclear cell density is also greater in the right colon than the left (descending and sigmoid colon), as are organized lymphoid aggregates, possibly related to the higher concentration of commensal microorganisms and resultant antigen sampling activities (20 ,22). As goblet cell concentration and mucin increases, lamina propria macrophages, specifically scavenging mucin (muciphages) are observed with an increasing gradient proceeding distally. In the sigmoid colon and rectum, most gastrointestinal pathologists will accept a few bifurcated crypts as being within the range of normal (20), although this has not been systematically studied nor reported.

Epithelium

The colonic mucosa is composed of continuous, polarized surface and crypt epithelium forming millions of crypts (26 ,128) invested in basement membrane, surrounded by a variably cellular and vascular lamina propria (20 ,125 ,127), and with a deep boundary formed by the muscularis mucosae.

The colonic mucosal microarchitecture shows remarkable stability along both the AP and radial axes, despite its high turnover rate and variety of highly specialized cell types (129 ,130). Albeit based upon circumstantial evidence, it is generally accepted that mucosal renewal is attributed to colonic epithelial stem cells located and maintained within a mesenchymal niche, situated near the base of the intestinal crypts (13 ,31 ,32 ,128 ,129 ,131 ,132 ,133 ,134). Multipotent stem cells slowly divide, under influence of reciprocal signaling by mesenchymal and other cells, giving rise to a transient population of progenitor cells that rapidly divide and undergo a well-controlled maturation process while migrating toward the lumen (31 ,128 ,134). The granule-containing epithelial cell types appear to ignore the rule of luminal progression during maturation, with Paneth's cells (of the right

colon) migrating to the crypt base (13 ,64 ,135 ,136) and enteroendocrine cells (throughout the colon) homing to the mid- and deeper regions of the crypts (Figure 25.7) (13 ,15 ,137).

During migration, dividing transit cells commit and differentiate to one of five distinct epithelial cell types: absorptive colonocyte, mucus-secreting goblet cell, enteroendocrine cell, Paneth's cell, or M cell. At any given time, 75 to 80% of all colonocytes are associated with the crypts, and only 10 to 15% of colonocytes form the surface epithelium (intercrypt table) (126 ,130).

Absorptive Colonocytes

Absorptive colonocytes compose the majority of the surface epithelium (80 ,82 ,138). The luminal surface is characterized by rigid, tightly packed apical microvilli, (13 ,130), the tips of which contain integral membrane mucinlike glycoproteins that form a continuous, filamentous brush border glycocalyx (139) that is visible as a striate luminal border. Absorptive

colonocyte cytoplasm is lightly eosinophilic, with small apical vesicles containing mucin (of different composition than goblet cell mucin) positioned for luminal release (21 ,63 ,89 ,99). The apical poles of columnar cells fan out over goblet cells such that only the small apexes of goblet cells contact the lumen (130). Basally aligned colonocyte nuclei are oval, uniformly sized, and aligned with the long axis parallel to the long axes of the cells, with smooth nuclear contours and frequently observed nucleoli.

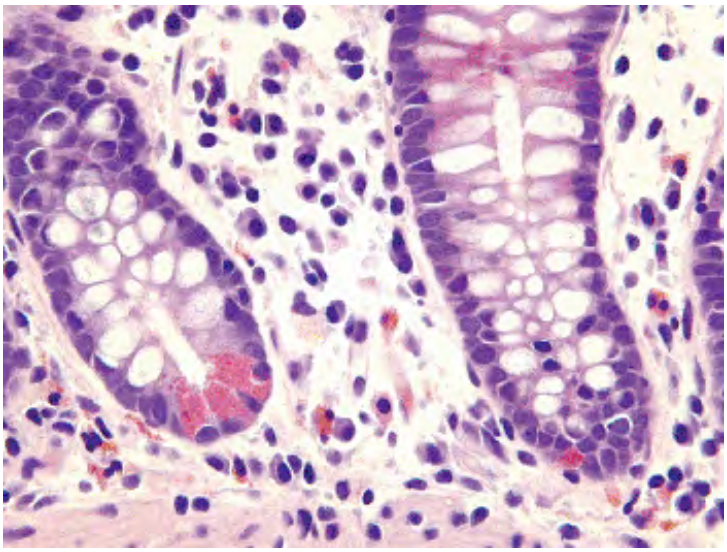

Figure 25.7 Normal right colon with Paneth's cells and an endocrine cell. Within the crypt on the left are three Paneth's cells at the base of the crypt. Note the basal nucleus and coarse, luminal-facing granules that empty into the crypt lumen. Within the crypt on the right is an endocrine cell at the base of the crypt. The endocrine cell is smaller, has a luminal nucleus and fine, basally facing granules, that empty into the pericrypt myofibroblast sheath and adjacent vasculature.

Goblet Cells

Goblet cells are dispersed throughout the surface epithelium and crypts and are distinguished by their â€œwine goblet shape,â€• which results from a large number of mucous granules in the apical pole. Mucin composition varies regionally along the length of the colon due to differential synthesis of the several known secreted and membrane-bound mucins (15). This variation is reflected in the differential histochemical staining patterns commonly observed (99 ,140 ,141). Goblet cell cytoplasm is relatively clear with standard hematoxylin and eosin (H&E) stains; however, mucin granules become distinct with mucicarmine, Alcian blue pH 2.5, and periodic acid-Schiff stains (15). Goblet cell

nuclei, when compared to adjacent absorptive colonocytes, appear hyperchromatic, dense, and irregular (130).

Endocrine Cells

Endocrine cells within the gut epithelium represent the largest population of hormone-producing cells in the body (128 ,137 ,142 ,143), comprising approximately 1% of the individual cells lining the intestinal lumen, predominantly located in the crypts and, rarely, scattered within the lamina propria (13 ,15 ,28 ,122 ,130 ,142 ,146 ,147). More than 30 peptide hormone genes are known to be expressed throughout the digestive tract, in a regionally and spatially distinct pattern (142 ,148). Enteroendocrine cells contain basally oriented, small, but distinct, deeply eosinophilic granules (137 ,142). The round, smoothly contoured nuclei of enteroendocrine cells are pushed lumenally, with opposite polarity to the other epithelial cell types (Figure 25.7).

Enteroendocrine cells may be further identified by their histochemical silver staining properties and may also be identified immunohistochemically with varying immunoreactivity to chromogranin A, synaptophysin, neuron-specific enolase, and specific antibodies to the putative peptide hormone of the cell or cell proliferation (i.e., carcinoid tumor) (Table 25.1).

Paneth's Cells

Paneth's cells disregard the rule of luminal migration and are normally encountered at the base of the crypts, within the midgut-derived right colon (13 ,65 ,114 ,128 ,135). These pyramidal-shaped cells have basally aligned oval nuclei and apical coarse, densely eosinophilic cytoplasmic granules (Figure 25.7) (13 ,65). Granule and cellular contents include: Î±-defensins, Î²-defensins, NOD2, lysozyme, phospholipase A2, secretory leukocyte inhibitor, monomer IgA, TNF-Î±, heavy metal ions, zinc binding protein, trypsin and trypsinogen, EGF, osteopontin, FAS ligand (CD95L),

CD44v6, CD15, REG protein, and numerous others (65 ,128 ,135 ,149 ,150). The diverse Paneth's cell contents reflect their significant role in innate immunity. Additionally putative roles in regulation of cell matrix interactions, apoptosis, and cellular immunity, as well as stem-cell niche maintenance, have been proposed (65 ,128 ,135 ,149 ,151).

In addition to characteristic granule staining with H&E stains, granules are conspicuously stained by periodic acid-Schiff, and phloxine-tartrazine (65); and, interestingly, Paneth's cell autofluorescence is elicited by eosin stain (Table 25.2) (114).

M Cells and Follicle-Associated Epithelium

Membranous (M) cells are distinctive epithelial cells that occur in the dome region of organized lymphoid follicles and associated with both the immunologic cells and variants of absorptive colonocytes (the follicle associated epithelium) unique to the dome region (59 ,126 ,128 ,152 ,154). Estimates of M cells in human colon vary widely, reported from â€œrareâ€• to approximately 10% of surface epithelial cells (126 ,153 ,154 ,155 ,156). Light microscopy has insufficient magnification to distinguish the unique features of M cells (reduced numbers of an irregular microvilli, apical microfolds, absence of thick filamentous brush border glycocalyx, and the presence of an unusual subdomain of the basolateral membrane that amplifies the cell surface and forms an intraepithelial pocket) visible with electron microscopy. The M cell intraepithelial pocket provides a

docking site for special populations of intraepithelial B and T lymphocytes, along with a small number of macrophages; and immediately overlies the dome region of lymphoid follicles (126 ,152 ,153 ,154). These unique morphologic features provide local, functional openings in the epithelial barrier through which M cells sample the contents of the lumen and transfer antigents to

antigen-presenting cells via a specialized method of transcytosis (67 ,71 ,152 ,155). The follicle associated crypts contains few or no goblet cells, enteroendocrine cells or Paneth cells (153 ,155). These closely apposed columnar enterocytes may mimic features of low grade cytologic dysplasia (adenoma), particularly with distortion of the crypt architecture generally produced by the adjacent lymphoid aggregate.

Intraepithelial Inflammatory Cells

Intraepithelial lymphocytes (IELs) occur in two compartments: within the paracellular spaces of the absorptive epithelium and in highest density associated with lymphoid aggregates within M-cell pockets (Figure 25.8) (125 ,127 ,157 ,158 ,159). The former are predominantly CD3+, CD8+, TCR-Î±Î²+ suppressor T cells, with between 15 and 40% TCR-Î³Î´+ T cells, while the latter are mixture of CD3+/CD45RO+ activated memory, some CD45RA+ naive T cells, and IgM-secreting B cells (86 ,127 ,160 ,161 ,162). Intraepithelial lymphocytes are the first members of the immune system to encounter dietary antigens and commensal and pathologic microorganisms, and they likely play an integral role in oral tolerance (58 ,158 ,161 ,163 ,164 ,165). The IELs home toward their intraepithelial destination, migrating along various chemokine gradients produced by adjacent epithelial, inflammatory, and mesenchymal cells (59 ,166).

Nuclear molding and indistinct cytoplasmic contours are characteristic of IELs as they extend through the basement membrane to occupy paracellular spaces (Figure 25.8). Retention of the classic lymphocyte round nucleus and thin rim of cytoplasm is more common in IELs overlying aggregates. Normal IEL density ranges from 1 to 5 lymphocytes per 100 colonocytes, except in follicle-associated epithelium, where M-cell associated IELs are abundant (162). The number of IELs decreases from the ascending colon to rectum, with highest concentration in the

lymphoid aggregate and commensal bacteria-rich cecum (125 ,126). It is imperative to ascertain the site of each colon biopsy to avoid misinterpretation of normal IEL density in right colon biopsies as lymphocytic colitis (Table 25.2). Generally, 20 or greater lymphocytes per 100 colonocytes are considered pathologic (59 ,125 ,127 ,168).

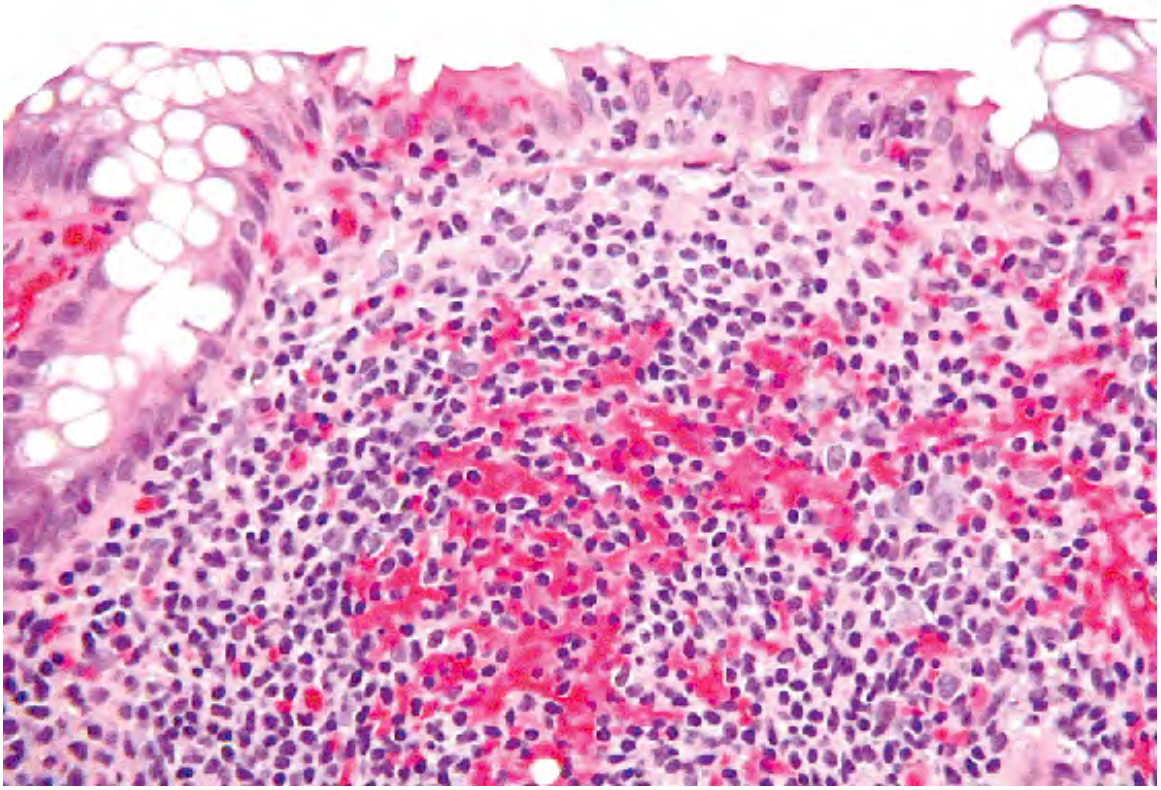

Figure 25.8 Intraepithelial lymphocytes (IELs) overlying a lymphoid follicle. Large numbers of IELs are typically seen overlying lymphoid aggregates. This should not be misinterpreted as lymphocytic colitis.

Intraepithelial eosinophils may occasionally be seen in the normal colon, although at much lower numbers than lymphocytes (168 ,169 ,170).

Stem and Dividing Transit Cells

It is estimated that between four and six stem cells are present per crypt, with some dividing transit cells apparently able to be â€œrecruitedâ€• to serve as stem cells following injury with stem cell loss (31). These proliferative and undifferentiated cells are morphologically indistinct; however, they appear to have a large nucleus with diffuse chromatin and scant cytoplasm with few small organelles (13 ,128). Mitotic activity is frequently encountered in the basal one-fifth of the crypt, and apoptosis may also be seen (129 ,131 ,134).

Apoptosis

The epithelial cells of the colon have remarkably short life spans (Table 25.3), during which they mature, migrate, and function (13 ,21 ,33 ,47 ,131 ,134 ,171). Programmed cell

death (apoptosis), is the conclusion of the normal process of colonocyte turnover, recognizable histologically by identification of apoptotic bodies and debris predominantly in the surface epithelium (Figure 25.9), and less frequently within the colonic crypts. Apoptotic bodies consist of vacuoles containing pyknotic nuclear debris, are surrounded by free space, and generally are at the basal portion of the epithelium or immediately subjacent to the basement membrane (23 ,132 ,134 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180). Lamina propria inflammatory cells similarly undergo apoptosis; however, this is frequently overlooked histologically (174 ,181 ,182). Sodium phosphate bowel preparations transiently increase the rate of apoptosis (see Bowel Preparation , below); similar effects are seen with other physical and chemical agents. Increased apoptosis (both surface and/or crypt) may also be seen in several disease states, including graft-versus-host disease, autoimmune enteropathies, systemic autoimmune disorders, and with certain medications (70 ,183 ,184

). Altered apoptosis (increased, decreased, and abnormal localization) is seen in neoplastic progression (185).

Cell Type	Life Span	Number of Replacements/Life
Absorptive Colonocyte	4â€“8 days	3285â€“6570
Goblet Cell	3â€“4 days	6570â€“8760
Enteroendocrine Cell	10â€“15 days	1750â€“2630
Paneth Cell	20 days	1300
M Cell	Unknown	Unknown
Stem Cell Lineage/Niche	8.2 years	9â€“10

Table 25.3 The Life Span of the Various Colon Epithelial Cells and Number of Replacements Per Average Human Life Span Vary Between Cell Types. Despite the High Rate of Turnover, Preservation of Genetic Information is the Rule Rather than the Exception

Basement Membrane

The basement membrane complex anchors the various epithelial cells to the underlying myofibroblast network and lamina propria.

This fenestrated extracellular support matrix is produced collaboratively by epithelial and mesenchymal cells (98 ,126 ,129 ,186). Basement membrane composition varies, regulated by several factors produced by the epithelium, myofibroblasts, and lamina propria cells (126 ,129 ,186 ,187). In addition to allowing intraepithelial lymphocytes to traverse the basement membrane, the fenestrations allow epithelial, mesenchymal, and dendritic cell processes to sample and/or present antigens and have functional implications in water and ion transport (21 ,32 ,129).

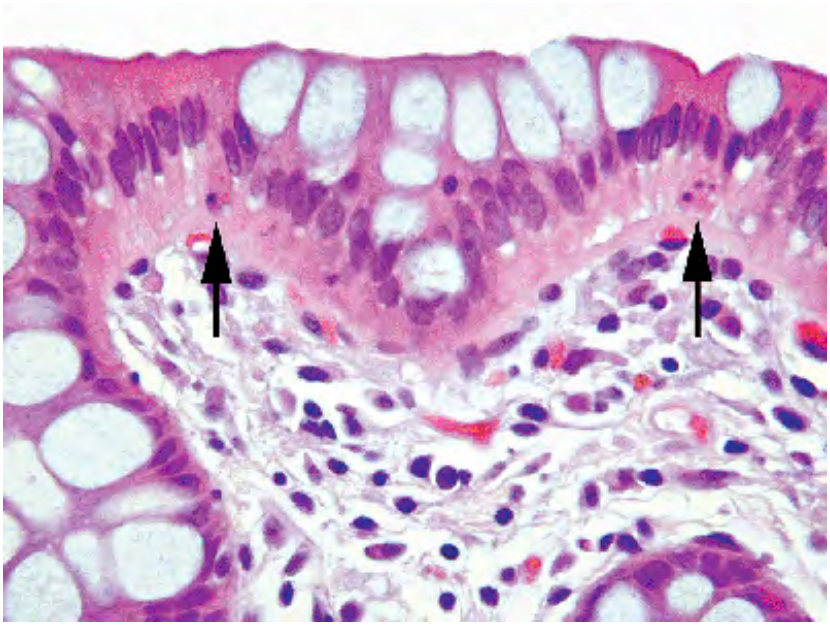

Figure 25.9 Apoptosis. Two apoptotic bodies are seen within the surface epithelium (*arrows*).

Figure 25.10 Normal basement membrane. The normal basement membrane is 3 to 5 Âµm thick and has a crisp, delicate, and regular lower border; it blends into the crypt sheath imperceptibly (trichrome stain).

In well-oriented sections, the normal basement membrane is between 3 Âµm and 5 Âµm thick, regular, and stains with connective tissue stains (Masson's trichrome, saffron, eosin von Gieson elastin) (Figure 25.10) (187 ,188). Similar to Paneth's cells, autofluorescence is elicited with eosin stain (115). Basement membrane thickness greater than 10 mm is considered pathologic, as is irregularity of the basement membrane, particularly entrapping superficial lamina propria capillaries (115 ,187).

Lamina Propria

The lamina propria invests the colonic crypts, extending from the fenestrated basement membrane complex to the muscularis mucosae. The various lamina propria inflammatory and mesenchymal cells are organized within extracellular matrix, each

performing integral immunologic, metabolic, proliferative, and motility functions.

Lamina Propria Inflammatory Cells

As dictated by the wide array of immunologic functions performed by the colonic mucosa, the lamina propria houses localized antigen-sampling and processing factories, with over 30,000 discrete lymphoid aggregates, concentrated within the blind-ended cecum and distributed along the length of the colon (189 ,190). In addition to lymphoid aggregates, the normal colon contains mature B lymphocytes, plasma cells, T lymphocytes [helper, suppressor, and lymphokine-activated killer (LAK) cells, but unlikely natural killer (NK) cells], eosinophils, mast cells, and macrophages, in combination filling between 30 and 50% of the â€œfreeâ€• lamina propria space (22). Normally, there is a decreasing inflammatory cell gradient from lumen to

muscularis mucosae, in which the lamina propria loose connective tissue is obscured within the superficial aspect of the lamina propria but becomes visible approaching the muscularis mucosa (191). The predominant cell type of the lamina propria is the IgA-secreting plasma cell, with much smaller proportions of IgM-, IgE-, and IgG-secreting plasma cells also present (181 ,192). Secreted IgA and IgM are transported luminally, providing humoral immune protection (138 ,181 ,192). The distinct â€œcartwheelâ€• nucleus, perinuclear Golgi zone, and amphophilic cytoplasm characteristic of plasma cells observed in other tissues are retained in colonic plasma cells. Of the remaining lamina propria lymphocytes, more than 90% of the lymphocytes were CD3+ T cells, with fewer than 50% also CD8+ (126 ,127 ,159). There are also CD 20-positive B lymphocytes present within and adjacent to lymphoid follicles (71 ,76 ,78 ,138 ,193).

Myeloid cells that normally reside in the lamina propria include

eosinophils and mast cells. In the normal colon, the number of eosinophils is highly variable, dependent upon both the region of colon sampled (168 ,169 ,170 ,171 ,172 ,194) and the geographic residence of the patient (195). A range of normal eosinophil counts in the lamina propria has been reported as 0 to 8 per high-power field (hpf); however, the eosinophil concentration should be interpreted on the basis of the â€œcompany it keepsâ€• (i.e., other features of colitis versus otherwise normal) (Rodger C. Haggitt, MD, personal communication). Higher mean eosinophil concentration is seen in biopsies of patients from the southern United States, compared to the northern United States, with a rather extreme degree of variability (195). Although eosinophils are increased in parasitic and allergic disease, collagenous colitis, ulcerative colitis, Crohn's disease, and other pathologic conditions, consideration of the geographic residence and site of biopsy are integral prior to considering increased eosinophils (as an isolated histologic finding) to be pathologic (170 ,195). Mast cells, or tissue based basophils, are less numerous than eosinophils, and their density appears to be increased in the ileocecal region compared with other sites of the colon (196 ,197). Mast cells are difficult to distinguish with routine H&E, but stain well with Giemsa, toluidine blue, tryptase, and CD117 (c-kit) (Figure 25.11 , Table 25.2) (194). Neutrophils are not normally seen in any significant number within the lamina propria, although they may be seen in areas of hemorrhage and within blood vessels.

Macrophages are commonly seen scattered throughout the lamina propria and are occasionally concentrated at the basal aspect of the crypts (70 ,198 ,199 ,200 ,201) (Figure 25.12). While macrophages are generally difficult to see with H&E stains, visualization may be enhanced by specific histochemical stains that detect the variety of materials they scavenge and store: apoptotic debris, microbes, lipofuscin, cholesterol esters, gangliosides, mucolipids, glycogen, mucopolysaccharides, and others (Figure 25.12 , Table 25.2) (199 ,200). Muciphages are the most

commonly recognized macrophages, ingesting mucin exuded from adjacent goblet cells (and to a lesser extent enterocytes) that crosses the basement membrane. These normal constituents of the lamina propria have increased concentration within the left colon, in keeping with the increased number of goblet cells present in this location. Distention of the lamina propria with the appearance of replacement of other lamina propria inflammatory cells is rarely normal and may indicate bacterial or fungal ingestion/infection (e.g., *Tropheryma whippelii* , *Mycobacterium avium-intracellulare* complex, *Histoplasma capsulatum,* and others) or various metabolic storage disorders, requiring use of histochemical, PCR, or electron microscopic methodologies as well as further laboratory evaluation (97 ,105 ,202 ,203 ,204 ,205).

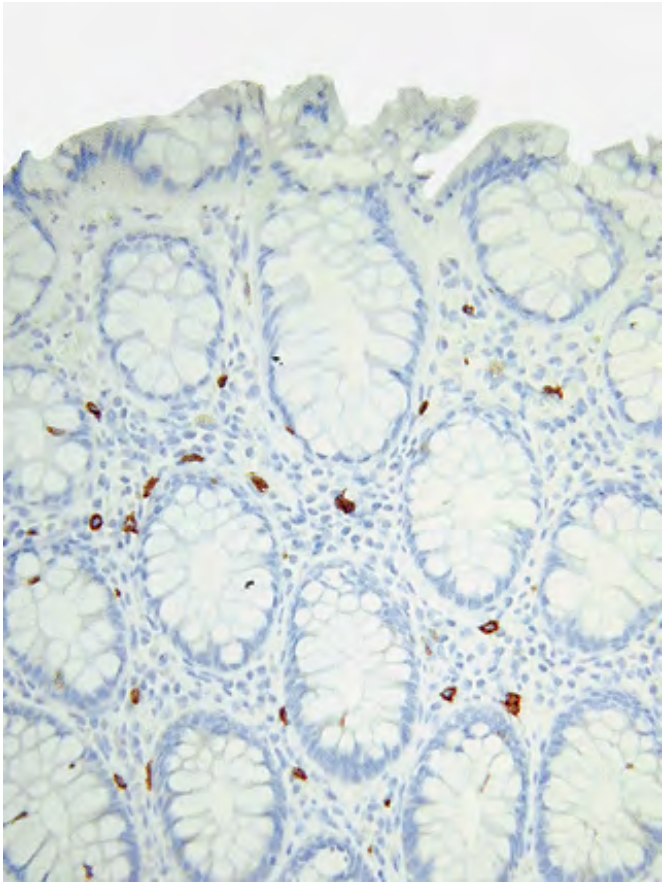

Figure 25.11 Mucosal mast cells. Although difficult to discern on H&E-stained sections, mucosal mast cells are easily identified with

CD117. Mucosal mast cells serve well as an internal control when evaluating CD117 stains of gastrointestinal tract mesenchymal tumors. (Anti-CD117 stain.)

Plasmacytoid dendritic cells are scattered throughout the lamina propria, while stellate dendritic cells are concentrated in the subepithelial dome space associated with lymphoid follicles (78 ,138 ,206 ,207). These are histologically indistinct and frequently require immunohistochemistry for definitive identification (Table 25.2) (70 ,71 ,76 ,138). The former have recently been implicated in allergic and autoimmune disorders (88), while the latter are integral in antigen presentation (70 ,73 ,208).

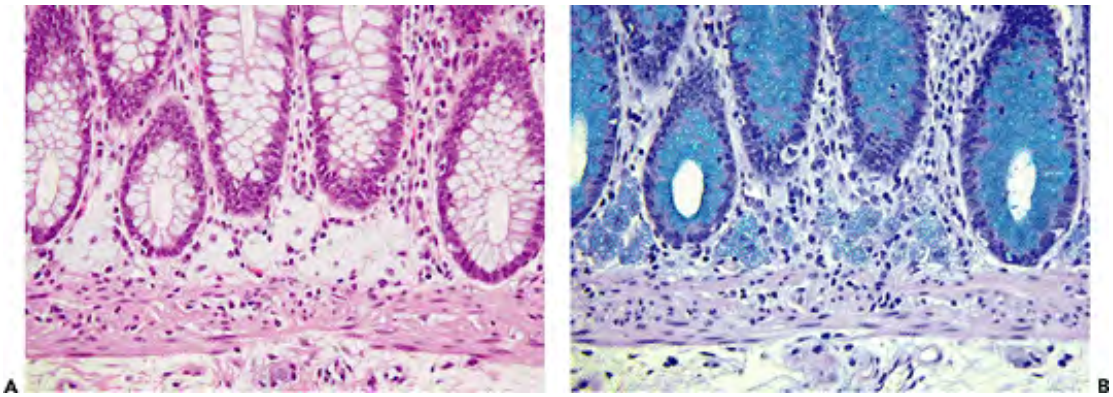

Figure 25.12 Lamina propria muciphages. A. These pale macrophages at the base of the mucosa are stuffed with mucins. This finding is not infrequent and does not generally correlate with disease. B. The same area stained with Alcian blue pH2.5; the muciphages show strong cytoplasmic staining. Similar findings are seen with PAS with diastase digestion. Of note, bacteria-laden macrophages in Whipple's disease are generally negative when stained with Alcian blue pH 2.5 but densely stain with PAS with diastase.

Myofibroblasts (Pericrypt Myofibroblast Sheath and Lamina Propria Myofibroblasts)

The lamina propria contains two distinct populations of myofibroblasts: the pericrypt myofibroblast sheath and the subepithelial myofibroblast (SEM) syncytia. Interacting closely with the epithelium, lamina propria inflammatory cells, and the muscularis mucosa, myofibroblasts function in absorption, ion and mucin secretion, immune regulation, and differentiation (maintenance of stem cell niche) (521,124 ,209). The rim of fusiform cells organized in close apposition to each colonic crypt was originally designated the pericryptal fibroblastic sheath (Figure 25.13) (186 ,209). This specialized population of mesenchymal cells is now known to be a syncytium (both anatomically and functionally) of cells that surrounds the crypts and extends into the lamina propria, forming a reticular network within the extracellular matrix, attaching to one another with both gap and adherens junctions (83 ,92 ,186 ,209 ,210), and displaying distinct immunophenotypes (Table 25.2).

In the region of the crypts, the myofibroblasts are oval and scaphoid in appearance and appear to overlap like shingles on a roof. The SEMs exist in two distinct morphological states: (a) the activated myofibroblast and (b) the stellate transformed myofibroblast, similar in appearance to macrophage dendritic cells (186 ,209). Myofibroblasts often are surrounded by an incomplete basal lamina and embedded in a subepithelial sheet of reticular fibers that also contains fenestrae or foramina through which lymphocytes and macrophages traverse. Gap junctions couple some myofibroblasts to the tissue smooth muscle, and the cells are commonly in close apposition to varicosities of nerve fibers; however, it is has not been determined whether the interstitial cell of Cajal network is physically connected to the SEM network (186 ,209 ,211).

Vasculature and Lymphatics

Vasculature is limited to capillaries and high endothelial venules scattered throughout lamina propria and to

lymphatic channels immediately superficial to the muscularis mucosa (212 ,213). Capillaries are composed of a circumferential endothelial lining and may contain red blood cells as well as inflammatory cells. Irregularly shaped, distorted, and engorged capillaries frequently indicate prolapse of the mucosa. In addition to provision of oxygen and nutrients to mucosal cells, vascular adhesion molecules participate in appropriate â€œhomingâ€• of circulating lymphocytes to their appropriate colonic microenvironment. Lymphatic tributaries rarely initiate within the lamina propria; however, when present, they appear to have thinner walls and cross the muscularis mucosae to join the readily observed submucosal lymphatics (213 ,214 ,215). Definitive differentiation between capillaries and lymphatics requires immunohistochemical analysis (Table 25.2) (84 ,94 ,100 ,216).

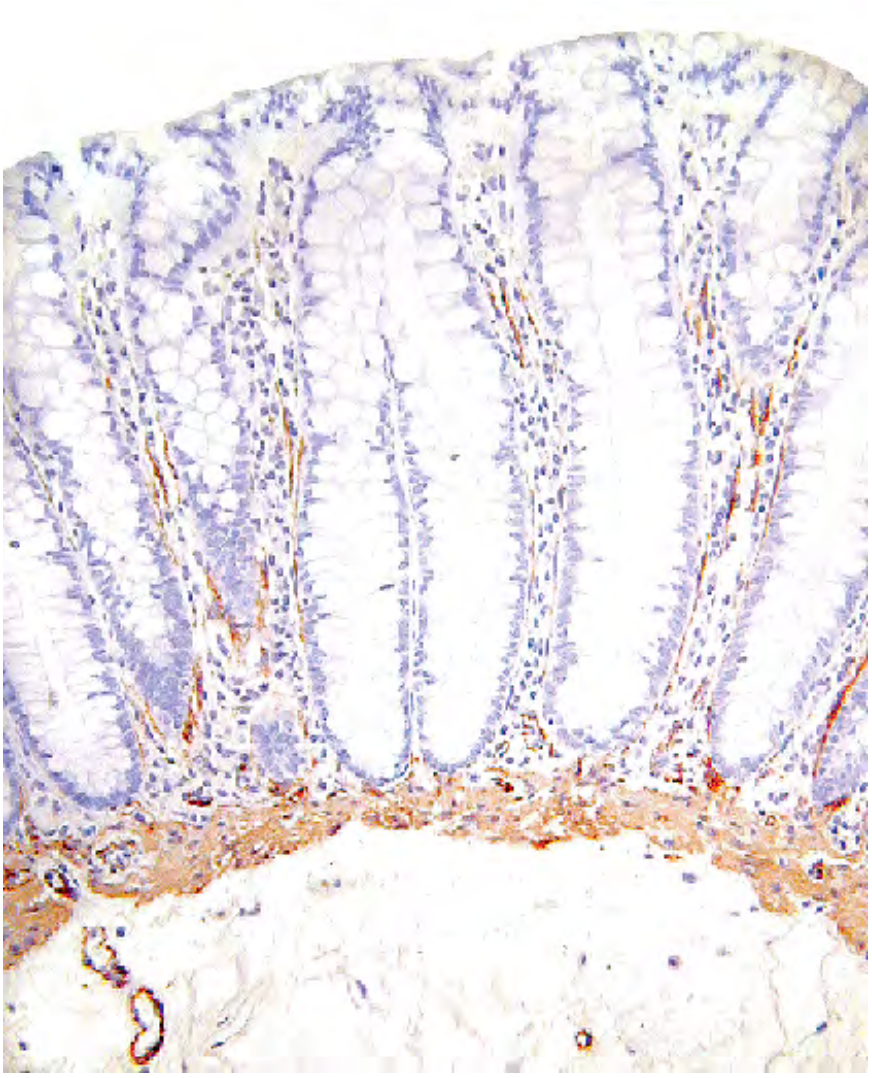

Figure 25.13 Lamina propria myofibroblasts, antimuscle-specific actin (MSA) stain. This stain for muscle-specific actin highlights the pericryptal myofibroblast sheath, muscularis mucosae, and submucosal blood vessels.

Muscularis Mucosae

Forming the deep limiting boundary of the lamina propria is a thin layer of smooth muscle, the muscularis mucosae. This muscle layer is physically tethered to the mucosa, with occasional smooth muscle cells extending into the lamina propria or coalescing with the pericryptal myofibroblast sheath. The muscularis mucosae

receives innervation via the submucosal plexus (92 ,217 ,218). Because the colonic glands are tethered to the muscularis mucosa, this structure is valuable in evaluating crypt architecture in endoscopic biopsies. Biopsies that do not contain muscularis mucosae may resemble architectural distortion, with glands adopting horizontal or curved configurations. Careful examination of other biopsy fragments with muscularis mucosae, as well as assessment for other features of mucosal injury (Table 25.1), may allow an accurate diagnosis. The muscularis mucosa is normally traversed by lymphoglandular complexes (Figure 25.5), vascular channels, and neural twiglets and participates in absorptive, secretory, proliferative, and possibly motility functions. Isolated thickening may occur with prolapse of the overlying mucosa and adjacent to diverticular orifices. Clear duplication of the muscularis mucosae is generally considered a feature of chronic mucosal injury.

Submucosa

The submucosa is composed of loosely arranged bundles of smooth muscle, fibroelastic tissue, and adipose, in which the local enteric nervous system, vasculature, and lymphatics are embedded. Lymphatic channels may be conspicuous and dilated immediately beneath the submucosa and do not contain cellular elements (213 ,214 ,216). Sparse inflammatory cells (relative to the dense â€œphysiologicâ€• inflammation of the mucosa) are scattered throughout, occasionally organized as submucosal lymphoid aggregates. The submucosa provides a flexible matrixâ€”allowing the mucosa to glide and move freely over the rigid muscularis mucosae during peristalsis.

Submucosal smooth muscle consists of loosely woven fascicles of individual smooth muscle cells, forming small bundles. These smooth muscle collections are closely apposed to interstitial cells of Cajal, which in turn are immediately adjacent to nerve

varicositiesâ€”forming the neuroeffector junctions that receive, transmit, and integrate central, parasympathetic, and sympathetic nervous system commands (211 ,219 ,220). The two submucosal neural plexuses are the submucosal plexus of Meissner (located immediately beneath the muscularis mucosae) and Henle's deep submucosal plexus (lying on the inner aspect of the muscularis propria). Neural plexuses are composed of neurons, glial cells, and stromal elements (221 ,222 ,223). Ganglion cells are unique in their histologic appearance with round or oval nuclei, a prominent (often eosinophilic) nucleolus, and ample basophilic cytoplasm stippled with Nissl substance (Figure 25.14). Ganglion cells characteristically cluster together and may mimic giant cells, epithelioid cells, or granulomas. Nerve axons are fibrillar and distinguishing these axons from fibroblasts or their elastofibrotic products may require the use of histochemical or immunohistochemical stains (Figure 25.14B , Table 25.2) (43 ,112 ,220 ,221 ,223 ,224).

Interstitial cells of Cajal (ICCs) are modified myofibroblasts. Histologic features evident with routine H&E stain include a fusiform cell body and large oval nucleus; silver stain or immunohistochemical evaluation will reveal two or more dendritic processes, connecting ICCs to one another, to ganglion cells, or to adjacent smooth muscle (210 ,220 ,225 ,226 ,227). These intriguing cells are thought to play an important role in the control of gut motor activity (220 ,228 ,229). The normal ICC density within the submucosa is substantially less than that seen surrounding the myenteric plexus (see below) (220 ,228 ,229 ,230). Arterioles (branches from the superior and inferior mesenteric arteries), venules, and lymphatics are present throughout the submucosa (Figure 25.15). These vessels in histologic sections are frequently distended by red blood cells and appear tortuous, with several cross sections of a single arteriole seen adjacent to one another within one field of section.

The amount of adipose within the submucosa varies substantially

between the right and left colon and among patients. The ileocecal valve and cecum submucosa may appear particularly expanded by mature adipocytes, resembling a lipoma. However, in the absence of the submucosal adipose forming a discrete, lobulated mass, this may be considered within the range of normal.

Muscularis Externa, Subserosal Zone, and Serosa

The muscularis propria or external smooth muscle layers of the colon consist of an inner circular layer and an outer

longitudinal layer (Figure 25.16) (231 ,232). Structural variations of the muscularis propria have been identified, which may reflect different motility and storage functions of various regions of the colon (225 ,226). Auerbach's plexus lies between the two muscle layers and resembles Meissner's plexus histologically. The interstitial cells of Cajal, the putative pacemaker cells of the gut that drive peristalsis, can be identified throughout the muscularis propria with immunizations for CD117 and CD34 (Figure 25.17) (111 ,233 ,234).

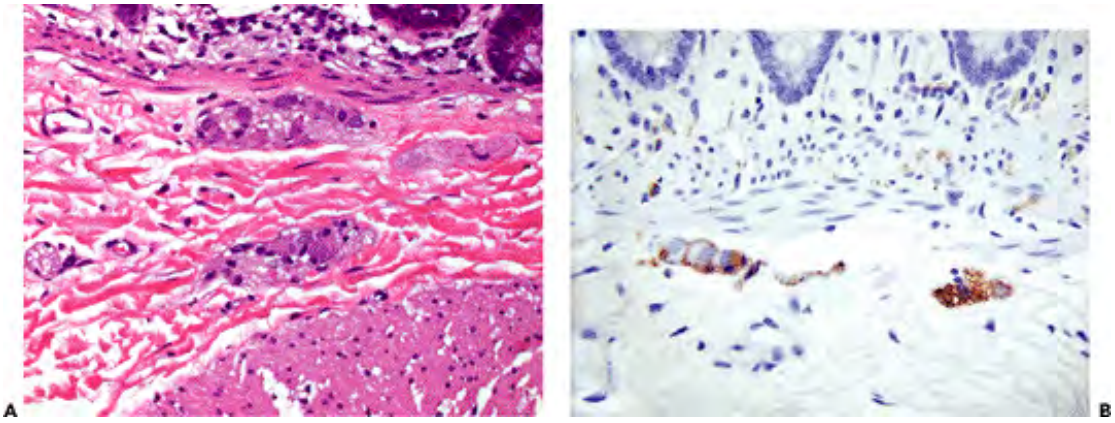

Figure 25.14 Ganglion cells of Meissner's plexus. A. Submucosal nerve twigs and clusters of ganglion cells comprising Meissner's plexus. (H&E stain, x20). B. Same area stained with S-100

(hematoxylin counter stain), highlighting the Schwann cells. The ganglion cells on the left are conspicuously negative with S-100 (also x20).

Figure 25.15 Colonic submucosal vasculature. Most of the blood vessels in this section contain erythrocytes.

Patients with motility disorders may have decreased numbers of these cells within their bowel walls (231 ,232). The muscularis is perforated by blood and lymphatic vessels and is encased in a subserosal zone of fibroadipose tissue. Strictly speaking, the serosa is limited to the mesothelial lining and immediately adjacent fibroelastic tissue.

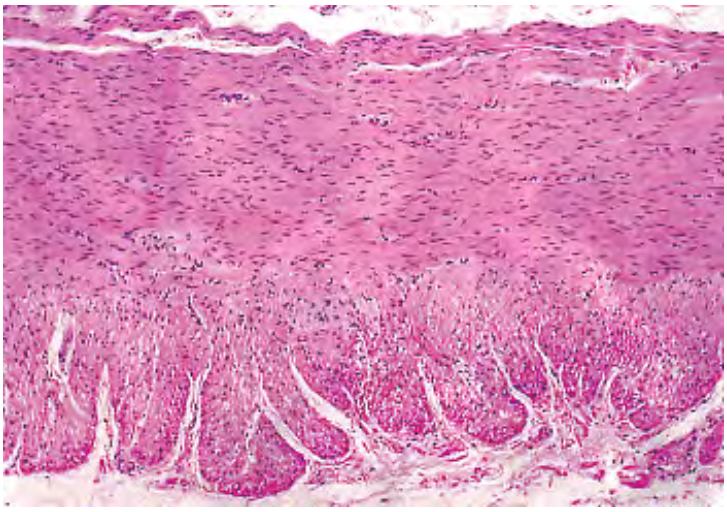

Figure 25.16 Muscularis propria and subserosal tissue. Both layers of the muscularis propria can be seen with the neural tissue of Auerbach's plexus. Below the muscle layers is the fibrovascular adipose tissue of the subserosa.

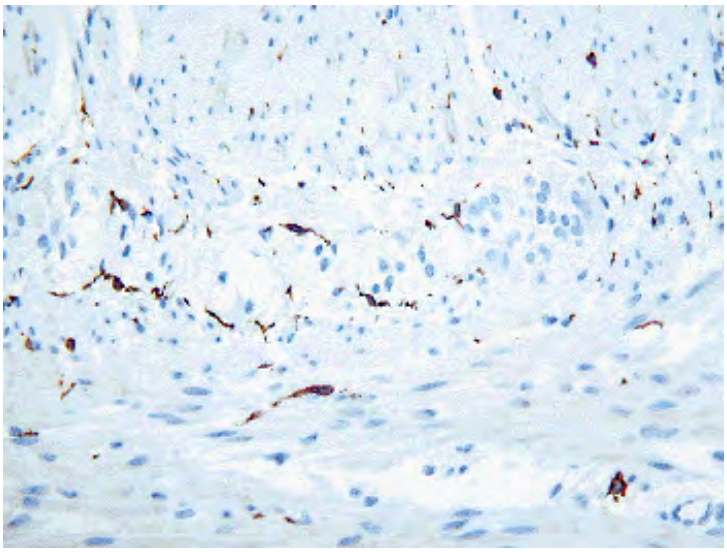

Figure 25.17 Interstitial cells of Cajal (ICC). The CD117 strongly positive, dendritic-appearing cells between the muscle layers and surrounding Auerbach's plexus are the ICCs. These cells are considered to be the pacemaker cell of the gut and perform other functions in gut motility. (Anti-CD117 stain.)

Effects of Preparation and Artifacts

Bowel Preparation Effects

The most commonly used bowel preparations for colonoscopy and sigmoidoscopy (sodium phosphate enemas, bisacodyl enemas and suppositories, dioctyl sodium sulfosuccinate, soapsuds enemas) can produce abnormalities of the mucosa that may mimic or obscure inflammatory conditions and impart an edematous or hyperemic appearance of the mucosa to the endoscopist (235 ,236 ,237). Histologic features suggesting bowel preparation include: flattening of the absorptive colonocytes to a cuboidal shape, reduction in goblet cell mucus (due to increased mucus secretion), detached surface epithelium leaving an exposed basement membrane, minimal or focal surface epithelial and crypt neutrophilic infiltrate, accentuated extravasation of red blood cells within the lamina propria, and increase in crypt or surface epithelial apoptosis (Figure 25.18). Oral sodium phosphate incites exaggeration of the previously described features of bowel preparation. Endoscopically visible aphthous erosions, erosions, and uncommonly frank ulcers have been reported. Histologically, neutrophilic cryptitis and increased basal apoptosis may be seen in addition to other common features of bowel preparation (Figure 25.19) (235 ,238 ,239). This basal apoptosis is histologically identical to low-grade graft-versus-host disease. Hence, oral sodium phosphate bowel preparations should not be used in bone marrow transplant patients. Although bowel preparation histologic changes may not interfere with rendering a polyp diagnosis, subtle inflammatory changes may be overlooked in the midst of various bowel preparation changes or alternately misdiagnosed as a pathologic condition. In the evaluation of patients for reasons other than colorectal cancer screening, bowel preparation with polyethylene glycol is suggested, as it appears to incite minimal

histologic alterations (240 ,241). Nonetheless, polyethylene glycol preparation has also been reported in randomized trials to result in superficial mucus loss, epithelial cell loss, lymphocyte and neutrophil infiltration, and rarely aphthous erosions (242).

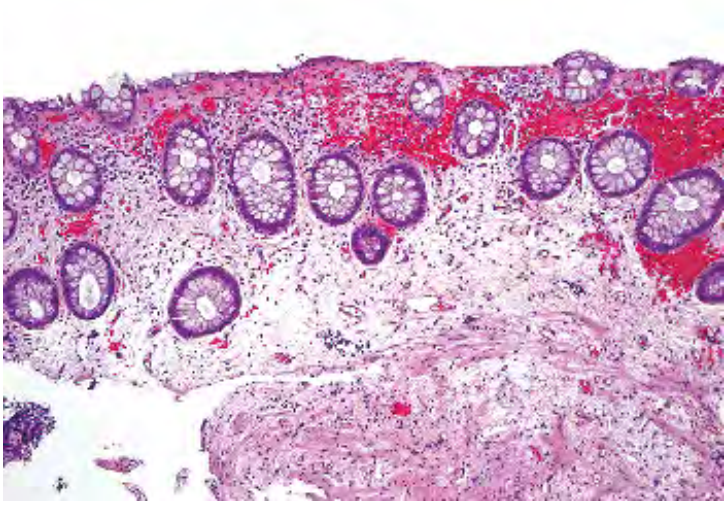

Figure 25.18 Enema effect. There is edema with extravasation and lysis of red blood cells (hemorrhage) within the lamina propria. The surface epithelium is largely denuded. Mucin depletion due to induced goblet cell secretion and increased apoptosis may also be seen.

Incorrect Tissue Orientation and Tangential Sectioning

Difficulties with proper tissue orientation are most common to endoscopically procured biopsy specimens, owing

to their small size (sometimes as small as 2 mm). In both endoscopic biopsies and surgical resections, the most accurate interpretation is possible when the tissue is sectioned perpendicular to the plane of the surface epithelium. Evaluation of crypt architecture, inflammatory cell gradient, and thickness and

regularity of the subepithelial collagen band may be hindered significantly by tangential sectioning (Table 25.1) (243). The appearance of acini (doughnuts) rather than â€œtest tubesâ€• within the lamina propria is a clear indication of tangential sectioning. Features of chronic mucosal injury may not be sampled in tangential sections that contain only the superficial most aspects of the mucosa. Cytoplasm of adjacent colonocytes in tangentially sectioned tissue may mimic a thickened (but regular) collagen band, risking a misinterpretation of collagenous colitis (Figure 25.20). Tangential sections with exaggerated samples of the basal portions of colonic crypts show cross sections of less mature colonocytes with larger nuclei, less cytoplasm, and without adjacent goblet cells, thus mimicking the features of a tubular adenoma.

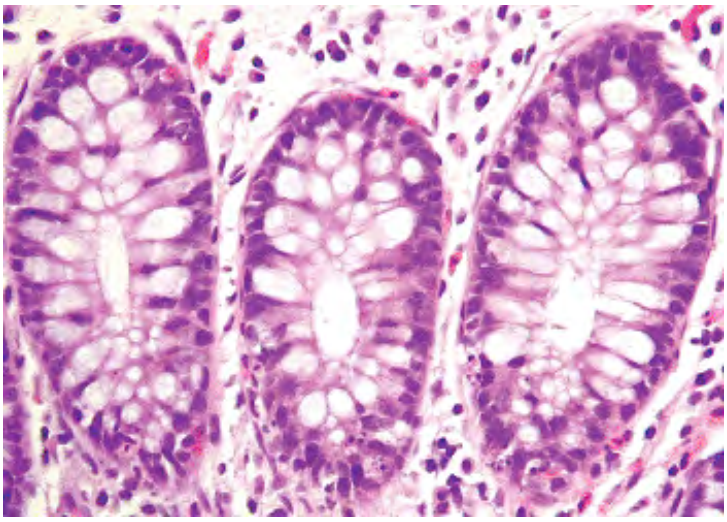

Figure 25.19 Oral sodium phosphate bowel preparation effect. Colonic crypts with apoptotic bodies and neutrophils are secondary to the effects of bowel preparation. Such changes could easily be interpreted as representing infectious colitis or graft-versus-host disease (GVHD) in the right clinical setting.

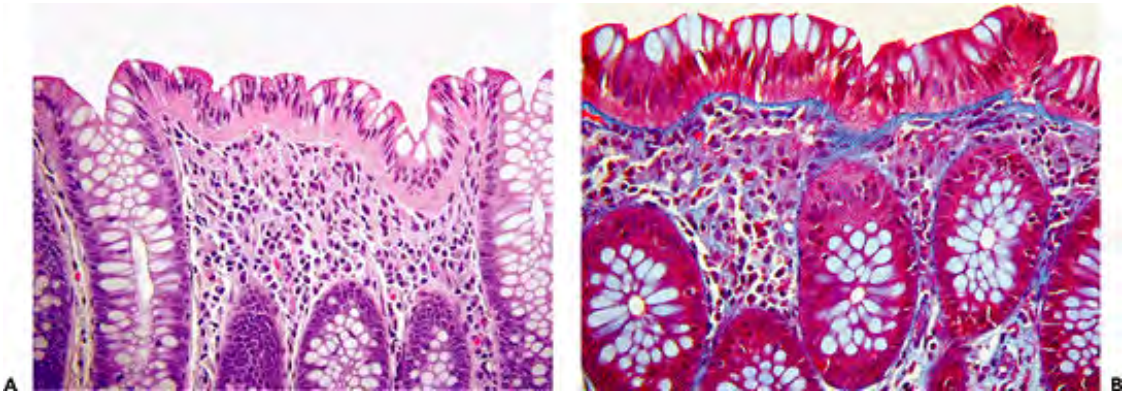

Figure 25.20 Normal colon mimicking collagenous colitis. A. This normal mucosa shows blending of the colonocyte cytoplasm with the basement membrane to give the illusion of a thickened subepithelial collagen table. Note that there is no surface damage or colitis present. B. This trichrome stained section shows focal thickening in an area where the crypt sheath joins the surface tangentially. Care must be taken when evaluating tangential sections. Again note the lack of colitis or surface damage.

Tissue Trauma

Tissue trauma occurs with avulsion of the mucosa during forceps biopsy or in improper handling in the pathology gross room. The former may produce endoscopically visible edema, petechiae, friability, tears, and hemorrhage (241 ,243), and there may be histologic features of â€œcrushâ€• artifact. Biopsy samples may contain increased cell free space in the lamina propria, resembling edema and extravasation of red blood cells primarily into the luminal portion of the lamina propria. In the absence of other features of mucosal inflammation (i.e., neutrophilic inflammation), these features should not be considered pathologic. Polyfoam pads may cause triangular artifacts in biopsy material and are not recommended (244). Despite relative fixation, crush artifact may occur with pressure applied to biopsy material with rigid forceps. Use of a plastic pipette with large bore opening (i.e., cutting the

tip off of a disposable pipette) to transfer biopsy material to the cassette avoids crush artifact. Crushing of the tissue results in crowding of glands and epithelial cells and is accompanied by stripping of the surface epithelium that then dislodges into the lumen.

Pseudolipomatosis

Pseudolipomatosis is characterized by vacuolated, unlined spaces in the lamina propria and mucosa that resemble loosely arranged adipocytes (Figure 25.21). These lesions are due to air trapping from insufflation of the colon during endoscopy (245).

Electrocautery

Endoscopic removal of polyps with electrocautery (â€œhotâ€• biopsy, or snare) frequently results in thermodessication of the tissue, compressing crypts together and altering the nuclear features. Characteristically, the crypts are closely apposed, with elongated, pyknotic and distorted nuclei (Figure 25.22). These features may be difficult or impossible to distinguish from a tubular adenoma. Prolonged electrodesiccation may result in loss of both overall architecture and nuclear detail.

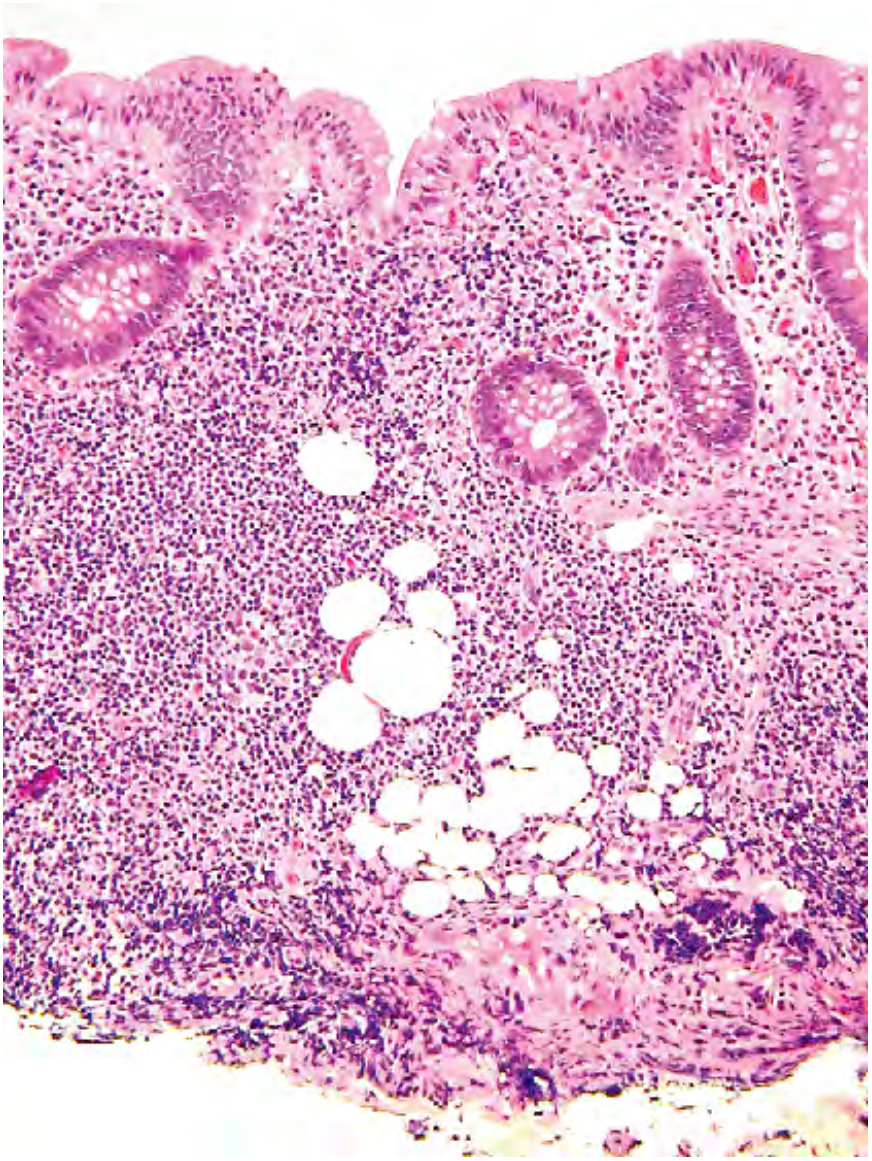

Figure 25.21 Pseudolipomatosis. The clear spaces within this lymphoid aggregate represent air bubbles due to insufflation during endoscopy. This artifact is frequently misinterpreted as adipose tissue/lipoma.

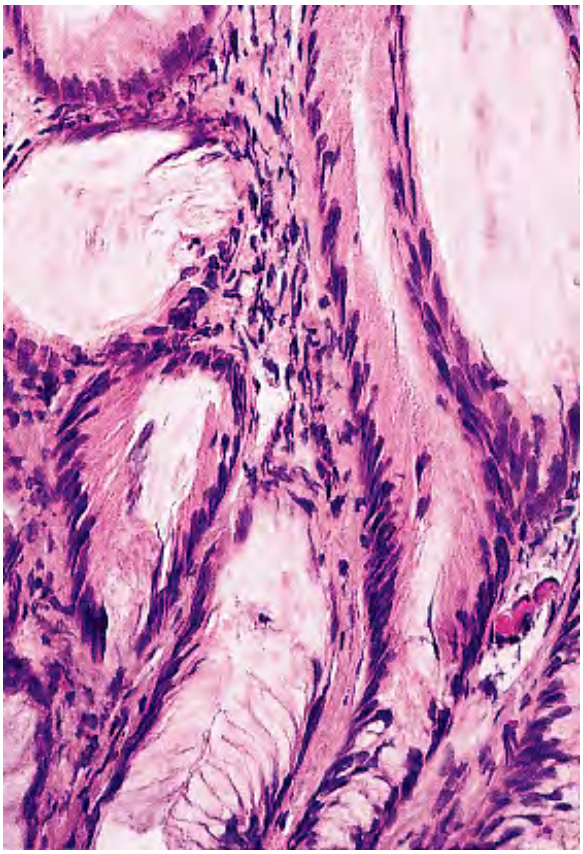

Figure 25.22 Electrodesiccation and compression artifact in the bases of adjacent crypts in normal colonic mucosa produced by an endoscopic electrocautery snare. Affected nuclei are pyknotic and elongated. Colonic crypts distorted by this artifact may be difficult or impossible to differentiate from the tubules of an adenoma.

Acknowledgments

Dr. Dahl is grateful for the continuing influence of the late Dr. Rodger C. Haggitt in the preparation of this manuscript. Dr. Charles Bevins and Richard Naftalin are thanked for their insight and dialogue.

Vermiform Appendix

Terry L. Gramlich

Robert E. Petras

Gross Anatomy/Surgical Perspective

The vermiform (wormlike) appendix is a slender tubular extension of the posteromedial aspect of the cecum originating below, and within 1 to 3 cm of, the ileocecal junction. Although the appendix has a relatively constant relationship with the cecum at the appendiceal base, the remainder of its length can be found in a variable number of positions, including retrocecal, subcecal, pelvic, and juxtaileal (1,2,3). A retrocecal position occurs most commonly, being present in nearly 70% of the population (3,4). Unusual locations, including a vermiform appendix buried within the cecal wall, have been documented (5). Although the appendix itself lacks taeniae, the base of the vermiform appendix lies at the convergence of the three cecal/ascending colon taeniae. These aid in locating the appendix when it is not readily apparent; the prominent anterior taenia is most easily traced for this purpose (1,6).

Vermiform appendices can vary remarkably in length but average 7 to 10 cm (2,4). The peritoneum covers almost all its external surface. The mesoappendix (mesentery of the appendix), a fold of

peritoneum contiguous with the mesentery of the terminal ileum, extends along its length, terminating just proximal to the tip (1).

The appendiceal vascular supply courses within the mesoappendix; and, with distal progression, these vessels gradually rest nearer to the appendiceal muscular wall. In the proximity of the tip where there is no mesoappendix, blood vessels lie essentially â€œunprotectedâ€• on its external surface (1). The appendicular artery, a derivative of the inferior branch of the ileocolic artery of the superior mesenteric trunk, provides the majority of blood to the appendix (4,7). However, a variable supply with accessory arterial contributions is not unusual (8). Branches of the ileocolic vein drain the appendiceal venous network into the superior mesenteric vein and eventually into the portal circulation, whereas lymphatic vessels drain into regional (e.g., ileocolic) lymph nodes (6). Innervation is derived from branches of the vagus

nerve (parasympathetic) and superior mesenteric plexus (sympathetic). Venous, lymphatic, and neural components closely follow the arterial vasculature (6).

Grossly, the external surface of the vermiform appendix appears smooth, pink-tan or gray, and glistening. The appendiceal diameter typically measures 5 to 8 mm. The wall is tan-white and the mucosal lining is light yellow, often disclosing a nodular appearance imparted by the characteristic and prominent lymphoid component (9). Because of these lymphoid aggregates, the central lumen on cross section is often irregular (stellate) rather than round. The normal luminal diameter measures 1 to 3 mm; however, in one study a luminal diameter of 1.2 cm or more was arbitrarily defined as dilatation (10). Focal occlusions of the appendiceal lumen are not uncommon (9).

Development of the Vermiform

Appendix and Congenital Anomalies

The vermiform appendix originates from the primordial structure termed the cecal diverticulum (5,11). First apparent during the sixth week of fetal life, this blind-ended sac progressively develops. Its most proximal portion, in continuity with the remainder of the large bowel, enlarges and expands, forming the cecum proper, whereas its distal aspect or apex simply elongates, remains narrow, and becomes the vermiform appendix (11). Continued growth through infancy and childhood leads to differing cecoappendiceal relationships over this period. For example, the â€œinfantileâ€• cecoappendiceal junction lacks a conspicuous transition; the appendix arises from the inferior aspect of the cecum in this age group. In contrast, an abrupt, easily recognizable junction on the posteromedial cecum is observed in the adult (2).

Abnormal embryologic development can result in agenesis, hypoplasia, and various duplications or even triplication of the appendix (5,9,12,13,14). Duplication of the appendix can mimic cecal duplication. In general, appendiceal duplication is recognized by the presence of complete and separate inner circular and outer longitudinal muscle bands and the presence of a prominent lymphoid component (12).

Duplications have been well described and categorized and can be associated with other complex and life-threatening congenital anomalies. The classification of appendiceal duplications includes type A, an appendix with a common base, single cecum, and bifurcated distal portion; type B, two separate appendices with distinct bases arising from a single cecum; and type C, two cecal structures, each with its own single appendix (12,13). The type C anomaly is always associated with other organ duplications and often necessitates extensive operative correction in infancy; a type B variant is also associated with other systemic anomalies (12). However, the majority of type B and all type A duplications

are found incidentally or during operation for suspected appendicitis in older children and adults.

Function

The exact role of the appendix is uncertain. However, rather than simply representing a vestigial, functionless structure, the abundant quantity of organized lymphoid tissue suggests involvement in mucosal immunity (15). It has been suggested that B lymphocytes derived from the appendix migrate and populate distant sites of the gastrointestinal tract lamina propria and evolve in these widespread foci into functional immunoglobulin (Ig)A-secreting plasma cells (15,16). In this role, the appendix can both attenuate potentially harmful immunoglobulin responses and enhance regional mucosal immunity (16).

Normal Histology of the Appendix

The histologic composition of the appendix is similar to that of the large bowel. The four layers, from its luminal to external surface, include the mucosa, submucosa, muscularis externa (or propria), and serosa. The distinctive features of the appendix are emphasized.

Mucosal Architecture and Design

A single layer of surface epithelium covers the luminal aspect of the appendiceal mucosa. This overlies the lamina propria within which crypts, or intestinal glands, contiguous with the surface epithelial cells are irregularly dispersed (Figure 26.1). The lamina propria is a cellular layer with an abundant migratory cell component and prominent, often

confluent, lymphoid aggregates. In contrast to the scattered lymphoid nodules within the large bowel proper, the appendix,

particularly in young individuals, contains abundant and organized lymphoid structures spread around its entire luminal circumference. These lymphoid nodules often distort the luminal contour (9,17). The outermost component and limit of the mucosa is the muscularis mucosae. This slender fibromuscular band is poorly developed in the appendix and often focally deficient.

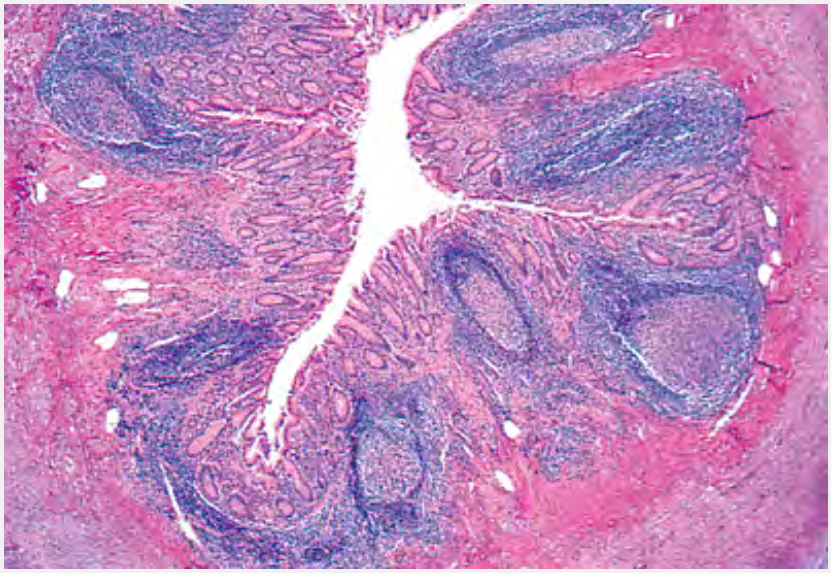

Figure 26.1 Low-magnification view of a cross section of the vermiform appendix. The irregular (stellate) lumen is lined by a single layer of surface epithelium. The remainder of the mucosa (crypts, surrounding lamina propria, and the rather inconspicuous muscularis mucosae) surrounds this surface epithelial layer. Note the characteristic lymphoid nodules within the lamina propria that also extend into the submucosa.

Surface Epithelium

Several different cell types comprise the surface epithelium. A prominent cell that can be identified at the light microscopic level

is tall and columnar with eosinophilic cytoplasm, and it has a round, basally located nucleus (Figure 26.2). These cells represent several distinct cell types that can be differentiated at the ultrastructural level, including â€œsenescentâ€• mucous cells, so-called absorptive cells, and membranous or M cells (18,19,20,21). Goblet cells with distinctive apical mucin droplets surrounded by eosinophilic cytoplasm and undermined by an attenuated basal nucleus intermix with the columnar cells (Figure 26.2). The goblet cell apical mucin droplet contains both periodic acid-Schiff (PAS)-positive neutral mucin and Alcian blueâ€“positive acid sulfomucin. This combination results in the formation of a blue-purple color in a mixed Alcian blue/PAS stain (19,22) (Figure 26.3). Overlying lymphoid aggregates, as in other portions of the small and large bowel, is a specialized or follicle-associated epithelium that is distinct from the surrounding surface epithelium. It characteristically has fewer goblet cells, and many of the columnar cells are of the M-cell type (22) (Figure 26.4). The M cell, a specialized epithelial cell, assists in luminal transport of antigens into the epithelium for appropriate immunologic processing (23,24); M cells are columnar in shape with an attenuated brush border; several lymphocytes are often seen deforming their dependent cytoplasm. Definitive characterization rests on ultrastructural examination, which shows apical cytoplasmic vesicles and shortened microvilli or microfolds (21,23). Because circumferentially distributed organized lymphoid aggregates and lymphoid tissue are prominent in the normal appendix, the specialized follicle-associated epithelium often lines the majority of the appendiceal lumen. Thus, functionally, the surface epithelium is probably primarily involved in antigen processing, as well as in forming a barrier to luminal contents. The luminal surface is also the site where senescent cells are sloughed into the lumen (19,20). Scattered endocrine cells can be seen within the surface epithelium but are more abundant in the underlying crypts. Migratory T and B lymphocytes can be found anywhere within the

surface epithelium (25,26) but are more abundant in the follicle-associated epithelium (Figure 26.4).

Figure 26.2 The surface epithelium is composed of a single layer of predominantly columnar cells with rare interspersed goblet cells. The crypt linings have a similar cellular composition but contain more goblet cells.

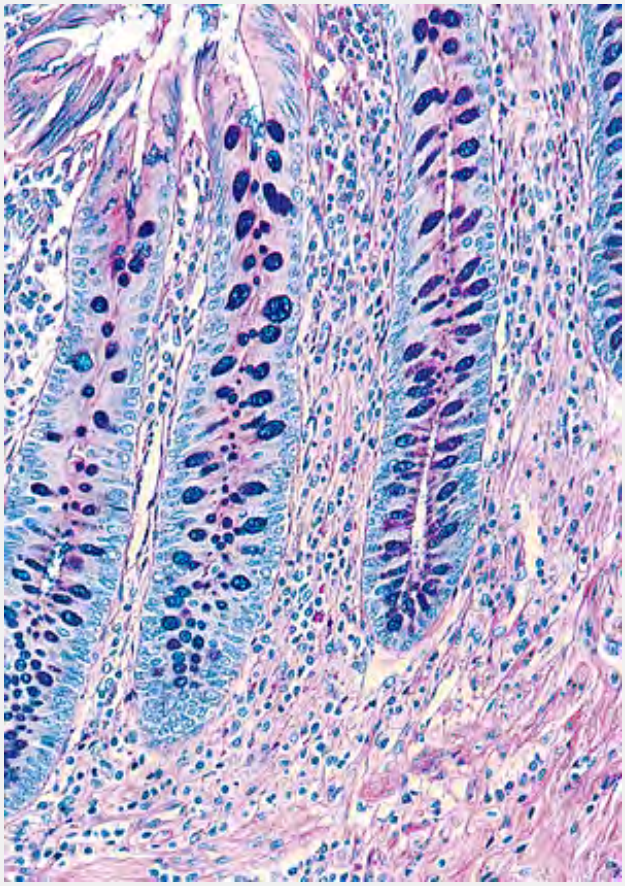

Figure 26.3 Because goblet cells contain both neutral and acid mucopolysaccharides, their apical mucin droplets stain blue-purple with the mixed Alcian blue/PAS preparation.

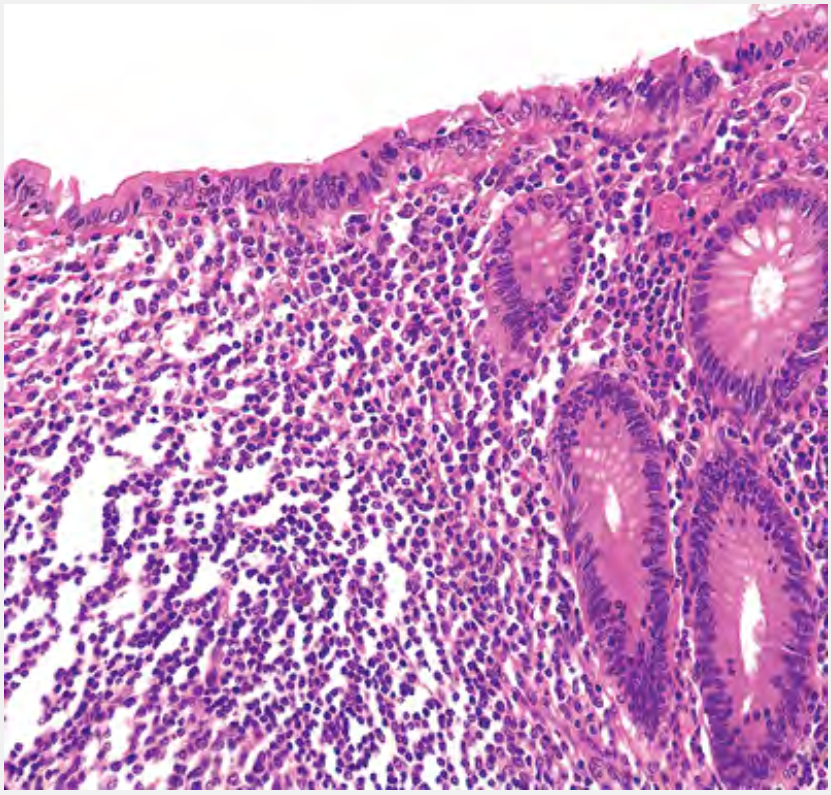

Figure 26.4 Surface epithelium overlying a lymphoid aggregate composed solely of tall columnar cells without intermixed goblet cells. Ultrastructurally, most of these would be classified as membranous or M cells. Note the increased numbers of intraepithelial lymphocytes between the individual columnar cells. Directly beneath the epithelium is the dome region of the lymphoid nodule. The apical portion of the germinal center with surrounding mantle zone is present near the bottom of the micrograph.

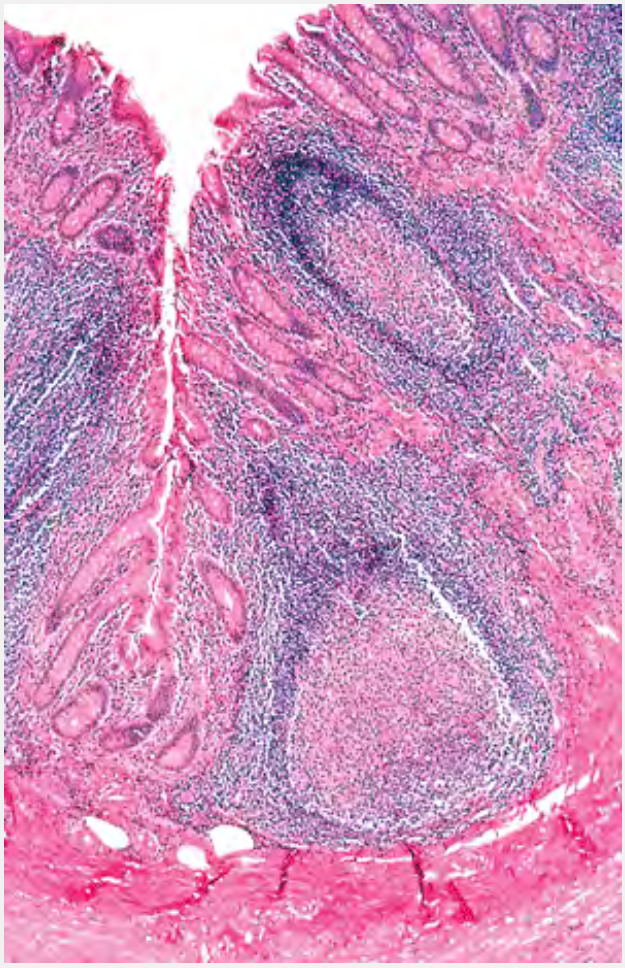

Figure 26.5 Lymphoid aggregates are often a prominent component within the appendiceal mucosa. Note the absence of crypts in the region of the lymphoid nodules and the distortion of surrounding crypts. This is a normal finding in the appendix and is similar to the alteration associated with isolated lymphoid aggregates in the colon.

Crypt Epithelium

In contrast to the colon, where crypts line up evenly like test tubes in a rack, appendiceal crypts are more irregular in shape,

length, and distribution (27). In areas with abundant lymphoid tissue or lymphoid aggregates, crypts are typically absent (28) (Figure 26.5).

Several different cell types line the crypts. The goblet and columnar cell variants discussed above are the most abundant (Figures 26.2, 26.6). Undifferentiated stem cells are scattered about but are inconspicuous. These are typically located at the crypt base, rest on the basement membrane, and do not extend to the crypt lumen; they are best identified by ultrastructural means (19). Isolated or clustered endocrine cells are seen along the crypt epithelium. Their appearance varies from a flask-shaped cell with a narrow strip of apical cytoplasm contiguous with the surface to a spindle-shaped cell with no luminal connection (29,30). Although some endocrine cells can be recognized on hematoxylin and eosin (H&E)â€“stained sections by their eosinophilic, infranuclear granules (31) (Figure 26.6),

definitive identification rests on immunohistologic analysis for chromogranin (or other pan-reactive neuroendocrine marker) (Figure 26.7) or ultrastructural analysis, which discloses neurosecretory granules within their cytoplasm. More specific immunohistologic methods show that endocrine cells within the appendiceal epithelium contain a variety of amine and polypeptide substances, including serotonin, substance P, somatostatin, and enteroglucagon (32). Paneth's cells also can be found in the crypt bases within the normal appendix in nearly 96% of specimens (33,34,35). This cell has a basally situated, round nucleus with a conspicuous nucleolus and abundant eosinophilic supranuclear granules (Figure 26.8); their function remains unknown, but they probably play a role in microbial regulation (33).

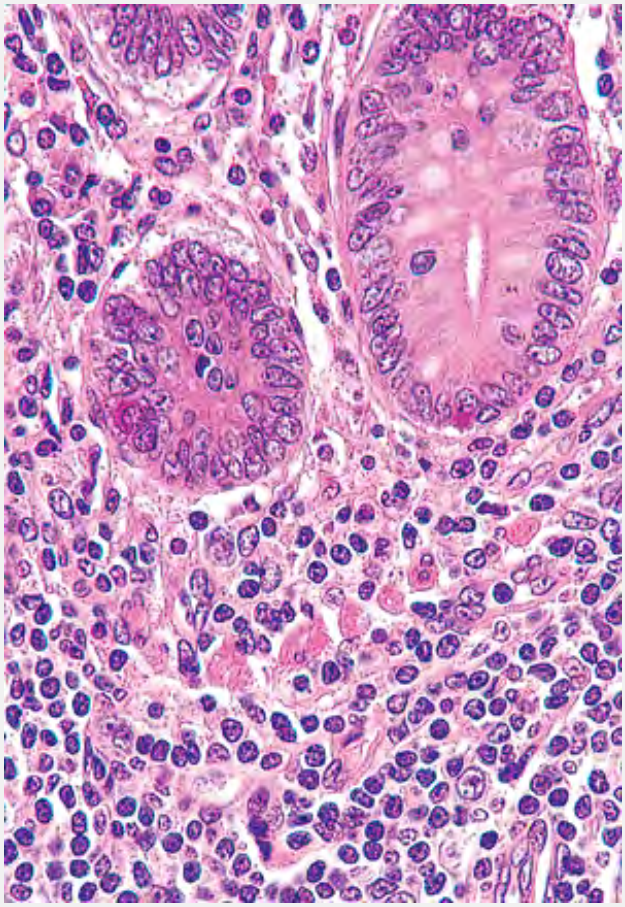

Figure 26.6 Crypts lying within a normocellular lamina propria. The round or ovoid crypts are lined predominantly by eosinophilic columnar cells and goblet cells. A single endocrine cell (containing infranuclear eosinophilic granules) is present at the base of each crypt. The lamina propria contains plasma cells, lymphocytes, and scattered eosinophils. Note the polygonal cells with abundant eosinophilic cytoplasm within the lamina propria. These are the subepithelial (laminal propria) endocrine cells that are often found near the crypt bases.

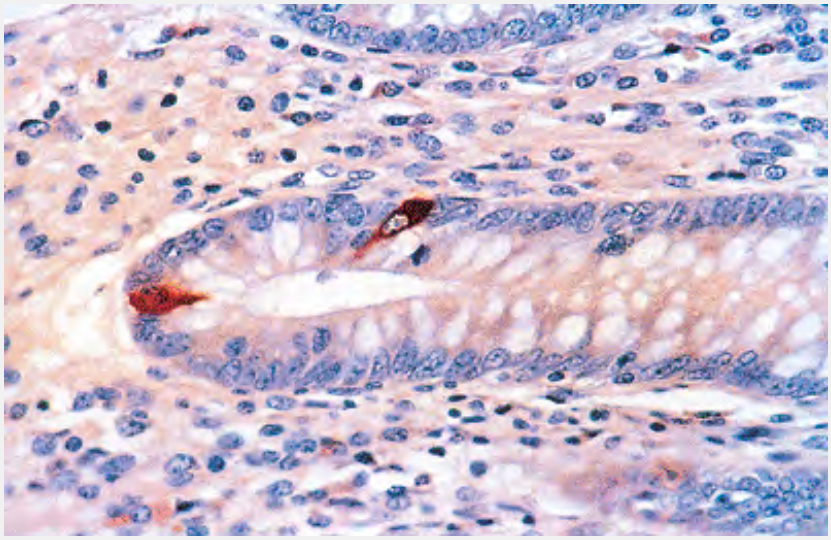

Figure 26.7 Scattered endocrine cells within the epithelium of an appendiceal crypt highlighted with antichromogranin. Intense red-brown cytoplasmic staining is evident in these endocrine cells.

Intraepithelial lymphocytes occur within the crypt epithelium (36,37), but neutrophils and plasma cells are not normal constituents of either epithelial compartment. Rarely, gastric, ileal, or esophageal squamous-type mucosa can be seen interrupting the normal appendiceal lining; some recognize these as true heterotopias (38,39,40).

The crypt functions in cell production and renewal because all cells of both epithelial compartments originate from the crypt's stem cells. Most of these cells travel to the surface epithelium, where they are subsequently sloughed intraluminally; the exception (Paneth's cell) remains in the crypt base (36,37). It is believed that apoptosis within the crypt probably functions to regulate cell migration toward the surface; however, it is uncertain whether this type of cell death is responsible for epithelial cell loss into the lumen (41).

Subepithelial Basement Membrane

A slender zone separates the epithelial compartments from the lamina propria and is composed of collagen and other matrix components (42). The subepithelial basement membrane stabilizes the epithelial layers. A PAS stain can be used to highlight this layer, which measures only microns in thickness (20,42) (Figure 26.3).

Lamina Propria

The lamina propria, the central layer of the mucosa, surrounds the crypts and forms a connective tissue framework around them. Its structural components are collagen and elastic fibers and associated fibroblasts intermingled with blood capillaries, lymphatics, and nerve fibers (18,19,20). As in the large bowel, its migratory cell component consists primarily of plasma cells and T lymphocytes, along with scattered macrophages, eosinophils, B lymphocytes, and mast cells (18,26,43) (Figures 26.6, 26.8). However, depending on an individual's age, a varying number of organized lymphoid nodules distort the lamina proprial architecture. These lymphoid aggregates can extend beneath the muscularis mucosae into the underlying submucosa (Figures 26.1, 26.5), are often confluent, and appear similar in composition and function to the Peyer's patches of the small bowel (21). As in Peyer's patches (see Chapter 24), this lymphoid network of the appendix is compartmentalized into (a) follicle, (b) dome, (c) interfollicular (or parafollicular) region, and (d) follicle-associated epithelium (44,45,46) (Figure 26.9). The follicle has, in most cases, a germinal center containing a polymorphic cellular population of small and large B lymphocytes in various stages of maturation, occasional CD4+ T-helper cells, and tingible body macrophages; these reactive centers invariably contain mitoses (15,45,46,47) (Figure 26.10). Immediately surrounding the

germinal center is the mantle zone, a darkly staining cuff of small, round B lymphocytes. Overlying the

lymphoid aggregate and beneath the epithelium is the dome region (mixed cell zone), which is composed of a heterogeneous population of cells including B and T lymphocytes, macrophages, and occasional plasma cells (21,46). Both the lymphoid aggregate and the dome region are supported by a structural framework provided by dendritic reticulum cells and their processes (16,47). A prominent collagenous network and closely associated lymphatic vessels surround and define the lymphoid nodule (16). This collagenous/fibrous border is contiguous with the connective tissue framework of the interfollicular zones and adjacent lamina propria (16). The zone surrounding a single lymphoid nodule (parafollicular region) and the area between confluent lymphoid aggregates (the interfollicular region) consist predominantly of T lymphocytes (46) (Figure 26.11). Moreover, the ratio of T-helper/inducer (CD4+) to T-suppressor/cytotoxic (CD8+) lymphocytes is normally about 8:1 in these T-lymphocyteâ€“rich areas (46). Finally, as detailed previously, the overlying epithelium is specialized and distinct from the usual surface epithelium.

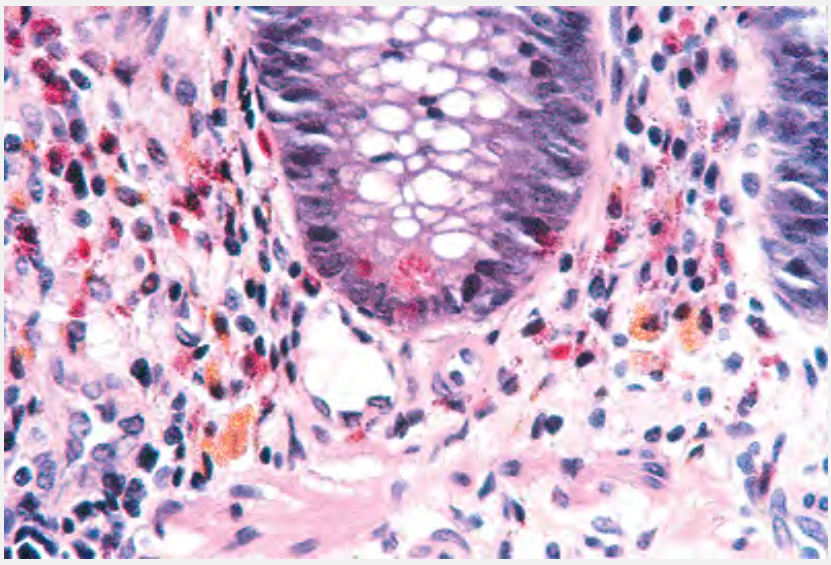

Figure 26.8 Appendiceal crypt disclosing Paneth's cell (at its base) with characteristic supranuclear eosinophilic granules. The surrounding lamina propria has a conspicuous, albeit normal, quantity of eosinophils. Also, note the golden brown, granular pigment within the macrophages, which is characteristic of melanosis.

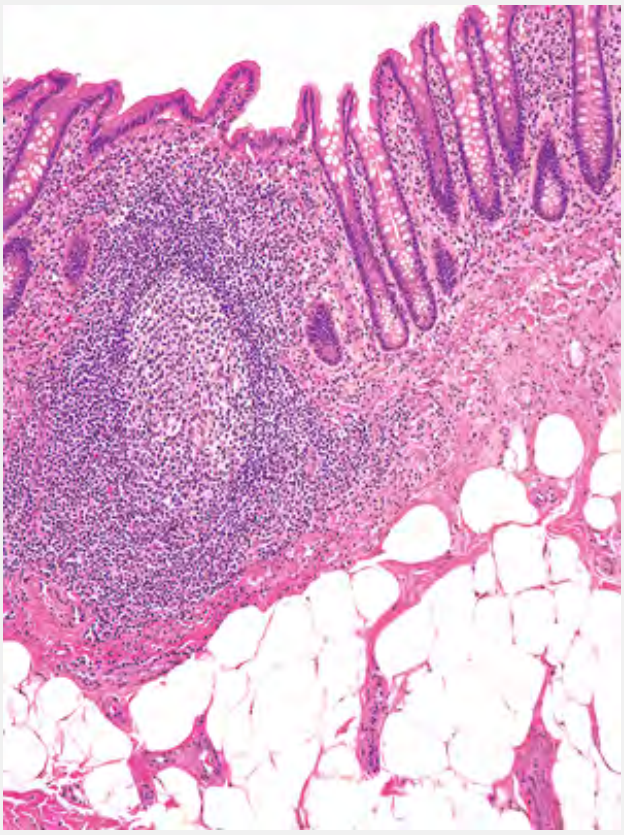

Figure 26.9 Characteristic lymphoid nodule within lamina propria of appendix. A germinal center forms the â€œcoreâ€• of the follicle and is surrounded, at least in part, by a mantle zone of small round lymphocytes. Between the overlying epithelium and the mantle is the dome, which contains a mixed cellular population of lymphocytes, plasma cells, and

macrophages. A portion of the parafollicular area (T-lymphocyte zone) is seen. Lymphatic and blood vessels are seen beneath the lymphoid nodule in the underlying superficial submucosa.

The immunophenotypic cellular composition of the appendiceal mucosa is different from the colon. Although the quantity of lymphoid and plasma cells containing IgA and IgM is similar in both, IgG-containing cells are more abundant in the appendix (15,46) (Figure 26.12). In fact, nearly 50% of the those along the follicle borders, including the dome region, are IgG immunoreactive, whereas IgA-containing cells are more abundant in distant lamina proprial sites (15).

Lymphoid tissue, although a characteristic feature of the appendix, varies in quantity with age. The newborn's appendix contains scant or no lymphoid tissue. With increasing age the lymphoid nodules accumulate, peaking in the first decade (17,48). Lymphoid aggregates then steadily diminish in quantity throughout the remainder of life. However, appendices excised incidentally from middle-aged adults can still occasionally show a prominent organized lymphoid component (10). In contrast, lymphoid nodules and associated lymphocytes can be scant in the central obliterative form of appendiceal neuroma (fibrous obliteration of the appendiceal lumen) and occasionally in appendices removed from normal patients at any age (10). Thus, a great range of normal variation exists in the appendix with respect to its lymphoid content.

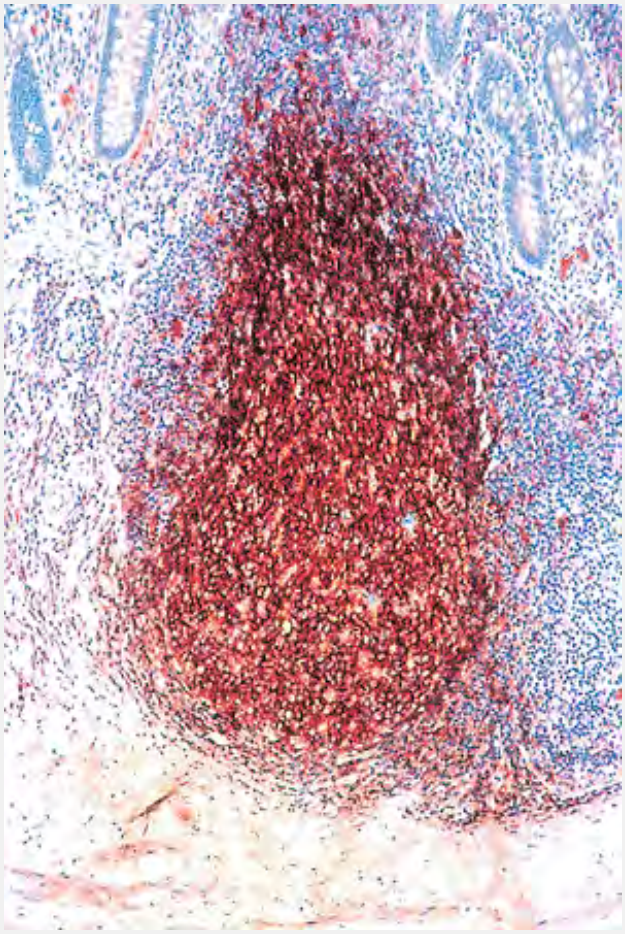

Figure 26.10 The germinal center and mantle zone contain predominantly B-lymphocytes. A panâ€“B-lymphocyte immunomarker, L26, discloses this characteristic immunophenotype. Scattered macrophages and occasional T lymphocytes (see Figure 26.11) are also normally found within the germinal center. Only scattered B-lymphocytes are present within the interfollicular zone and adjacent lamina propria.

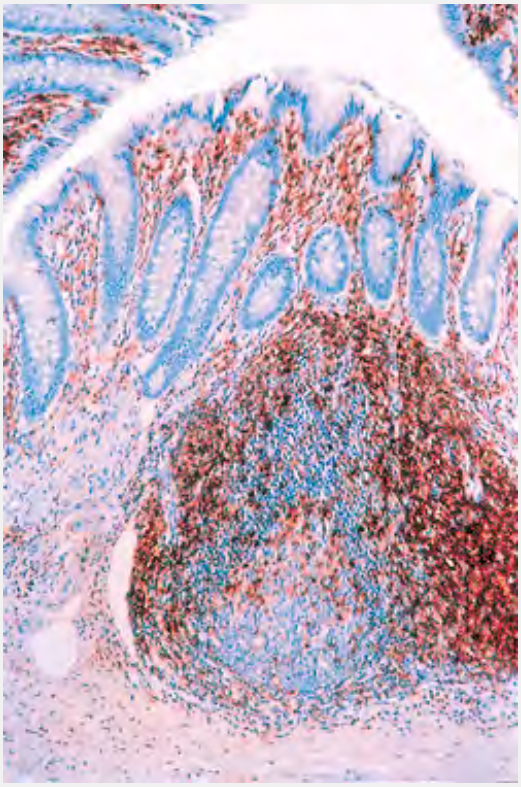

Figure 26.11 A panâ€“T-cell immunomarker, Leu-22 (CD43), disclosing the characteristic T-lymphocyte distribution within the appendiceal mucosa. The lamina propria and interfollicular regions (between lymphoid follicles) are normally populated by numerous T lymphocytes. There is a sprinkling of T lymphocytes within the germinal center; these are predominantly T-helper/inducer (CD4+) lymphocytes.

Histiocytes with intracellular golden-brown pigment (lipofuscin), not infrequently observed in the colonic mucosa, can also be found in the appendiceal lamina propria; this alteration results from anthracene-containing laxative abuse and has been termed melanosis coli when seen in the colon proper (9,49) (Figure 26.8). Interestingly, this pigmentation is a result of apoptosis induced by anthraquinones (41).

The lamina propria of the appendix contains a well-developed mucosal nervous plexus that is different from the more prominent submucosal and myenteric plexuses. Although all contain neurons (ganglion cells), Schwann cells, and neural processes (axons and neuropil), only the mucosal plexus contains endocrine (neurosecretory) cells. As a consequence, this network has been termed the mucosal neuroendocrine complex (50). These complexes, located just beneath the crypts, are composed of collections of endocrine cells and seen on H&Eâ€“stained preparations as polygonal cells with pale granular cytoplasm (Figure 26.6), often intimately associated with spindled Schwann cells, neural processes, and occasional neurons. These collections, or neuroendocrine ganglia, are interconnected by neural fibers that can be highlighted immunohistologically with antibody preparations to neuron-specific enolase and, in a subset, to substance P (32); antiâ€“S-100 also can outline this network as it marks the accompanying Schwann cells. The mucosal plexus also communicates with other neural networks of the enteric nervous system (50,51,52,53). The subepithelial endocrine cells are not always conspicuous but can be highlighted using general neuroendocrine immunomarkers, such as antichromogranin (Figure 26.13) and antineuron-specific enolase, or by using electron microscopy (54,55). Most of these cells have been shown by specific immunohistologic analysis to contain serotonin (51,55). The mucosal neuroendocrine complex is believed to modulate neural communication, through serotonin mediators, between the epithelium and the deeper submucosal and intermuscular plexuses (55). Interestingly, because most appendiceal carcinoids are biphasic, consisting of an admixture of endocrine cells and S-100+ Schwann cells (similar to the architecture of the mucosal neuroendocrine complex), the majority of these appendiceal neoplasms are believed to be derived from these lamina propria endocrine cells rather than from the epithelium-based ones (51).

Muscularis Mucosae

The muscularis mucosae is a thin band of fibromuscular tissue separating the lamina propria and mucosal epithelium from the underlying submucosa. It characteristically forms a continuous layer in the large bowel (18); but, in the appendix, the muscularis mucosae is attenuated, poorly developed, and often focally absent, particularly in the region of penetrating lymphoid aggregates (28,56) (Figure 26.14). In these areas the muscularis mucosae may exist solely as isolated smooth muscle cells in the underlying submucosa (56).

Submucosa

The submucosa separates the mucosa from the muscularis externa. Its loose architectural framework contains a meshwork of collagenous and elastic fibers and associated fibroblasts (Figure 26.15). The submucosa can also contain inconspicuous migratory cells, such as macrophages, lymphoid and plasma cells, and mast cells, along with adipose tissue (17,57) (Figure 26.14). The morphologic appearance of the appendiceal submucosa and its primary role in maintaining structure are similar throughout the gastrointestinal tract (57). Arterioles, venules, blood capillaries, and lymphatic vessels are a prominent component of the submucosa (7,18) (Figure 26.15). Lymphatic vessels (or sinuses) are most prominent just beneath the bases of lymphoid aggregates (16). Neural structures, particularly Meissner's

plexus, are also conspicuous (Figure 26.16). This plexus consists of ganglia, collections of neurons (ganglion cells) with associated neuronal processes, and Schwann cells that interconnect, creating a neural network throughout the submucosal layer (58,59). The ganglion cell is large and oval with abundant eosinophilic cytoplasm; its vesicular nucleus is often eccentrically placed and contains a prominent nucleolus. The surrounding spindle and wavy

Schwann cell component of the ganglia is less conspicuous on H&Eâ€“stained preparations but can be highlighted with antiâ€“S-100 (Figure 26.16).

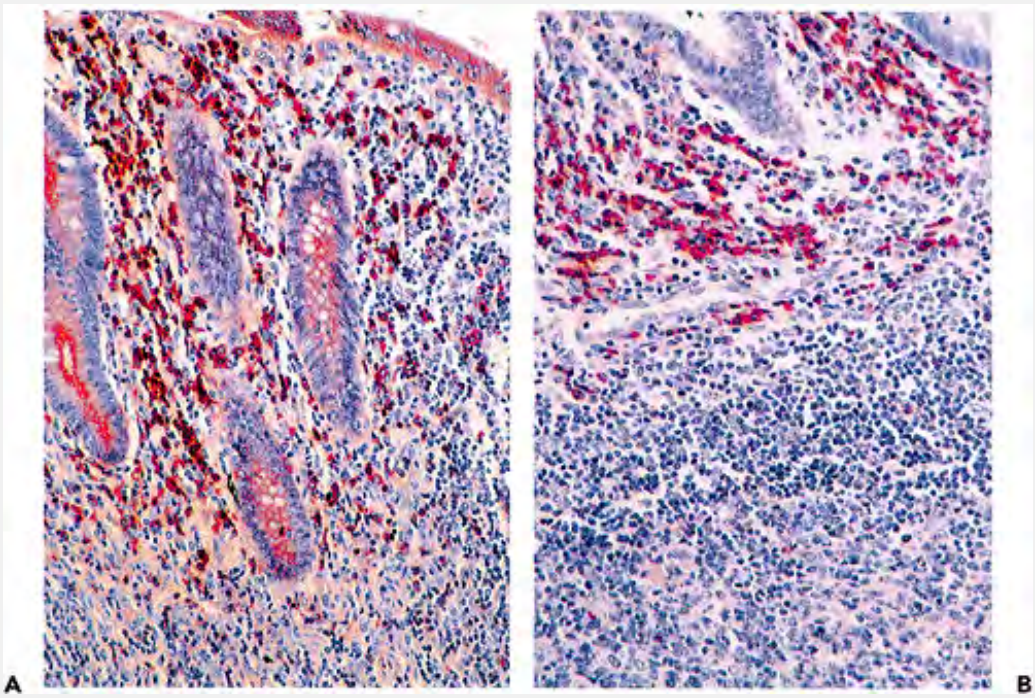

Figure 26.12 A. Immunohistologic preparation showing abundant IgA-containing plasma cells within lamina propria; the epithelial staining is a consequence of the secretory nature of the IgA molecule. B. Abundant IgG-bearing cells are characteristically located within the dome region and along the margins of lymphoid nodules in the appendix.

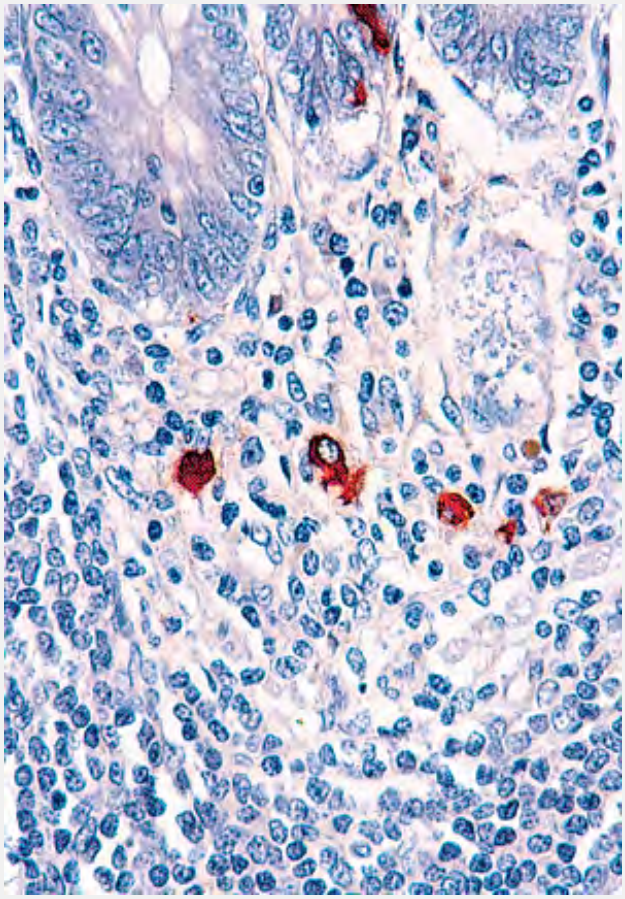

Figure 26.13 Antichromogranin highlights the subepithelial (lamina propria) endocrine cells beneath the crypts. These are more prominent and abundant in the appendix than in any other portion of gastrointestinal tract. Note also the epithelial-based endocrine cell in the overlying crypt.

Muscularis Externa, Subserosal Region, and the Serosa

The thick smooth muscle layer lying between the submucosa and serosal portions of the appendix is the muscularis externa (or muscularis propria). It is separated into an inner circular layer and

an outer longitudinal band (28). The individual smooth muscle cells are oval with blunted ends and form bundles of varying size. Occasionally, granular degeneration (eosinophilic cytoplasmic granularity) of individual or groups of smooth muscle cells is seen, particularly within the inner circular layer (56,60). Between the two muscle bands lies the myenteric (Auerbach's) plexus, which is similar morphologically and functionally to the previously described submucosal plexus of Meissner (59) (Figure 26.17).

Additionally, blood and lymphatic vessels and nerve fibers course through this muscular layer (16). Just external to the outer longitudinal smooth muscle layer is the subserosal region, consisting of loose connective tissue and ramifying blood vessels, lymphatics, and nerves. The exteriormost surface, or serosa, is lined by a single layer of cuboidal mesothelial cells that overlies a slender band of fibrous tissue. Only the attachment of the fibrofatty mesoappendix lacks a serosa (1).

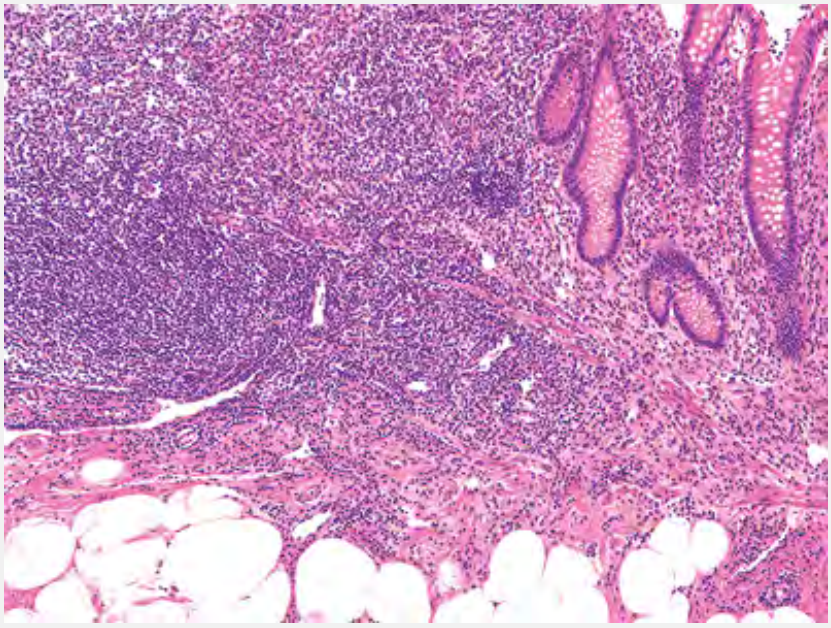

Figure 26.14 Characteristic focal deficiency of muscularis

mucosae in region of lymphoid nodule. There is adipose tissue within the submucosa; this is a normal finding.

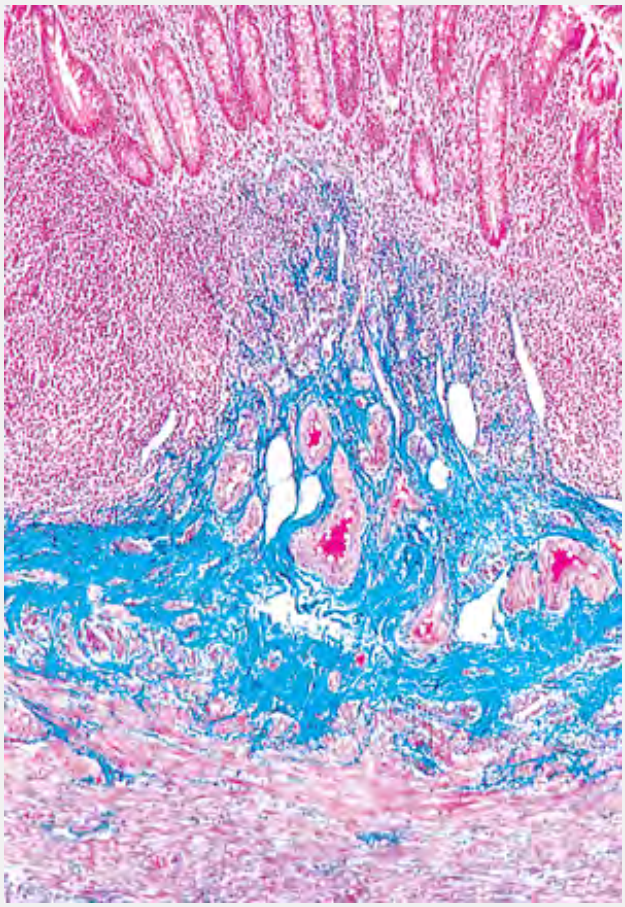

Figure 26.15 Normal appendiceal submucosa outlined in blue, highlighting its prominent collagenous framework. Numerous vascular spaces are also present within this layer. The mucosa (crypts) is *above*, and the inner circular layer of the muscularis externa is *below* (Masson's trichrome).

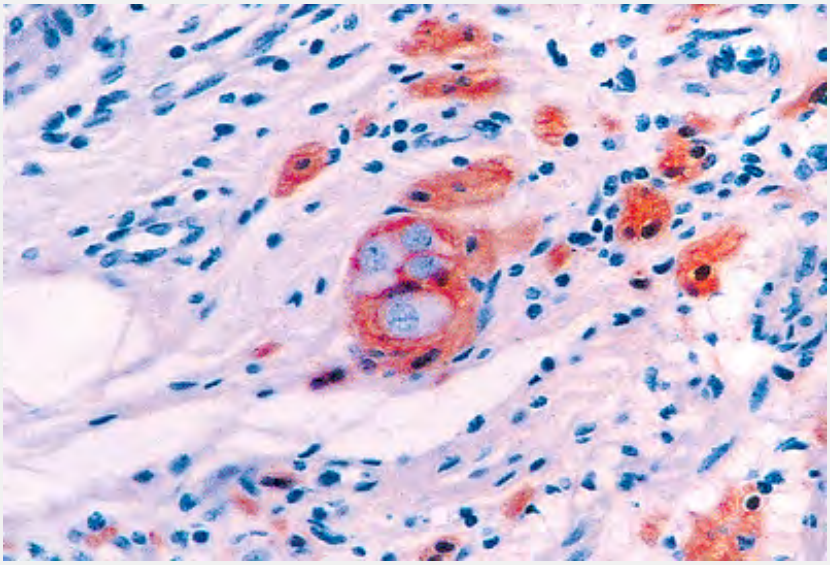

Figure 26.16 Submucosal neural network outlined with antiâ€“S-100. A single ganglion of Meissner's plexus is at the center; the ganglion cells (neurons) have abundant pale cytoplasm, a large eccentric nucleus, and show no immunoreactivity. The Schwann cells of the ganglion and those ensheathing the neuronal processes of the remainder of the plexus are highlighted.

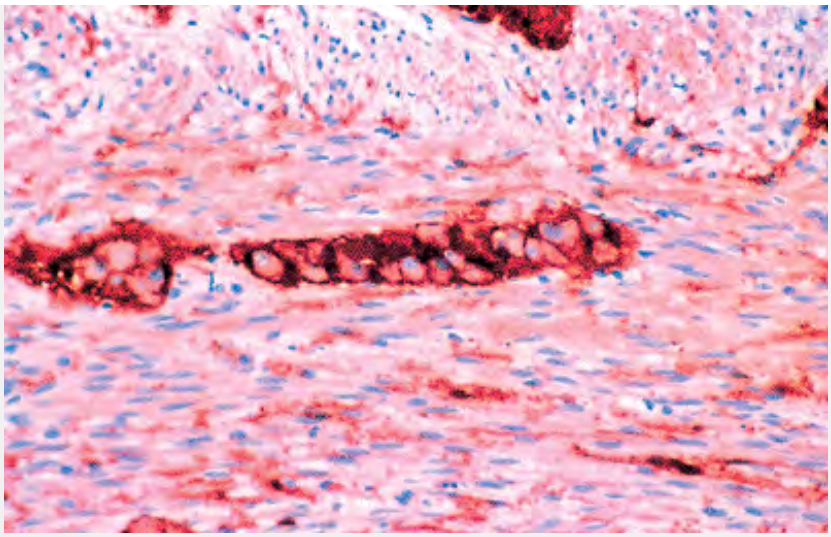

Figure 26.17 Antiâ€“S-100 highlighting Schwann cells of the neural network of the muscularis externa and a ganglion of the myenteric (Auerbach's) plexus.

Special Considerations

Normal Variation of Mucosal Inflammation Versus Acute Appendicitis

Acute appendicitis is usually characterized by an abundant neutrophilic and eosinophilic infiltrate within the mucosa, submucosa, and often muscularis externa with at least focal mucosal ulceration; frequently suppurative inflammation extends into and through the appendiceal wall (9,10). However, the changes seen in early appendicitis can be quite minimal, and criteria considered sufficient to diagnose early acute appendicitis have varied (9,10,61,62,63,64,65,66). We agree that

â€œreactiveâ€• lymphoid follicles are not a reliable sign of acute appendicitis (9). Focal collections of neutrophils within the lumen and lamina propria have been considered nondiagnostic by some investigators because many â€œincidentalâ€• appendectomy specimens contain these changes (9,10,61,64,65,66). However, we believe that if care is taken to recognize marginating neutrophils and early mucosal migration of these acute inflammatory cells (i.e., a result of the operative procedure alone), then other collections of neutrophils within the mucosa or intraluminal pus reflect stasis, infection, and changes of early appendicitis (62,63,64). Whether acute appendicitis becomes chronic or whether it can be recognized in a chronic state has long been debated (63). Fibrous obliteration of the appendiceal lumen is probably not a sequelae of acute appendicitis (53). However, prominent fibrosis, a marked chronic inflammatory cell infiltrate within the wall, and granulation tissue are abnormal and suggest an organizing appendicitis (9). Occasional specimens exhibit infiltration of the appendiceal wall by eosinophilic leukocytes with no other apparent abnormality (10). This change could reflect appendicitis elsewhere in the specimen that was not sampled; however, it remains possible that an infiltrate composed predominantly of eosinophils could represent appendicitis in a resolving phase or be a manifestation of eosinophilic gastroenteritis (62,67,68).

Obliteration of the Appendiceal Lumen (Appendiceal Neuromas)

Obliteration of the appendiceal lumen with absence of the lining mucosa and underlying crypts frequently occurs and has a prevalence in surgical specimens of nearly 30% (9,53). This process usually affects the distal aspect or just the tip, but occasionally the entire lumen is obliterated. This process is often termed fibrous obliteration; however, more recent studies have

shown that in some cases the occlusive proliferation appears to be predominantly neurogenic (32,53,69). Other diagnostic terms have been proposed, including neurogenic appendicopathy and appendiceal neuroma. The typical appendiceal neuroma, or the central obliterative form, is composed of a collection of spindle cells in a loose myxoid background with varying amounts of collagen, fat, and chronic inflammatory cells (Figures 26.18,26.19). This typically occludes the lumen and blends imperceptibly with the surrounding submucosa (53). The involved segment usually lacks a mucosa, and lymphoid follicles are typically not seen (20). Immunostaining for neuron-specific enolase and S-100 highlights the spindle cells and identifies their neuronal (axons) and perineuronal (Schwann cell) nature, respectively (32,53) (Figure 26.20). Moreover, endocrine cells visualized with antineuron-specific enolase and antichromogranin (Figure 26.21) occur in many of the cases, usually intermingled with the other elements; serotonin and somatostatin have been identified in some of these endocrine cells by immunohistologic methods (32,53). Ultrastructural analysis discloses neuronal

processes, Schwann cells, and cells with neurosecretory granules (endocrine cells) corroborating the immunostaining results (53).

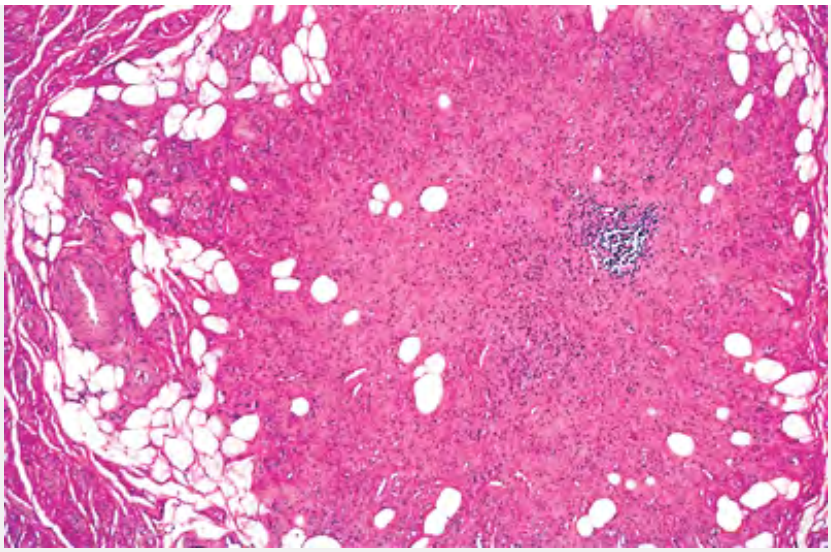

Figure 26.18 Obliteration of appendiceal lumen. The occlusive proliferation is composed of spindled cells within a collagenous and myxoid background, along with scattered adipocytes. A focus of chronic inflammatory cells is also present.

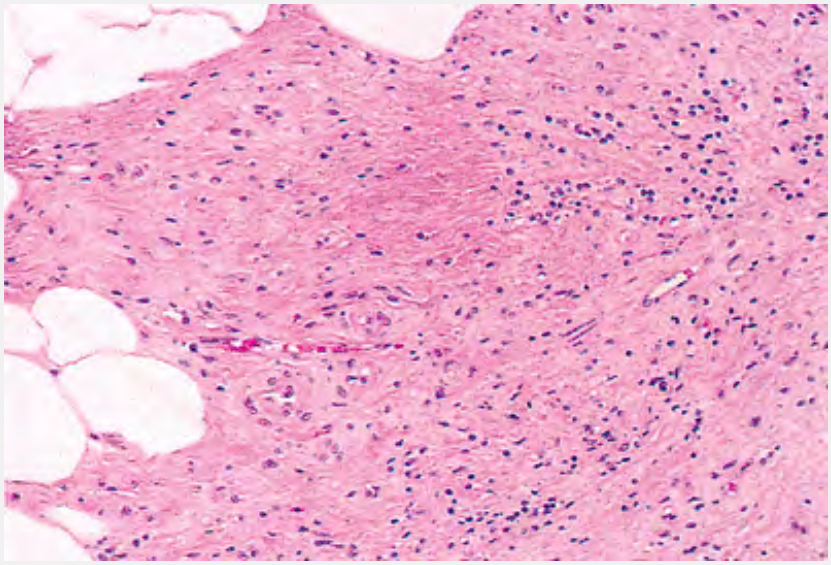

Figure 26.19 High magnification of Figure 26.18 showing

spindled cell proliferation in an eosinophilic, fibromyxoid background.

Another variant of this entity, the intramucosal appendiceal neuroma, primarily affects the mucosa, causing no luminal obliteration. Although morphologically similar to the central obliterative form, this intramucosal variant deceptively expands the lamina propria, separates the crypts, and replaces the usual prominent migratory cell population (53) (Figure 26.22). Immunostaining with S-100 can be helpful in visualizing these more subtle changes.

Both of these entities are believed to be proliferative rather than involutional, progressing through consecutive stages of growth, regression, and finally an end-stage with fibrosis (53,70). Overlapping features are therefore expected with varied admixtures of neurogenic components, collagen, and fat. It is hypothesized that associated endocrine cell hyperplasia, often found in adjacent uninvolved appendiceal segments, may be responsible for painful stimuli mimicking typical acute appendicitis (53). However, appendiceal neuromas are often found in specimens removed at incidental appendectomy.

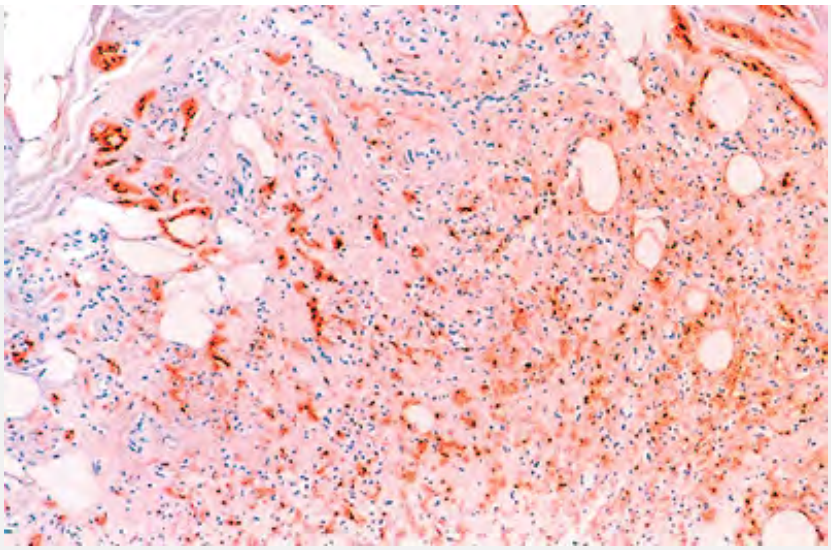

Figure 26.20 Prominent neurogenic (Schwann cell) component highlighted by antiâ€“S-100 within the obliterated lumen.

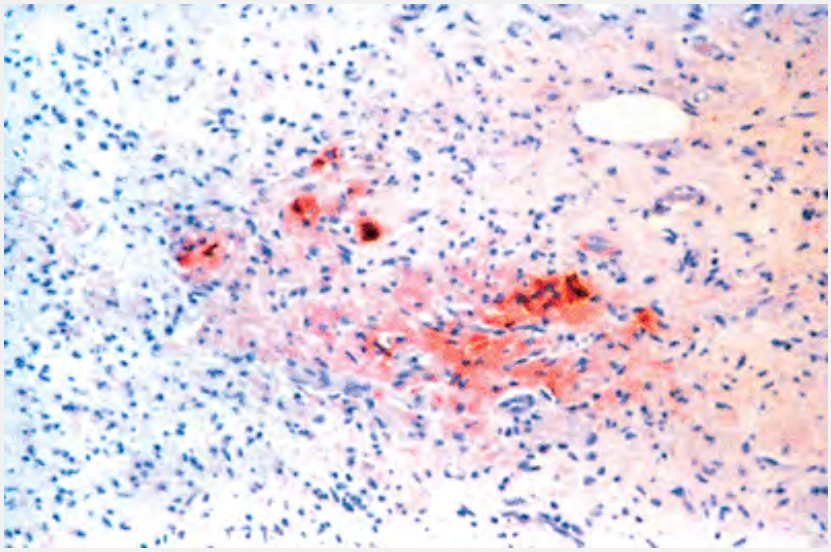

Figure 26.21 Scattered endocrine (neurosecretory) cells are evident within the obliterative luminal proliferation as highlighted by antichromogranin; specific immunomarkers

show some of these to contain serotonin or somatostatin.

Mucocele of the Appendix

The term *mucocele* has been used to describe a dilated appendiceal lumen filled with mucin (71). *Mucocele,* however, should not be used as a specific diagnostic term because the condition is almost always caused by a neoplastic proliferation, either a mucinous cystadenoma or mucinous cystadenocarcinoma (63,71,72). Characteristic architectural and cytologic features should permit identification of these entities.

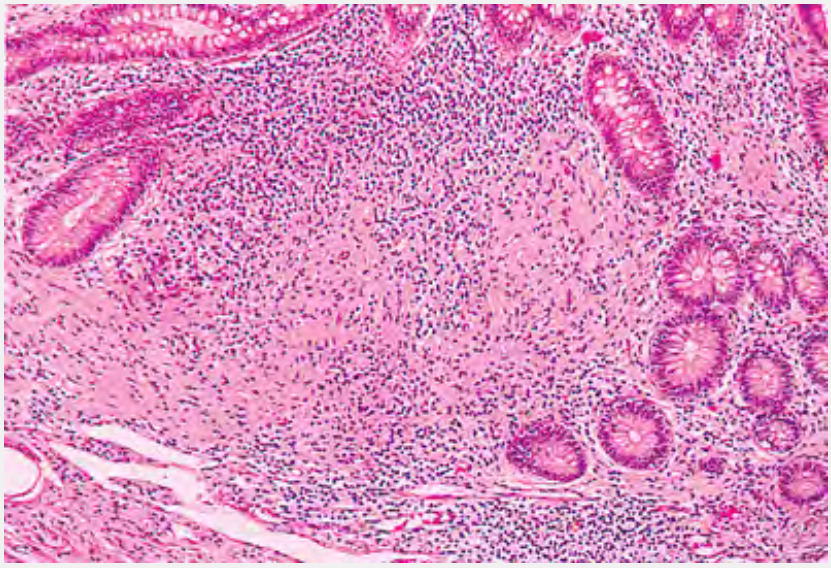

Figure 26.22 Intramucosal variant of appendiceal neuroma. The characteristic subtle spindle cell (schwannian) proliferation expands the lamina propria and separates the crypts. A diminished number of migratory cells is evident in this area.

Dissection and Processing Techniques

Gross dissection and processing of the appendix are generally straightforward. Routine description of size, appearance, and any unusual lesions should be recorded. Luminal patency should be assessed (i.e., obliteration or dilatation) along with the focality and regional distribution of any changes. The tip should be closely inspected for carcinoid tumors because these commonly occur in the distal portion of the appendix (9,73). When grossly evident, they often appear as bulbous, tan-yellow expansions or nodules. However, a routine section of the tip is standard at most institutions and will identify small, grossly unidentifiable tumors (9). The common recommendation of a longitudinal section of the distal several centimeters is often difficult to orient, and we prefer a cross section of the tip. In the usual specimen, 1-cm serial cross-sectioning is performed along the entire length of the appendix. Two cross sections, one from the middle and one of the proximal line of resection, should be submitted for embedding. Because neoplastic proliferations of the appendix (e.g., mucinous cystadenoma/cystadenocarcinoma, carcinoid tumor, and its variants) are not infrequently discovered incidentally during microscopic evaluation of the specimen, we routinely sample the margin of resection. Otherwise, it could be difficult to reconstruct the gross specimen in an attempt to assess the adequacy of excision. The choice of a fixative is not crucial. However, we prefer the superior nuclear detail afforded by Hollande's solution over routine 4% formaldehyde solution. Modifications of dissection and processing may be necessary in certain situations.

Anal Canal

Claus Fenger

Introduction

The anal canal has a complex anatomy and histology, and new information still turns up with regard to its embryology, structure, function, and pathology. Unfortunately, much confusion continues about definitions and nomenclature. This chapter therefore includes a historical review and a discussion of the terms used for the different structures (1).

Historical Review

Anal diseases and their treatment are mentioned as far back as the Egyptian papyri (2). Nevertheless, there are few early descriptions of anal anatomy. Of note is Galenos (130â€“200 AD), who compared the anus to a laced-up purse (3). The first observations on the anal canal mucosa were published by Glisson (1597â€“1677) (4), who noted the anal valves. In 1717, Morgagni (5) mentioned the anal columns and included the now famous drawing in the *Adversaria* (Figure 27.1); in addition, it shows pronounced papillae. In 1727, Heister (6) described the smooth zone between the anal valves and the perianal skin; and, in 1732, WinslÃ¶w (7) described the semilunar lacunae between the valves

and the bases of the anal columns.

The first exact microscopic description of the different epithelial zones in the anal canal was given by Robin and Cadiat in 1874 (8). The perianal apocrine glands were found by Gay in 1871 (9), and in 1878 Chiari introduced the theory of the anal sinus infection in the pathogenesis of anal fistulas (10). Hermann and Desfosses' (11) microscopic description of anal glands followed shortly afterward.

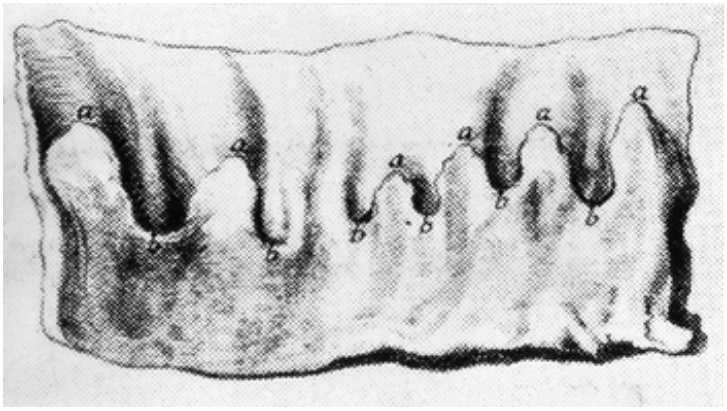

Figure 27.1 The anal canal as seen by Morgagni. Reprinted from: Morgagni GB. Adversaria anatomica omnia. Advers III Animadv. VI. Patavii, Italy: Josephus Cominus; 1717:10â€“11.

In 1877 Hilton (12) introduced the term *white line* for the junction between the skin and the mucous membrane and corresponding to the linear interval between the internal and external sphincter muscle. In 1896, Stroud (13) introduced the term *pecten* for the smooth area between the anal valves and Hilton's white line. However, later investigators recommended that use of the term *Hilton's white line* should be discontinued because no anatomic feature identified it (14 ,15). Detailed macroscopic and stereomicroscopic investigations of surgical specimens of the anal canal have not shown any such structure (16 ,17).

The term *anal canal* was proposed by Symington in 1888 (18) for

what had earlier been described as the third or perineal part of the rectum, that is, the part extending from the level of the pelvic floor backward and downward to the anal opening. This definition corresponds to the *surgical anal canal* , whereas the term *anatomic anal canal* has been used for the area between the line of anal valves and sinuses [dentate line (DL)] and the anal verge alone (Figure 27.2). The anal verge can be defined as the point (line) where the walls of the anal canal come in contact in their normal resting state (19).

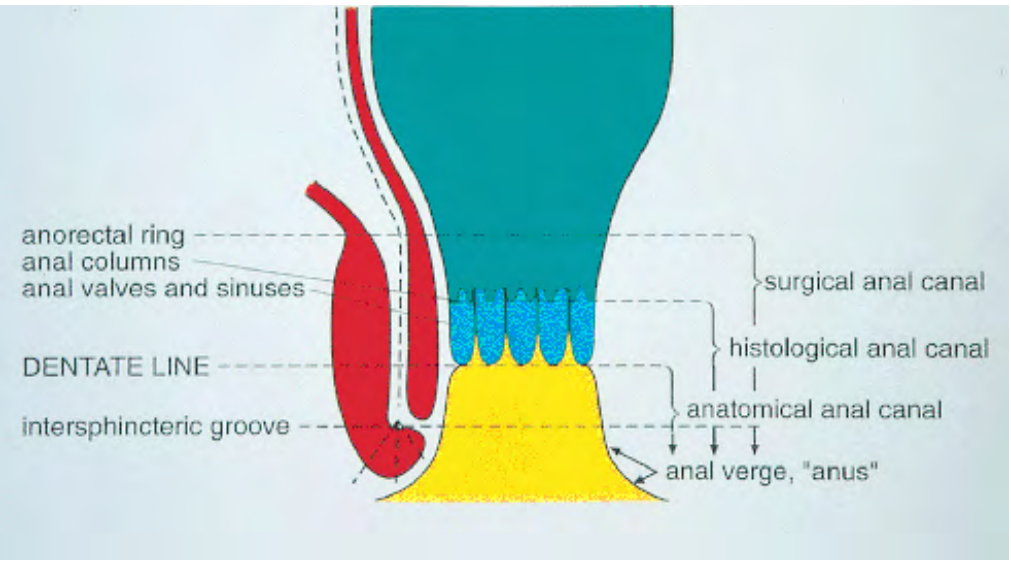

Figure 27.2 Schematic drawing of the anal canal showing the macroscopic landmarks. The â€œsurgicalâ€• and â€œanatomicalâ€• anal canals have their lower border at the rather ill-defined anal verge, or anus. This point has sometimes been called the anal margin, whereas other authors have used this term for the same area as the anatomic anal canal. Hilton's â€œwhite lineâ€• was meant to be located at the intersphincteric groove; Stroud's â€œpectenâ€• was the area between the dentate line and Hilton's line. The â€œhistologicâ€• anal canal begins at the irregular upper border of the anal transitional zone (compare to Figures 27.9 ,27.10 ,27.11 ,27.12 ,27.13).

As to embryology, Tourneux in 1888 (20) and Retterer in 1890 (21) wrote that the cloacal membrane was divided into anal and urogenital membranes by a descending septum, thus giving basis for the often quoted but never illustrated delusion that the DL is the site of a former anal membrane.

Embryology

In the early embryo (Carnegie stage 13, crown-rump length 5 mm), the primitive urogenital sinus and anorectal canal are separated by the urorectal septum and open into a common cloaca, which is closed at its ventral surface by the cloacal plate. As the embryo grows and its caudal curvature decreases, the distance between the urorectal septum and the cloacal plate decreases, but these two structures never fuse.

Due to apoptosis, the dorsal part of the cloacal plate gradually becomes more like a membrane, which ruptures about 49 days postfertilization (Carnegie stage 19, crown-rump length 16â€“18 mm). Soon after, a secondary occlusion of the anorectal canal occurs as a result of cell adhesion and formation of an epithelial â€œplugâ€• at the level of the anal orifice. Recanalization takes place at 30 to 35 mm crown-rump length, again due to apoptosis. The cloaca itself does not contribute to the formation of the anus or rectum (22 ,23). The characteristic epithelium of the anal transitional zone is present already in the thirteenth week (Figure 27.3).

The prevalence of anal anomalies in Europe is 4 per 10,000 births, and two-thirds occur together with other anomalies. Most of the isolated anomalies are atresias with or without fistula, and 90% of these are located below the levator ani. The etiology to anal atresia is still under discussion (24).

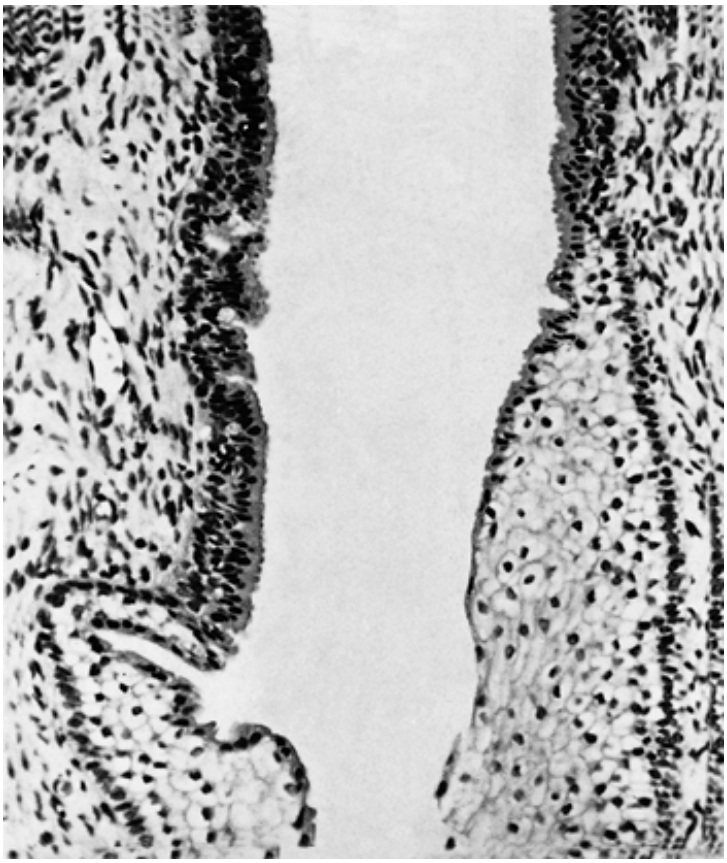

Figure 27.3 Longitudinal section through the middle of an anal canal in a 13-week-old fetus. Squamous epithelium is seen in the lower part; anal transitional zone with the characteristic epithelium is seen in the upper part (H&E).

Nomenclature of the Anal Canal

It would seem natural to start with a definition of the anal canal; but, because there are several definitions and new terms are still introduced (25,26), a description of the anatomical landmarks and epithelial zones may be the best introduction to this never-ending discussion.

Official Terms

Official terms (27) for the structures seen on the anal canal surface include columnae anales, sinus anales, valvulae anales, linea pectinata, pecten analis, and linea anocutanea. However, the latter three terms are not generally accepted, and many synonyms have been used. Among the epithelial zones, only the anal transition(al) zone has got its own name.

When discussing anal nomenclature, one must always bear in mind that the terms *anal columns, valves,* and *sinuses,* and the line composed by the latter two structures are macroscopic landmarks. However, although they can be visualized by using macroscopic staining (28), the different zones in the anal canal are microscopic structures, and they do not correspond exactly to the macroscopic landmarks (16).

The most important macroscopic landmark is the line composed of the anal valves and sinuses and the bases of the anal columns (Figures 27.4 ,27.5). A list of names introduced for this line is given in Table 27.1 (1). Among these, the term *dentate line* is chosen by the International Union Against Cancer (UICC) and the World Health Organization (WHO) and is also widely used in textbooks (25 ,29 ,30 ,31 ,32). Anal valves and papillae are not present as often as reported in anatomy textbooks, and crypts and sinuses may be found over a larger area than compatible

with the definition of a line. *Anorectal* and *anocutaneous* refer to special definitions of the anal canal. When no valves, columns, or papillae are present, the line should be defined by the lowest sinuses visible.

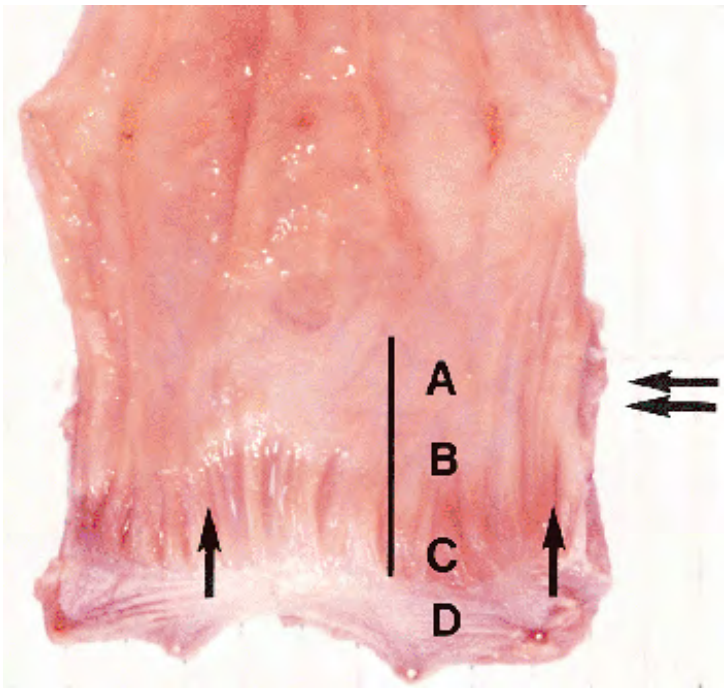

Figure 27.4 Autopsy specimen of the lower rectum and anal canal from an infant. The dentate line is composed of the bases of the well-defined anal columns. Only a narrow rim of perianal skin is at the bottom. The *black vertical line* indicates the extent of the anal canal, the *single arrows* the dentate line, and the *double arrows* the upper border of the anal transitional zone (formalin). (*A*, colorectal zone; *B*, anal transitional zone; *C*, squamous zone; *D*, perianal skin)

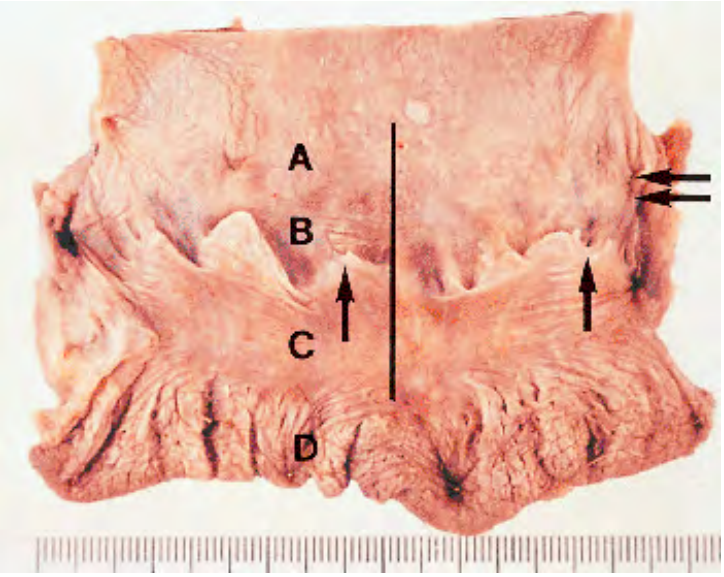

Figure 27.5 Surgical specimen of the lower rectum and anal canal from an adult. Here the dentate line is composed of anal sinuses, valves, and pronounced papillae, whereas the anal columns are nearly invisible. At the bottom, there is a broad rim of wrinkled perianal skin with hairs (formalin). (*Black vertical line* , extent of the anal canal; *single arrows,* the dentate line; *double arrows,* upper border of the anal transitional zone; *A,* colorectal zone; *B,* anal transitional zone; *C,* squamous zone; *D,* perianal skin)

Epithelial Zones

Whatever definition of the anal canal is used, the sequence of epithelial zones in this area (i.e., rectum to perianal skin) follows (Figure 27.6):

- the zone covered with uninterrupted mucosa of colorectal type
- the zone with epithelial variants [anal transitional zone (ATZ)]
- the zone covered with uninterrupted squamous epithelium
- the perianal skin with keratinized squamous epithelium and skin appendages

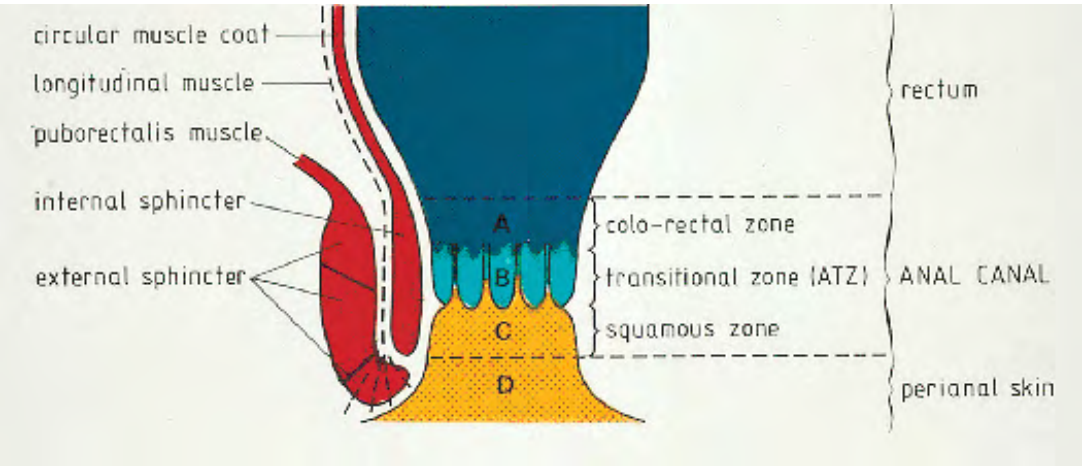

Figure 27.6 Schematic drawing of the anal canal showing the different zones and the proposed nomenclature. Colorectal zone (of anal canal) above (*A*). The extent of the anal transitional zone (*B*) is highly variable. The squamous zone (*C*) gradually merges into the perianal skin (*D*).

These zones have been given many different names over the past century (Table 27.2) based on macroscopic, histologic, and embryologic considerations. Among the terms applied to the zone with epithelial variants, situated between the colorectal-type mucosa above and the squamous epithelium below, the most widely accepted term is now the *anal transition(al) zone* (28). The term *zona columnaris* refers to a macroscopic observation; the names *membranous, cloacogenic,* and *junctional zones* all indicate the site of the cloacal membrane in early fetal life and the meeting point of endoderm and ectoderm, a theory that was rejected decades ago. The terms *intermediate* or *middle zone* could be used, but neither gives any information about the character of the epithelial lining. *Hemorrhoidal zone* is misleading because hemorrhoids are not confined to this area.

The definition of the anal transitional zone is as follows. The ATZ is the zone interposed between uninterrupted colorectal mucosa above and uninterrupted squamous epithelium below, irrespective

of the type of epithelium present in the zone itself (28).

From this it follows that names related to the histologic appearance also would be appropriate for the other zones. One can therefore use the term *colorectal zone* for the mucosa above the ATZ and *squamous zone* for the area below, which gradually merges into the perianal skin (Figure 27.6).

These zones are not always clearly visible to the clinician, and biopsy specimens should therefore be forwarded to the pathologist with an explanation of their location in relation to the DL. Biopsy samples from the lower part of the anal canal can be guided using a colposcope (Figure 27.7) (33 ,34).

Extent of the Zones

The colorectal zone, ATZ, and the area covered by squamous epithelium can easily be distinguished on longitudinal histologic sections (Figure 27.8). However, this method gives only limited information regarding the extent of the zones because the outlines are highly irregular. A better

impression is provided by staining the whole anal canal with Alcian dye. This method results in dark staining of the abundant mucus in the colorectal zone and an absence of staining in the squamous zone. The interposed ATZ is turquoise, due to sparse mucin production in the surface epithelium and scattered crypts (16). Subsequent serial sectioning of the whole specimen and comparison with the macroscopic picture gives a reliable measurement of the extent of the zones in the whole circumference of the anal canal (28).

Table 27.2 List of Terms for the Various Zones in the Anal Canal and Perianal Skin [a]

By using this method on a consecutive series of 113 anal canals, four main variants could be visualized. In most cases (88%), the ATZ started at the DL and extended on average 9 mm cranially (range: 3â€“20 mm) (Figure 27.9). In a few cases (7%), the ATZ started below the DL (Figure 27.10) or above the DL (4%) (Figure 27.11). In one case, the ATZ was totally absent (Figure 27.12). In addition, the method clearly demonstrated the highly irregular

outlines of the ATZ, especially at the upper border, as visualized by stereomicroscopy (Figure 27.13) (17). Others, using slightly different techniques on 28 anal canals, have found the median length of the ATZ to be about 5 mm (35).

The squamous zone normally extends downward from the DL, but squamous epithelium is often found covering parts of the anal columns (17). The lower border of the squamous zone is difficult to determine because the squamous zone gradually merges into the perianal skin. If the transition is defined by the occurrence of skin appendages, the lower border of the squamous zone is located outside the anal canal. This is particularly the case when hemorrhoids or prolapse is present. From this it follows that the histologic transition to perianal skin does not necessarily correspond to the definitions of the lower border of the anal canal.

The perianal region is not well defined; but, for the purpose of tumor classification, a boundary located 5 to 6 cm from the transition to squamous mucosa is recommended by the American Joint Committee on Cancer (AJCC) (36). This might be inappropriate as the region thus includes the most posterior parts of the vulva or scrotum.

Definitions of the Anal Canal

Various definitions of the anal canal have been suggested through the ages. Some are based on macroscopic landmarks (Figure 27.2), others on the extent of the epithelial zones (Figures 27.2 , 27.6). Of the two based on macroscopy, the anatomic anal canal, which extends from the DL down

to the anal verge, has been abandoned by most investigators because the definition leaves the ATZ and the characteristic tumors in this area outside the anal canal. The question is, therefore, to choose between the definitions of the *surgical anal*

canal and *histologic anal canal* , and there are advantages and drawbacks to both.

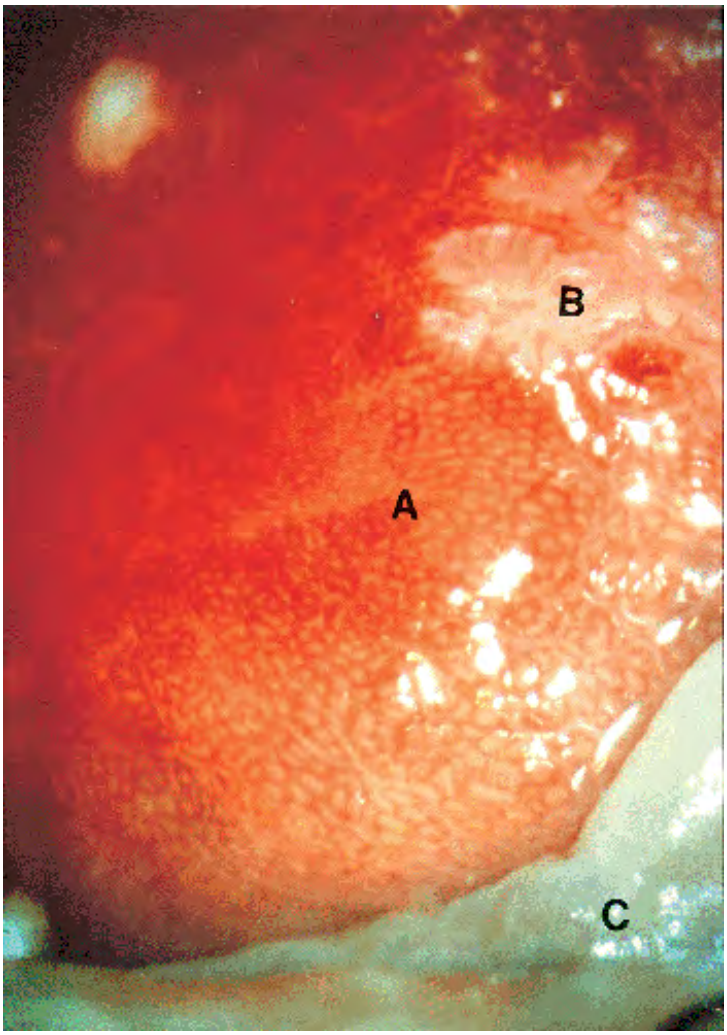

Figure 27.7 Colposcopy of the anal canal at the level of the dentate line. Compare the irregular outlines of the anal transitional zone with Figure 27.13 . (*A*, colorectal zone; *B*, anal transitional zone; *C*, squamous zone)

Figure 27.8 Longitudinal section of the anal canal showing the anal transitional zone (ATZ) and parts of the neighboring zones. At the upper border of the ATZ, a little island of squamous epithelium can be seen. The ATZ extends down into an anal sinus. The *vertical arrows* indicate anal glands in the submucosa and internal sphincter (H&E). The double horizontal arrows indicate the upper border of the AZT; the single horizontal arrow, the dentate line. (*A*, colorectal zone; *B*, anal transitional zone; *C*, squamous zone)

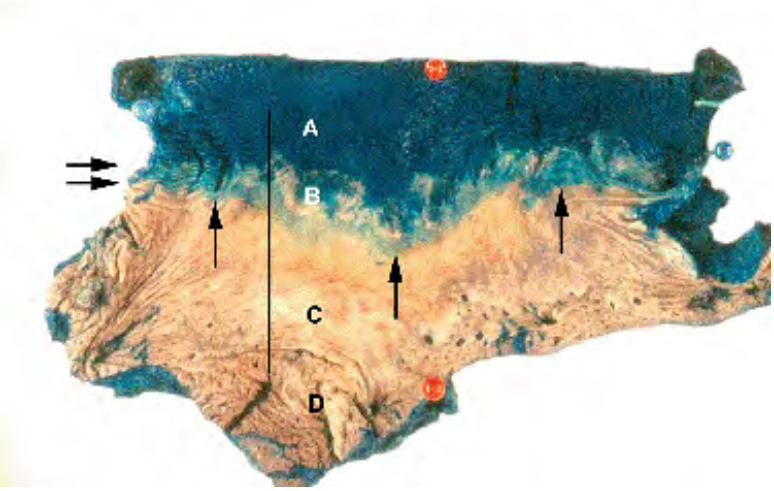

Figure 27.10 Surgical specimen of adult anal canal: low location of anal transitional zone (Alcian green for 15 min). (*Black vertical line* , extent of the anal canal; *single arrows,* dentate line; *double arrows,* upper border of the anal transitional zone; *A,* colorectal zone; *B,* anal transitional zone; *C,* squamous zone; *D,* perianal

skin)

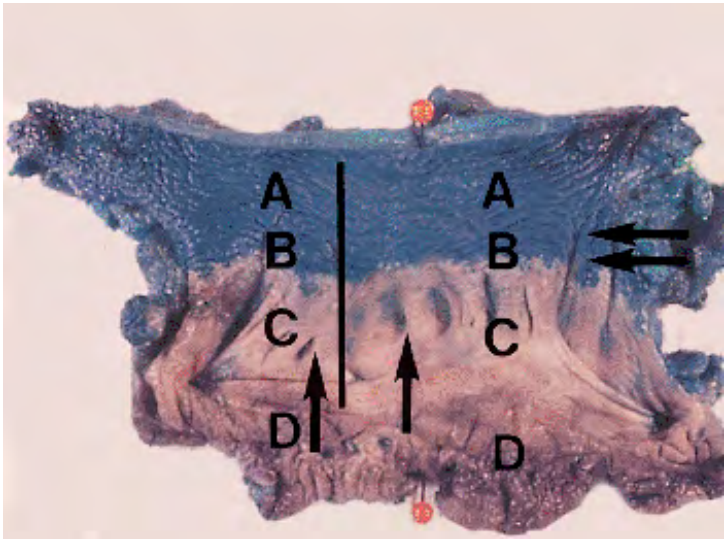

Figure 27.11 Surgical specimen of adult anal canal: high location of anal transitional zone, which here is very narrow (Alcian green for 15 min). (*Black vertical line* , extent of the anal canal; *single arrows,* dentate line; *double arrows,* upper border of the anal transitional zone; *A,* colorectal zone; *B,* anal transitional zone; *C,* squamous zone; *D,* perianal skin)

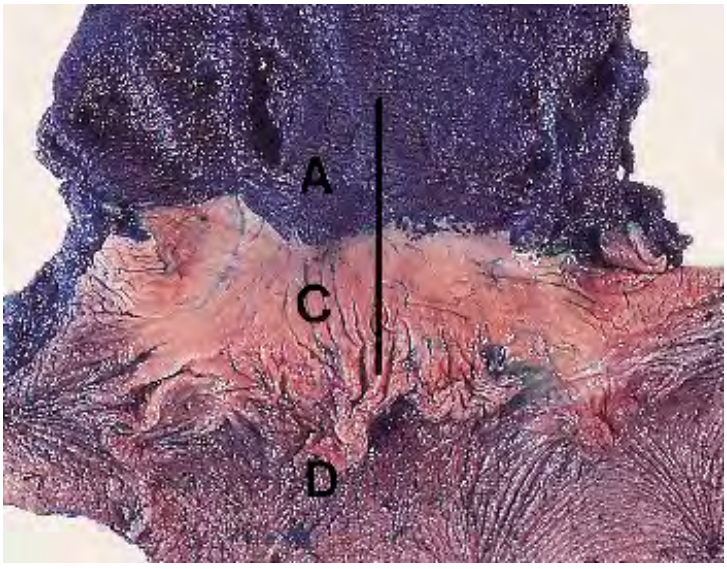

Figure 27.12 Surgical specimen of adult anal canal: no anal

transitional zone (Alcian green for 15 min). (*Black vertical line* , extent of the anal canal; *single arrows,* dentate line; *double arrows,* upper border of the anal transitional zone; *A,* colorectal zone; *C,* squamous zone; *D,* perianal skin)

The histologic anal canal is defined by the extent of the special mucosa in this area (i.e., the ATZ and the squamous epithelium down to the perianal skin). Using this definition, microscopic identification of the canal is reasonably easy, and all the special tumors in this area have their origin in the canal. The drawback is that the extent of the anal canal cannot be estimated by the clinicians and that colorectal neoplasias can have their origin inside the histologic anal canal because it also harbors colorectal-type epithelium scattered in the ATZ.

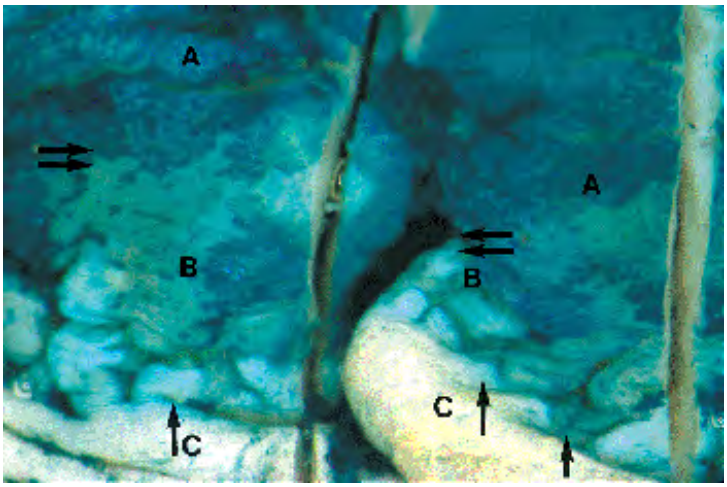

Figure 27.13 Close-up of the anal canal mucosa at the level of the dentate line. The highly irregular outlines of the anal transitional zone (*B*) contrasts to the heavily stained colorectal-type mucosa above (*A*) and the unstained squamous zone below (*C*). The vertical line is for later histologic control of the macroscopic staining (Alcian blue for 15 minutes).

The surgical anal canal can be identified easily by the clinician and described in the surgical report, thus making communication

between surgeon and pathologist easier. The surgical anal canal is also regarded as a functional unit. However, with regard to the mucosal lining, the surgical anal canal most often includes a ring of more or less normal appearing colorectal mucosa at its upper border.

The lack of agreement between macroscopic and microscopic definitions is well known from other areas (i.e., the cervical transformation zone and the esophagogastric junction) and must be accepted. The essential point is that when the clinician describes the location of a process or a biopsy, the position in relation to the DL is the important message. The pathologist will then report what epithelial types are present in the material and, considering the above-mentioned variations, decide whether it is normal.

As the anal canal is described using the definition of the surgical anal canal by the WHO (31), as well as in the tumor-node-metastasis (TNM) system (32), this definition will also be used in the following text.

Anatomy

Mucosal Surface

Following the definition of the surgical anal canal (18), the structure extends from the level of the pelvic floor (pelvic visceral aperture, anorectal ring) to the anal opening (anal verge) (Figure 27.2) and in a living person has an average length of 4.2 cm (37). Histologically, the anal canal extends from the upper to the lower border of the internal anal sphincter and has, on formalin-fixed specimens, an average length of 3 cm (16). This slight difference in definitions and measurements must be accepted because the curved appearance of the anal verge cannot be evaluated histologically and because loss of tonus and the fixation

procedures may influence the appearance of the specimens.

The anal lumen often forms a more or less triradiate slit when seen at anoscopy. The stem of the Y so formed approaches the midline posteriorly, and the arms embrace a pad of tissue anteriorly. Thus, three folds are seen, named the anal cushions (38). According to some investigators, the Y is asymmetric and usually embraces a pad of tissue to the right anteriorly (38 ,39). The anal cushions are present already in fetal life. In an opened surgical specimen from adults, these cushions are often inconspicuous.

The surface relief of the anal canal varies with age. The characteristic relief described in all anatomy textbooks is

most distinct in children (Figure 27.4). Here the mucosa shows six to ten vertical mucosal folds (the anal columns) that extend from a little below the middle of the anal canal and gradually disappear near the upper end. The anal columns are connected at their bases by small semilunar valves, which occasionally take the form of small papillae. Small pockets, the anal sinuses or crypts, are found behind the valves.

In adults (Figures 27.5 , 27.9 ,27.10 ,27.11 ,27.12), the mucosa often shows less pronounced valves and columns and may exhibit a smooth surface with or without scattered anal sinuses and papillae (16).

The three epithelial zones are faintly visible to the naked eye on unstained, formalin-fixed specimens (Figure 27.5). The upper third shows the same relief as the mucosa of the rectum above. The area immediately above the anal valves and sinuses usually appears more smooth and gray-blue. This is the ATZ. Distal to the sinuses, the squamous epithelium appears as a smooth gray-brown area (Stroud's pecten). At the lower border of the anal canal, the dull, wrinkled perianal skin with hair follicles is obvious.

Musculature

The exact arrangement of the anal musculature is still a subject of debate, and new information is still being added using anal endosonography, magnetic resonance imaging, and manometry (40 ,41). The muscles here are described from the inside out (Figure 27.6).

Musculus Submucosae Ani

The musculus submucosae ani, originally described by Treitz (42), also have been called musculus sustentator tunicae mucosae, musculus mucosus ani, and musculus canalis ani (43). They consist of fibers from the intersphincteric longitudinal muscle, which pass through the internal sphincter, and from the internal sphincter itself. In the submucosa, they form a network around the vascular plexus (Figure 27.14) and are sometimes connected to the muscularis mucosae upward. Caudally, they rejoin the muscles from which they came. Some fibers fan out in the perianal skin, where they may join fibers from the corrugator cutis ani muscle (38 ,43).

Internal Anal Sphincter

The internal anal sphincter is a continuation of the circular muscle coat of the rectum but is considerably thicker. In histologic sections it measures 5 to 8 mm in thickness and ends 5 to 19 mm (average: 11.4) below the DL (16). Using anal endosonography, the thickness is maximally 4 to 5 mm (41). The muscle receives sympathetic (motor) fibers and parasympathetic (inhibitory) fibers from the inferior hypogastric plexus. In contrast to the adjacent rectum, the internal sphincter contains no enkephalin-immunoreactive fibers, few substance Pâ€“reactive fibers, but moderate numbers of fibers reactive for neuropeptide Y and vasoactive intestinal peptide (44). Collagen fiber deposition

increases with age (45) and is higher in patients with neurogenic fecal incontinence (46). Pelvic irradiation may result in increased fibrosis and nerve density (47).

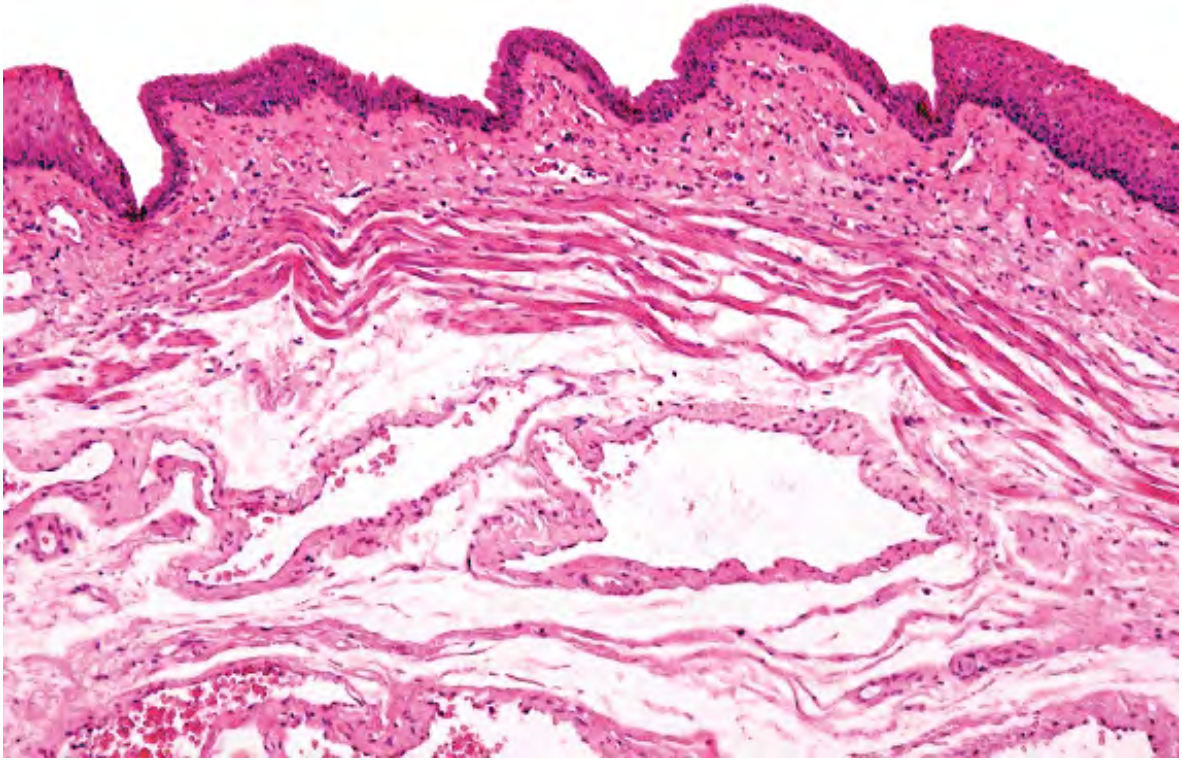

Figure 27.14 Anal transitional zone with columnar surface cells (*central*) and squamous epithelium (*left* and *right*). Vascular spaces located below fibers from the muscularis mucosae (H&E).

Intersphincteric Longitudinal Muscle

The intersphincteric longitudinal muscle is situated between the internal and external sphincters (Figure 27.6). Its thickness varies, and its exact function is unknown (40 ,48). It contains unstriped fibers from the longitudinal muscle coat of the rectum and striped fibers from the levator ani muscles. At the lower end of the internal sphincter, it breaks up into a number of septae,

which diverge fanwise through the subcutaneous part of the external sphincter to end in the corium, thus forming the characteristic corrugation of the perianal skin. These bands are, therefore, referred to as the corrugator cutis ani muscle.

External Sphincter

The striated anal sphincter is traditionally described as a circular muscle, which can be divided into a deep part and a superficial part that surround the internal sphincter and a subcutaneous part below these muscles (Figure 27.6). Most investigators have been unable to find a clear separation between these three parts (40). The puborectalis muscle is situated above the external sphincter. There are two prevailing theories about the arrangement of these muscles.

Shafik (49) has described three U-shaped loops, with their convexity directed backward, forward, and backward,

respectively. The top loop comprises the deep part and the puborectalis muscle, which is attached to the lower part of the symphysis; the intermediate loop is formed by the superficial part and is attached by a fibrous tendon to the dorsal part of the tip of the coccyx; the base loop is formed by the subcutaneous part, which is attached anteriorly to the perianal skin and is split from the longitudinal muscle by the above-mentioned fibers. Oh and Kark (50) described a double-loop theory according to which the puborectalis is directed anteriorly and most of the external sphincter posteriorly. This is in better accordance with recent endosonographical studies (40 ,41).

The superficial and subcutaneous parts differ from normal striated musculature. They consist of relatively small muscle fibers, in the adult predominantly of the slow switch type (type 1), separated by delicate strands of connective tissue (51 ,52).

Blood Supply

The arterial supply to the anal canal is considerably greater than would be necessary for metabolism alone. Branches from the superior rectal artery reach the ATZ in nearly all cases, but the middle and inferior rectal arteries often also make substantial contributions (38).

The terminal branches of the arteries split up into small tortuous vessels, some of which form tiny arteriovenous anastomoses with the submucosal venous plexus. This plexus consists of small convoluted vessels with discrete dilatations, which may be fusiform, saccular, or serpentine. Connective tissue fibers and fibers from the musculus submucosae ani are situated between the vessels, thus anchoring them to the internal sphincter. The picture is more complex above the DL, whereas the dilatations are fewer and often larger below it. The drainage is mainly cranial to the superior rectal vein, but branches of the superior, middle, and inferior veins communicate freely below as well as through the internal sphincter (38).

Some investigators have described so-called anal glomeruli, in which groups of small convoluted vessels were surrounded by connective tissue, which separated them from the surrounding loose tissue (Figure 27.15). Such structures probably represent thrombosed vessels with recanalization. The whole system has been referred to as the corpus cavernosum recti (although it is situated in the anal canal) and is more pronounced in the areas corresponding to the anal cushions (39) (Figure 27.16).

Hemorrhoids

According to this new understanding of anal vasculature, hemorrhoids or hemorrhoidal disease should be defined as enlargement or prolapse of the anal cushions, in some cases followed by bleeding and thrombosis (53 ,54 ,55). However, it is

still debated whether the term *hemorrhoid* or *hemorrhoidal tissue* also should be used to describe the normal anatomical structure or asymptomatic enlargement of the anal cushions (56 ,57).

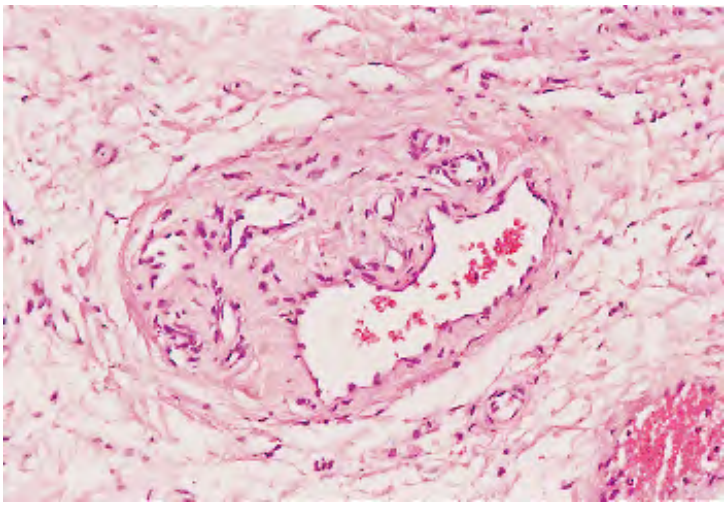

Figure 27.15 So-called anal glomerulus (H&E).

The pathogenesis of symptomatic hemorrhoids has been debated for many years, and a low-fiber diet, constipation and prolonged straining, abnormal anal pressure, hypertension in the anal cushions, and hereditary and hormonal factors may be involved. Others have found hemorrhoids associated with diarrhea and obesity but not with age, constipation, cirrhosis, or varicose veins (58).

Deterioration of the supporting and anchoring connective tissue and degenerative changes of the collagen fibers, together with replacement of muscle tissue by collagen, which begins in the third decade, make the structures less stable. The result is venous stasis and dilatation and sliding down of the anal cushions, sometimes followed by prolapse. Damage to the surface may lead to bleeding of arteriolar origin. Inflammation and focal pressure may be

followed by further stasis, edema, thrombosis, and

neovascularization (59).

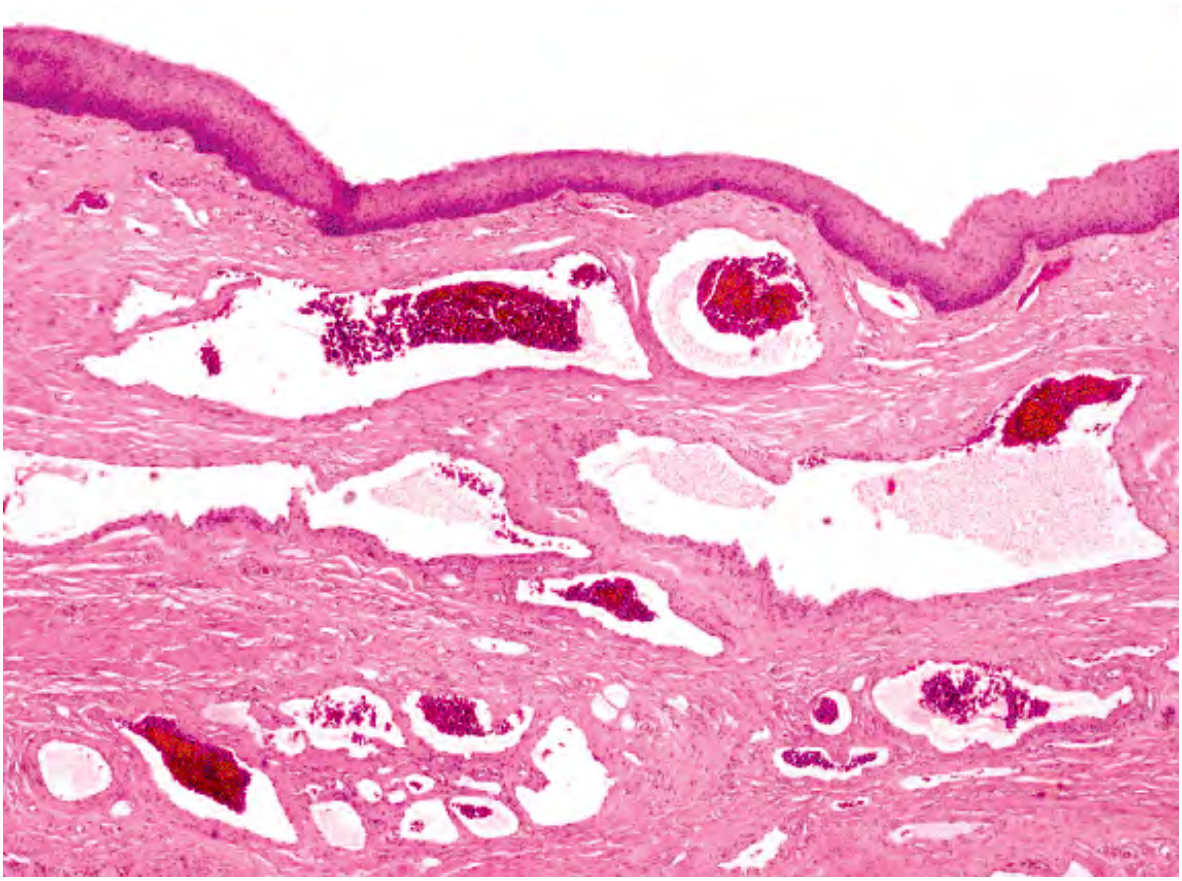

Figure 27.16 Longitudinal section through the anal transitional zone showing an anal cushion (H&E).

This new understanding harmonizes well with the histologic picture of tissue from hemorrhoidectomies. The specimens most often consist of connective tissue stroma with scattered fibers of smooth muscle. The stroma may contain many blood vessels and larger vascular spaces that vary in size and configuration and are often less than 2 to 3 mm in diameter. Inflammatory changes and signs of recent or past thrombosis may be present, as may stromal fibromuscular hyperplasia and elastic fiber proliferation. In some cases the removed hemorrhoid more resembles a fibroepithelial polyp (54). Neuronal hyperplasia is common (60). The surface lining depends on the degree of descent of the cushion and of

course the extent of the surgical excision. It therefore may show colorectal, ATZ, or squamous epithelium, as well as perianal skin. The mucosa may show inflammatory reaction or frank erosion or may be the site of regenerative, metaplastic, or keratotic reactions due to recurrent or permanent prolapse. The so-called fibrous anal polyp is assumed to represent an end stage of a prolapsed cushion (61).

Other Vascular Changes

There are a few differential diagnoses to chronic hemorrhoidal disease. Perianal thrombosis, formerly referred to as perianal hematoma, is an acute dark hard lesion arising under the squamous zone of the anal canal or the perianal skin. It represents a thrombus lying in the larger venous dilatations (61 ,62). Rectal varices are a result of portal hypertension and represent dilated submucosal veins formed when the communicating veins that connect the superior with the middle and inferior hemorrhoidal veins become enlarged. They extend above the level of hemorrhoids and occasionally downward to reach the buttock, perineum, or upper thigh (63 ,64). Diffuse cavernous hemangioma of the rectosigmoid is a vascular malformation consisting of vascular channels of variable size and thickness, which may involve the whole bowel wall and mesentery or perirectal tissue and may extend down to the DL (65). Recently, two cases of Dieulafoy's lesion in the anal canal have been described (66).

The vast majority of anal fissures occur in the posterior midline. A variant of the course of the inferior rectal artery has been blamed for a reduced perfusion of the posterior commissure and thereby of significance in the pathogenesis (67). Using Doppler laser flow cytometry, it has been shown that the blood flow in the posterior quadrant of the anal canal and perianal skin is significantly lower than in the anterior left and right quadrant and that the higher the anal pressure, the lower the perfusion (68). In addition, histologic

studies have shown a lesser arteriolar density in the posterior quadrant throughout the anal canal (69). These observations have led to the hypothesis that anal fissures are ischemic ulcers.

Nerves

Ganglion cells in the rectum are found in three separate plexuses: the superficial and deep submucous and the myenteric. In the anal canal, ganglion cells belonging to these plexuses are absent or sparse in the first centimeter above the DL (70). The diagnosis of ultrashort Hirschsprung's disease can be made by finding increased acetylcholinesterase reaction in muscularis mucosae and submucosa immediately above the DL (71). The density of interstitial cells of Cajal is significantly lower in the internal sphincter than in the circular muscle layer of the rectum (72).

The sensory innervation (73) of the lower part of the anal canal is accomplished by the inferior rectal nerves. The lining contains free nerve endings as well as organized endings (Meissner's corpuscles, Krause's end bulbs, Golgi-Mazzoni bodies, and genital corpuscles). It is sensitive to touch, pain, heat, and cold.

Sensitivity also can be demonstrated just above the DL in the ATZ, where the same endings can be found just above the anal valves. Thus, pain occasionally can be felt from injections given just above the DL. The ATZ is well supplied with intraepithelial nerve fibers and endings (74). Both types of nerve endings cease abruptly at the transition to the colorectal zone, where only a poorly defined dull sensation is present. However, discrimination seems not to be impaired by excision of the ATZ after restorative proctocolectomy (75).

Patients with hemorrhoids have a mild anal sensory deficit, probably due to the mucosal descent (76). Surgical specimens of hemorrhoids and their end stage, the fibrous polyp, may show proliferation of peripheral nerves without increased terminal

density (60) (Figure 27.17).

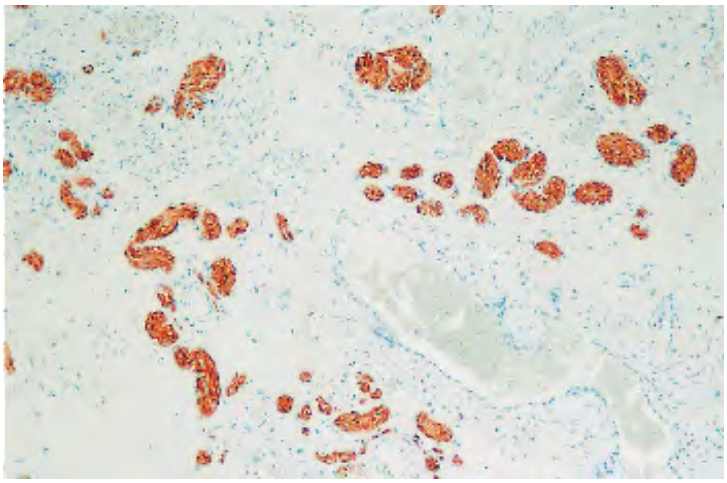

Figure 27.17 Neuromatous hyperplasia in the anal canal (S-100 protein).

Lymphatics

Lymphoid follicles are present in the anal canal from the DL and upward in approximately the same number as in the rectum (about 25/cm^2) (77).

The lower part of the anal canal (below the DL) and the perianal skin are drained to the superficial inguinal nodes. The drainage of the upper part is more complex, and varying results have been obtained from injection studies. Most investigators agree that an indirect or intramural system connects lymphatics in the anal canal to the lymphatic plexuses of the rectum (78). Other more direct lymphatics follow the inferior or medial rectal vessels to end in the hypogastric, obturator, and internal iliac nodes, or they follow the superior rectal vessels to end in nodes in the sigmoid mesocolon and near the origin of the inferior mesenteric artery. Occasional connections also have been demonstrated to the common iliac, middle and lateral sacral, lower gluteal, external iliac, and deep

inguinal nodes (79).

Lymphatic metastases from carcinoma of the anal canal are most often found in the inguinal, femoral, pararectal, and iliac nodes, and eventually in the mesenteric or para-aortical nodes. Hematogenous metastases are most often located in the liver and lungs (31 ,36). Studies on sentinel nodes in anal cancer are ongoing (80).

Histology

Colorectal Zone

The mucosa of the upper, colorectal zone is a continuation of the rectal mucosa, and no line of demarcation marks the transition to the anal canal. However, some shortening and irregularity of the crypts often are found in the area closest to the ATZ (Figure 27.18).

Anal Transitional Zone and Anal Glands

As stated above, the upper border of the ATZ is defined by the appearance of other epithelial types. In one-third of cases, the upper part of the ATZ consists of a small rim of mature squamous epithelium (Figures 27.8 , 27.18) (16). Many epithelial variants can be found in the ATZ, the most prominent being the so-called ATZ epithelium.

The term *ATZ epithelium* (81) is not generally accepted but can be used until an exact classification is established. It consists of four to nine cell layers. The basal cells are small, and their nuclei are arranged perpendicular to the basement membrane. The surface cells can be columnar (Figure 27.19), cuboidal or polygonal (Figure 27.20), or flattened (Figure 27.21). Small areas can show umbrella-shaped surface cells and more distinct cell borders (Figure 27.22). Other epithelial types are often

present in the ATZ. Small areas of mature squamous epithelium may be present, especially at the upper border. Scattered crypts of colorectal type and small areas of simple columnar epithelium also may be found.

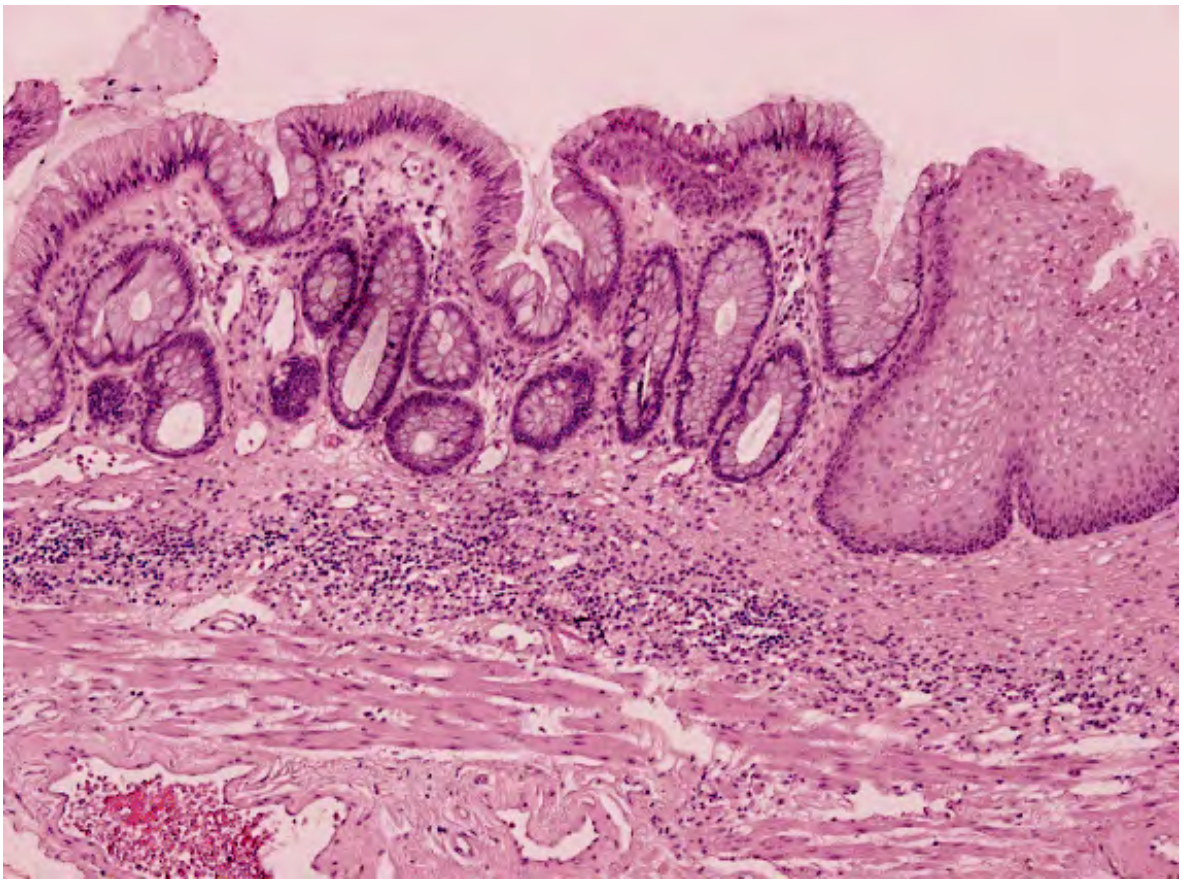

Figure 27.18 Transition between the colorectal zone of the anal canal and the anal transitional zone. Short, slightly irregular crypts. Muscularis mucosae still present (H&E).

The anal (intramuscular) glands open in the ATZ (Figure 27.8). These glands seem to be present in all anal canals and the median number is six, with a range of three to ten. Four of five are only present in the submucosa, but the rest extend into the internal sphincter and a few percent reach the intersphincteric space or even penetrate the external sphincter (82 ,83). The epithelial lining and mucin production are similar to the ATZ epithelium (84

), and endocrine cells are occasionally present (85). A characteristic feature is the presence of intraepithelial microcysts and occasionally goblet cell metaplasia (Figure 27.23). The epithelium is surrounded by one or two cell layers of myoepithelial cells that stain positive for smooth muscle actin (83). The glands are often surrounded by groups of lymphocytes. It is

believed that the anal glands may take part in the formation of fistulas. Cysts are usually due to trauma and inflammation. Well-documented cases of anal gland carcinoma are rare (84 ,86).

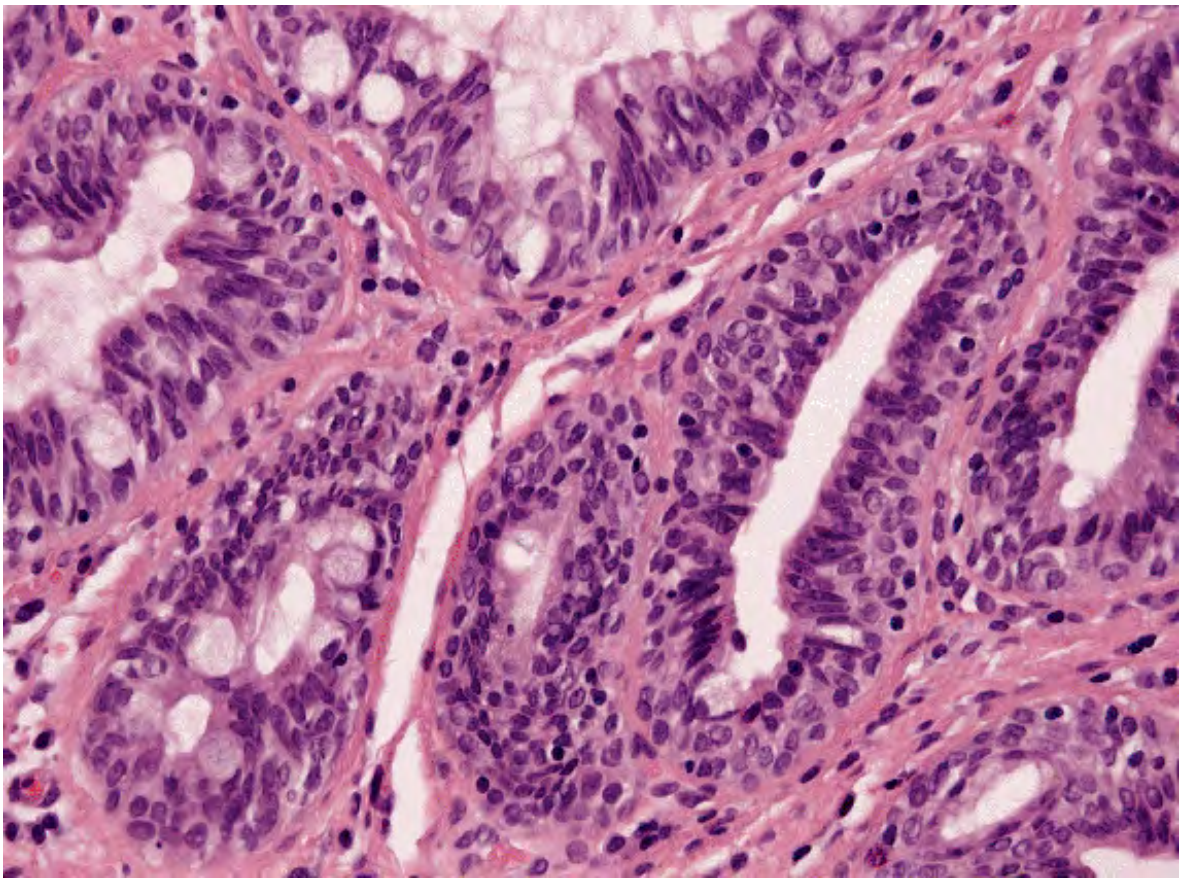

Figure 27.23 Anal gland in the submucosa of the anal transitional

zone (ATZ). Epithelium is as in ATZ with scattered goblet cells (H&E).

Squamous Zone

The transition to uninterrupted squamous epithelium usually takes place at the level of the DL. The squamous epithelium is unkeratinized with short or no papillae. Melanocytes increase in number as the perianal skin is approached, and the epithelium contains dendritic (Langerhans) cells (60) (Figure 27.24), T lymphocytes (87), and Merkel cells (88) (Figure 27.25). These cells also may be present in squamous metaplasia covering hemorrhoids. The number of dendritic cells is increased in cases of condylomata but decreased in case of concomitant HIV infection (89). Glands or skin appendages are never present in the squamous zone.

Perianal Skin and Glands

Keratinization becomes apparent at the lower end of the anal canal, and the squamous zone gradually merges into the perianal skin with sweat glands, hairs, and sebaceous glands. A characteristic finding is the presence of apocrine glands in the subcutaneous tissue (Figure 27.26). An additional type of glands, the so-called anogenital sweat glands, are lined by a simple columnar epithelium with cytoplasmic â€œsnoutsâ€• protruding into the lumen and resting on a layer of flat myoepithelium (90) (Figure 27.27). These glands are probably the point of origin for papillary hidradenoma (91).

Lamina Propria and Muscularis Mucosae

The lamina propria consists of loose connective tissue which in the

squamous zone often contains a variable number of

mast cells and small mononuclear or multinucleated CD34+ stromal cells probably of fibroblastic origin (Figure 27.28). It has been suggested that these cells are involved in the formation of fibroepithelial polyps (92 ,93 ,94). Fibroepithelial polyps occasionally also show neuronal hyperplasia and hyaline vascular changes (60 ,94).

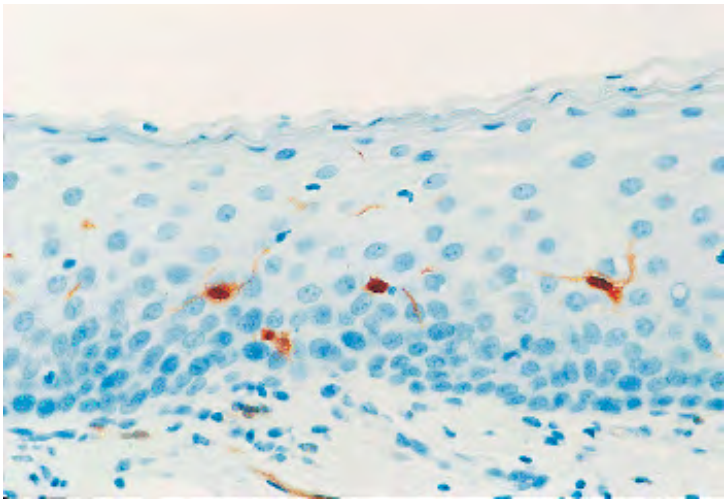

Figure 27.24 Langerhans cells in the squamous zone (S-100).

The well-defined muscularis mucosae of the rectum continue in the colorectal zone of the anal canal (Figure 27.18) and can be found in the upper part af the ATZ (Figure 27.14). Fibers extending up between colorectal crypts indicate mucosal prolapse, and most fibroepithelial polyps also contain fibers from the muscularis mucosae (92 ,94).

Special Techniques

Mucin Histochemistry

The columnar variant of the ATZ epithelium produces small amounts of a mixture of sulfomucins and sialomucins,

characterized by a scarcity of O-acylated sialic acids, in contrast to the colorectal type mucosa above (95).

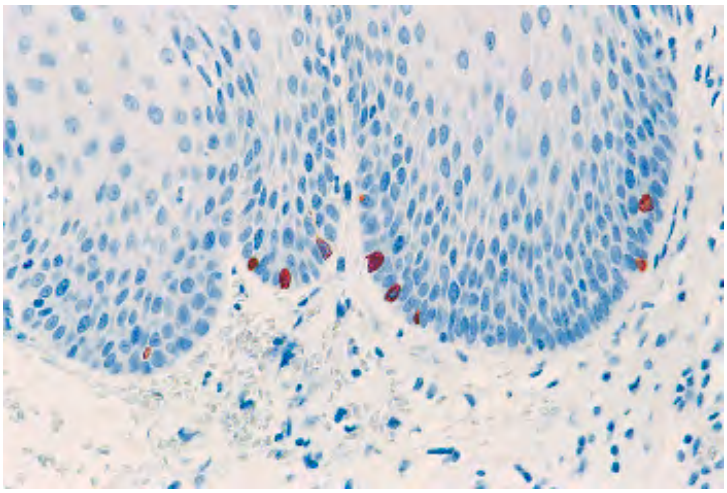

Figure 27.25 Merkel cells in the squamous zone (CK20).

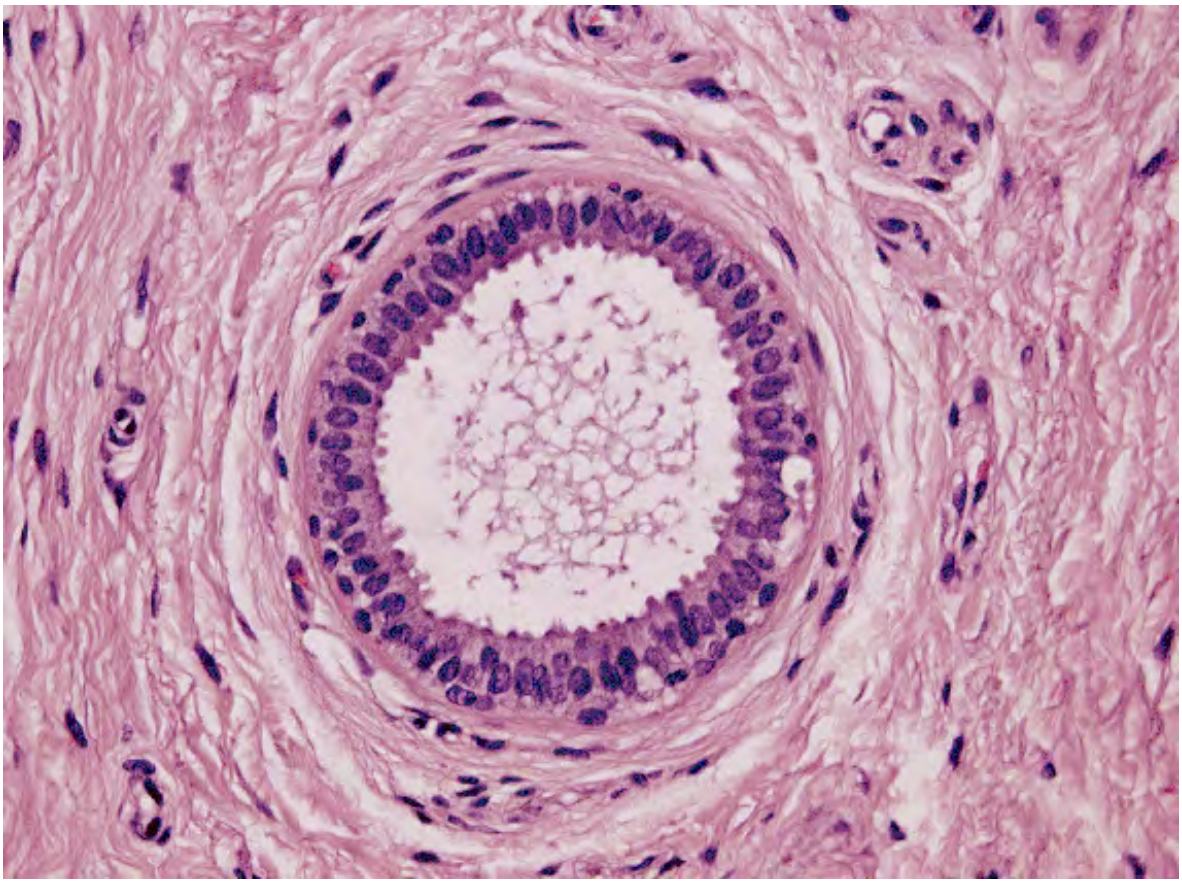

Figure 27.26 Apocrine gland (H&E).

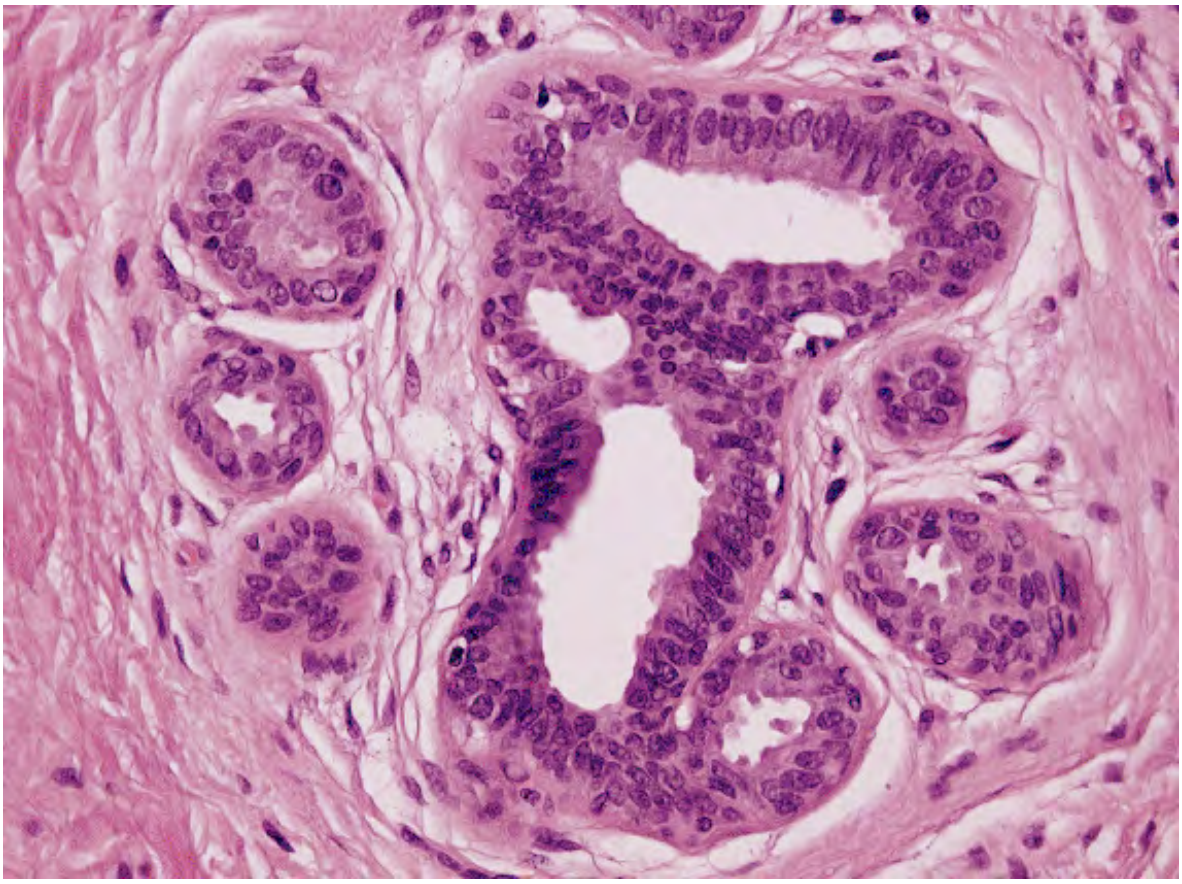

Figure 27.27 Anogenital sweat gland (H&E).

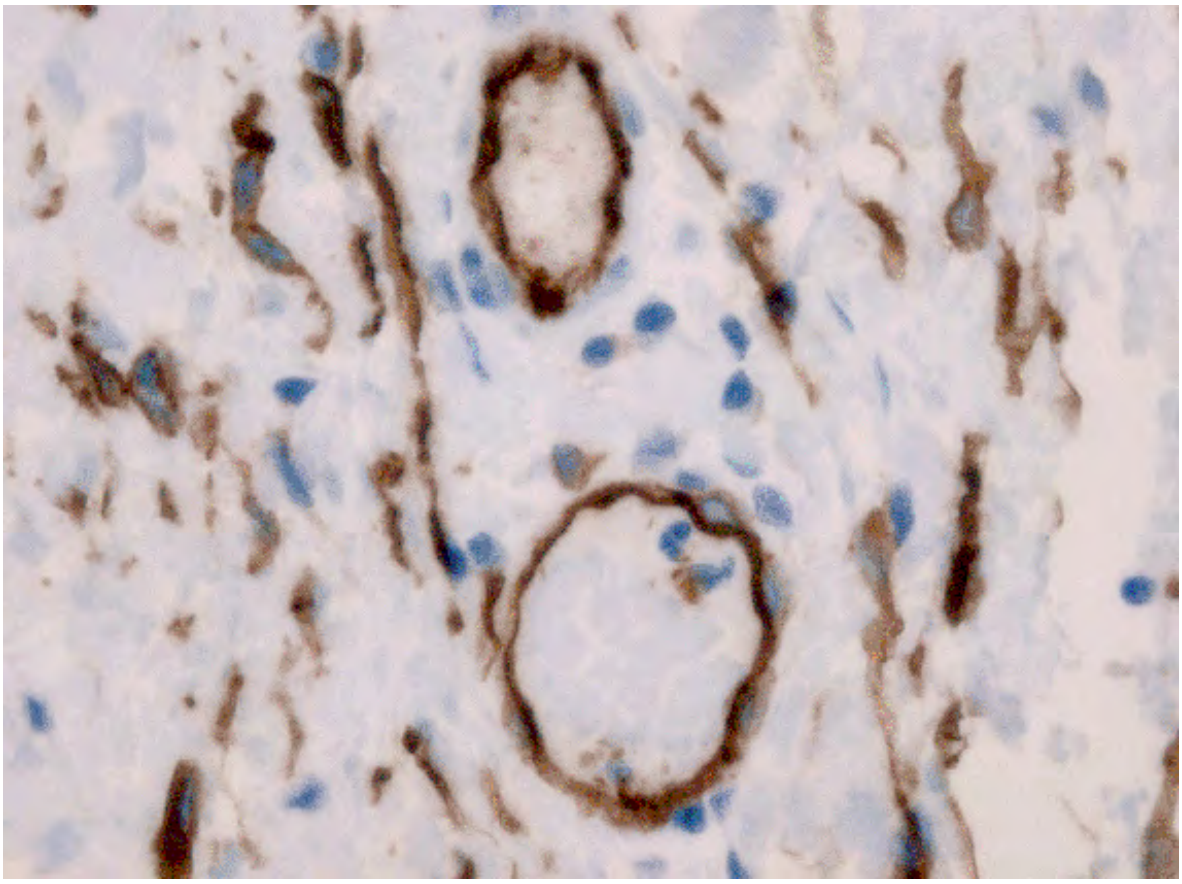

Figure 27.28 Stromal cells (CD34).

Cytokeratins

The keratin expression of the various epithelial types in the anal canal is complex (96). Briefly, the typical reactions in colorectal type epithelium are CK20+/CK7â€“ and in ATZ epithelium and anal glands CK7+/CK20â€“, and this pattern is also found in tumors originating in the respective epithelia (86 ,97 ,98).

The reaction for CK7 varies in the ATZ epithelium, sometimes being very strong throughout all layers, sometimes being absent in the basal layer or the whole epithelium (Figure 27.29). In addition, the ATZ and anal glands are usually positive for cytokeratins 4, 8, 13, 16, 17, 18, and 19. The coexpression of CK4 and CK13 has also been observed in the transitional epithelium of

the urinary bladder.

Proliferation Markers

The proliferative marker MIB-1 for Ki-67 is positive in a layer of cells immediately above the basal layer and may be quite pronounced, especially in cases of hemorrhoids and prolapse (Figure 27.30). However, the reaction still differs from that seen in anal intraepithelial neoplasia (Figure 27.31).

Hormone Receptors

Androgen, estrogen, and, to a lesser degree, progesterone receptors have been demonstrated in the squamous epithelium, as well as in the underlying stroma and in the smooth muscle cells of the internal sphincter in most individuals and at all ages, indicating that the organ is a target for sex steroid hormones (99). The anogenital sweat glands and the corresponding papillary hidradenoma show positive reaction for estrogen and progesterone receptors, in contrast to conventional sweat glands (91) (Figure 27.32).

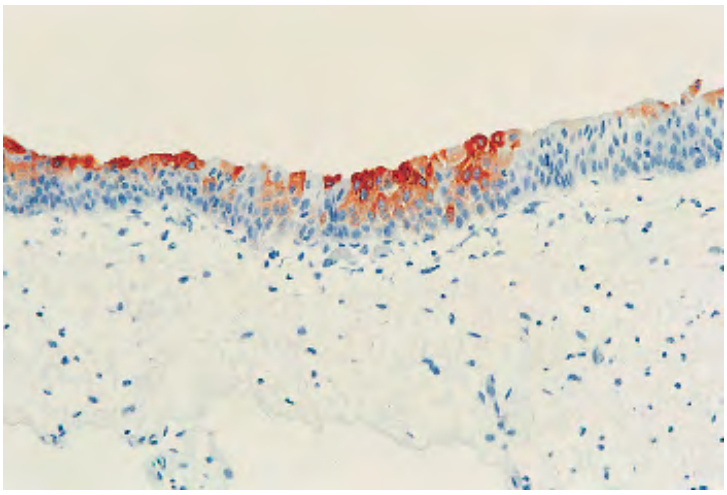

Figure 27.29 ATZ epithelium with varying cytokeratin expression (CK7).

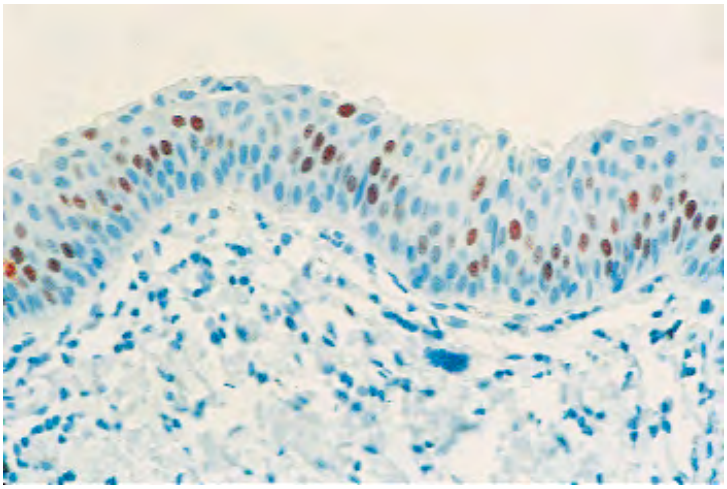

Figure 27.30 ATZ epithelium: proliferative activity (MIB-1).

Neuroendocrine Markers

The characteristic epithelia of the ATZ and anal glands contain a heterogeneous population of endocrine cells (81 ,85), which all show positive reaction for synaptophysin and chromogranin A (Figure 27.33). The cells have slender processes that approximate the surface and a fine granular cytoplasm. The number varies, and the largest population also reacts for serotonin and pancreastatin, but cells positive for somatostatin, peptide tyrosine tyrosine, glucagon-like peptide 1, calcitonin geneâ€“related peptide, protein gene product 9.5, and neurotensin are occasionally present. The pattern is a mixture of products typical for colorectal epithelium and for Merkel cells in the squamous epithelium (88 ,100).

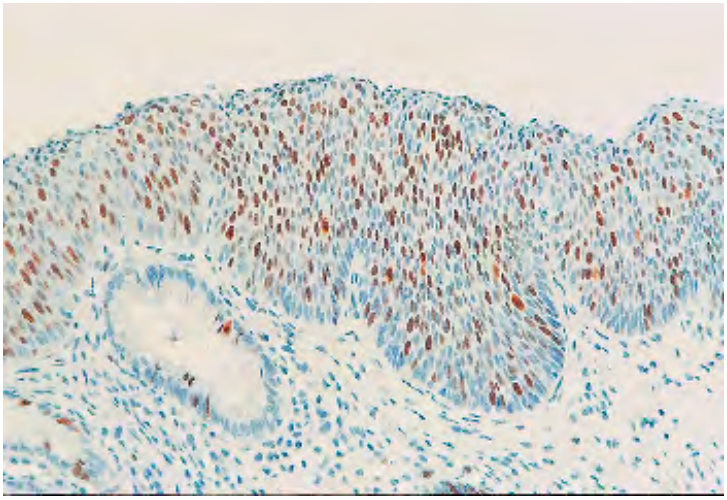

Figure 27.31 Anal intraepithelial neoplasia (AIN): proliferative activity (MIB-1).

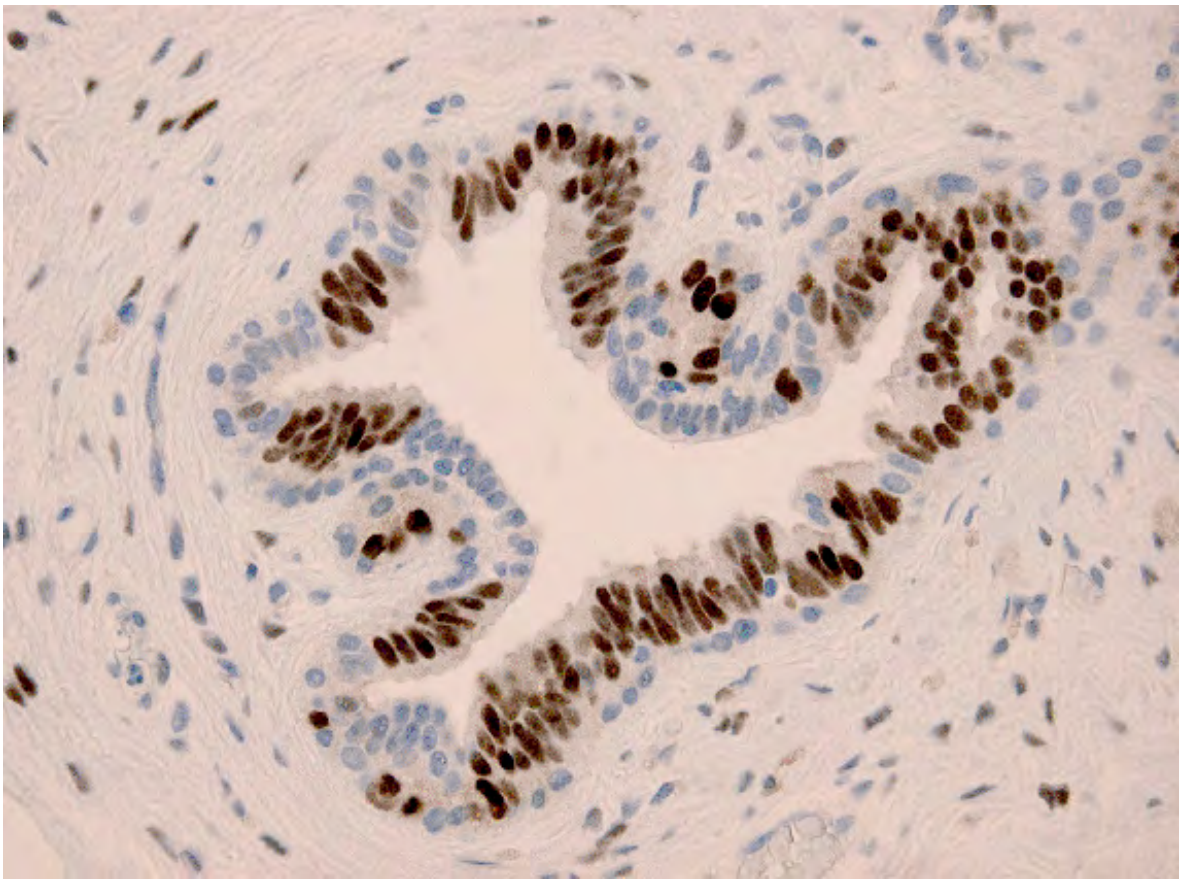

Figure 27.32 Anogenital sweat gland (estrogen receptor).

Melanin-Containing Cells

A few melanocytes are also occasionally present in the ATZ (85 ,101 ,102). These are CK7â€“/CK20â€“ and positive for S-100 protein, Melan A, and HMB-45 (Figure 27.34). The corresponding malignant melanoma may be amelanotic and positive for polyclonal but not monoclonal carcinoembryonic antigen (CEA) (103).

Flow Cytometric Microscopy and Electron Microscopy

Flow cytometric DNA analyses of the ATZ epithelium have shown a dominating diploid population with a small hyperdiploid peak, resembling the picture of metaplastic epithelium (104). Transmission electron microscopy has not shown asymmetric unit membranes. In scanning electron microscopy, the surface cells show distinct cell borders and short microvilli (Figure 27.35) (81).

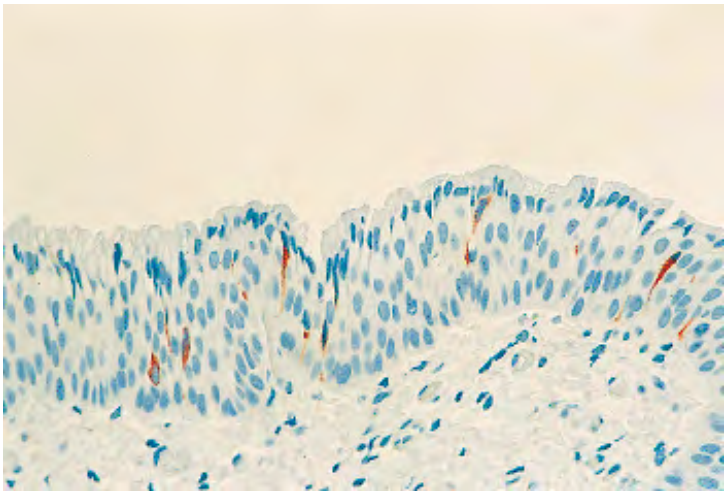

Figure 27.33 Anal transitional zone epithelium: endocrine cells (chromogranin).

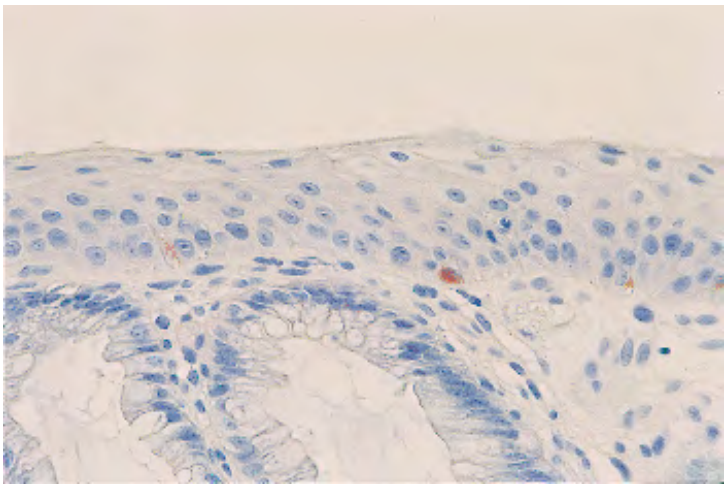

Figure 27.34 Anal transitional zone: three melanin-containing cells in the surface epithelium (HMB-45).

Metaplasia and Heterotopia

Other epithelial types may be present and sometimes indicate pathologic conditions. Occasionally, colorectal-type crypts in the ATZ may contain Paneth's cells (Figure 27.36) or show pyloric metaplasia (Figure 27.37), probably as a result of mucosal damage (as in longstanding colitis). Squamous metaplasia in the ATZ and even in the colorectal zone is seen in cases of prolapse, and keratinization may be present (Figure 27.38).

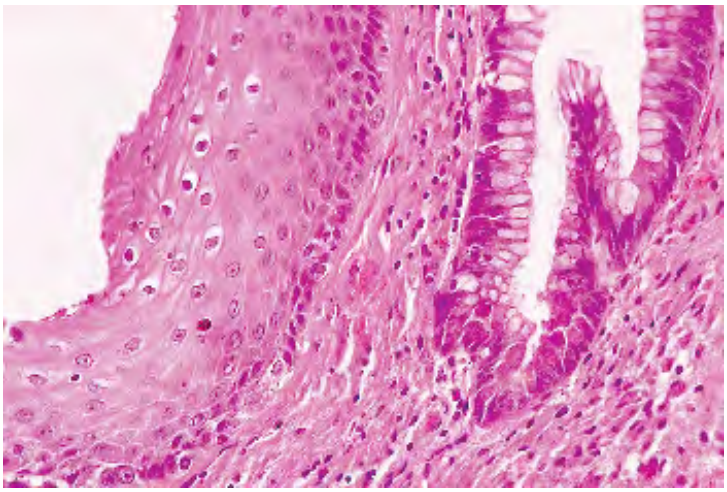

Figure 27.36 Anal transitional zone: area with squamous epithelium covering a colorectal-type crypt with Paneth's cell metaplasia (H&E).

I have seen a single example of fundic gastric mucosa in the anal canal. Such areas, rarely found in the rectum, are histochemically almost identical to their orthotopic counterpart (105). Probably *Helicobacter pylori* can turn up in the anal canal as it has done in body-type gastric epithelium in the rectum (106). A unique case has been reported showing ectopic prostatic tissue in the lower anal canal (107).

Viral and Neoplastic Changes

Cytomegalovirus, which occasionally infects the rectum, is rarely

seem in the anal canal histiocytes (108). Herpesvirus-induced changes are more commonly found in the squamous epithelium (Figure 27.39), and koilocytotic changes due to human papillomavirus (HPV) can be found as high up as in the ATZ (Figure 27.40).

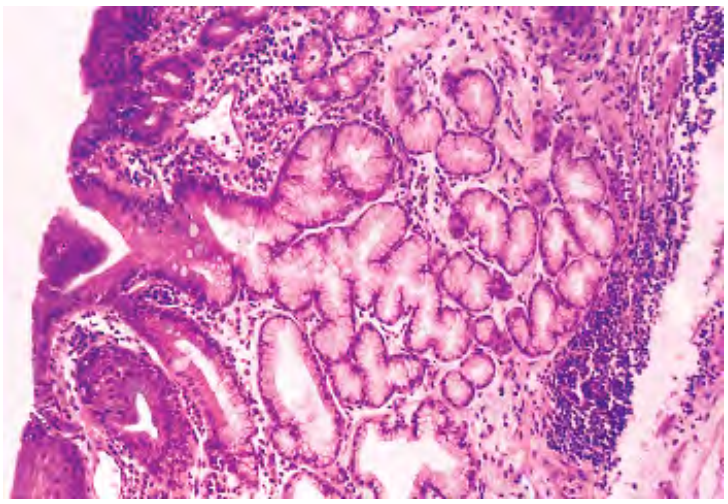

Figure 27.37 Anal transitional zone: area with group of pyloric-type glands (H&E).

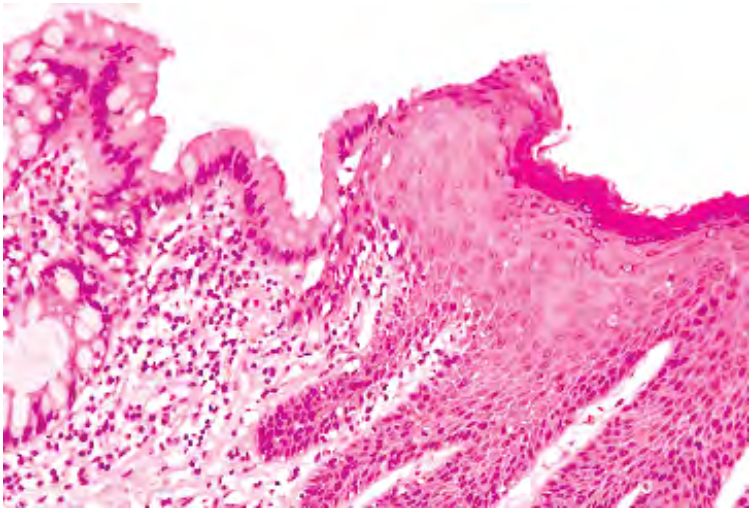

Figure 27.38 Anal transitional zone: keratinizing squamous epithelium extending up to the colorectal zone, as is typical in cases of prolapse (H&E).

Anal intraepithelial neoplasia (AIN), also referred to as dysplasia or anal squamous intraepithelial lesion (ASIL), is not uncommon. It may be present in the squamous zone as well as in the ATZ and in minor surgical as well as in resection specimens (Figures 27.31 , 27.41) (109 ,110). Squamous carcinoma and AIN are particularly common among men who have sex with men, patients with HIV/AIDS, and transplant recipients and in the rare syndromes Wiskott-Aldrich and epidermodysplasia verruciformis, indicating an attenuated immune response is of importance (111). High-risk HPV is found in most lesions, in particular those located high in the anal canal (112). Exact and reproducible grading of AIN is difficult in biopsies, as well as in cytologic specimens (113 ,114 ,115). Follow-up studies have shown that many cases of AIN Iâ€“II will regress but that a considerable number of AIN III will recur, even aften highly active antiviral therapy. There are however only few documented cases of transition to

squamous carcinoma, and the real risk is unknown (33 ,116 ,117).

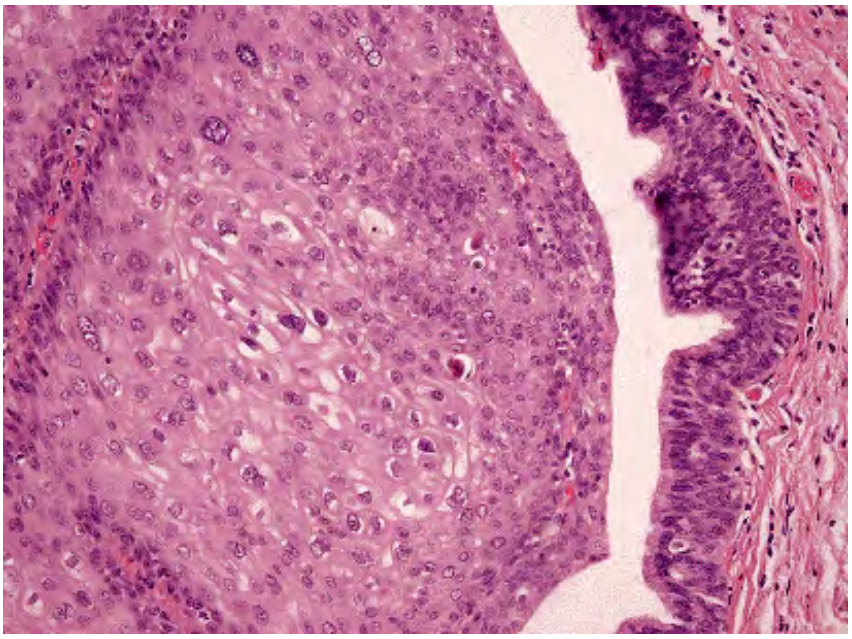

Figure 27.40 Anal transitional zone: area with squamous epithelium showing koilocytotic changes. Normal ATZ epithelium to the *right* (H&E).

Squamous carcinoma of the anal canal may have different appearances (i.e., basaloid or keratinizing), but there is substantial overlap of the histologic features found in these tumors (112 ,118), and the reproducibility of the older WHO classification is rather low (119). In the recent WHO classification, it is therefore recommended that the generic term *squamous carcinoma* be used for these tumors (31). Prognostic markers have not yet been identified (120). A summary of tumors originating in the different zones is listed in Table 27.3 .

Finally, it should be remembered that the anal area is a common site of extramammary Paget's disease and that many of these patients have a synchronous or metachronous malignant tumor. Paget's cells must be distinguished from artifactual clear cells, glycogen-rich cells, koilocytes, and clear cells in pagetoid dyskeratosis, pagetoid Bowen's disease and pagetoid melanoma (121) (Figure 27.42).

True Paget's cells nearly always show positive reactions for mucin, CEA, and CK7 (Figure 27.43) (122). Primary Paget's is usually positive for gross cystic disease fluid protein and negative for CK20, while the opposite pattern is found in Paget's secondary to colorectal adenocarcinoma (98).

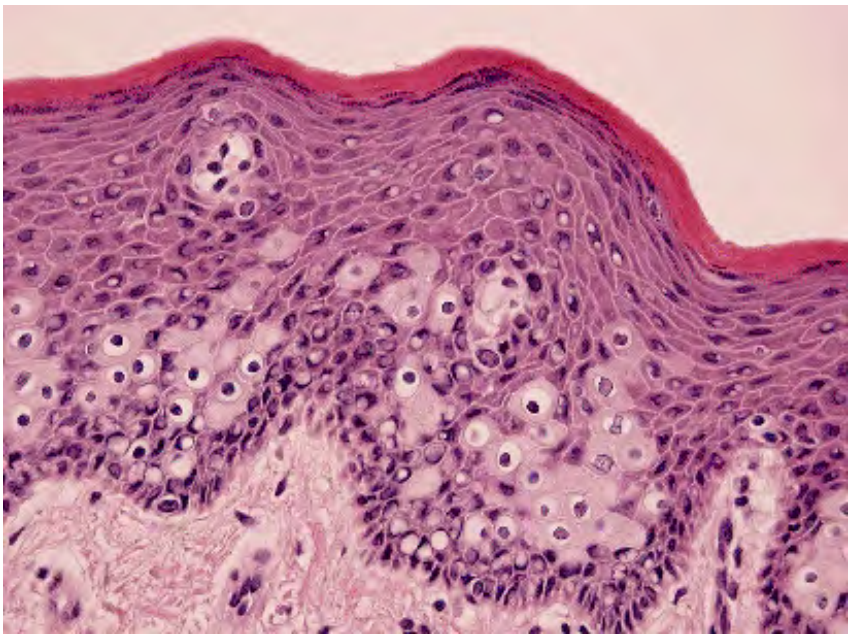

Figure 27.42 Squamous zone: clear cells in pagetoid dyskeratosis (H&E).

Function

The normal function of the rectum and anal canal is the result of a combination of factors, including not only the puborectalis and sphincter muscles, but also stool volume and consistency, rectal storage capacity, sensation, and delivery, as well as cognitive and behavioral influences. The functional disorders, the various techniques for investigation of anorectal dysfunction, and the diagnosis and treatment have been extensively reviewed recently (123 ,124 ,125). The significance of the ATZ for normal anal function is still a subject of debate (126).

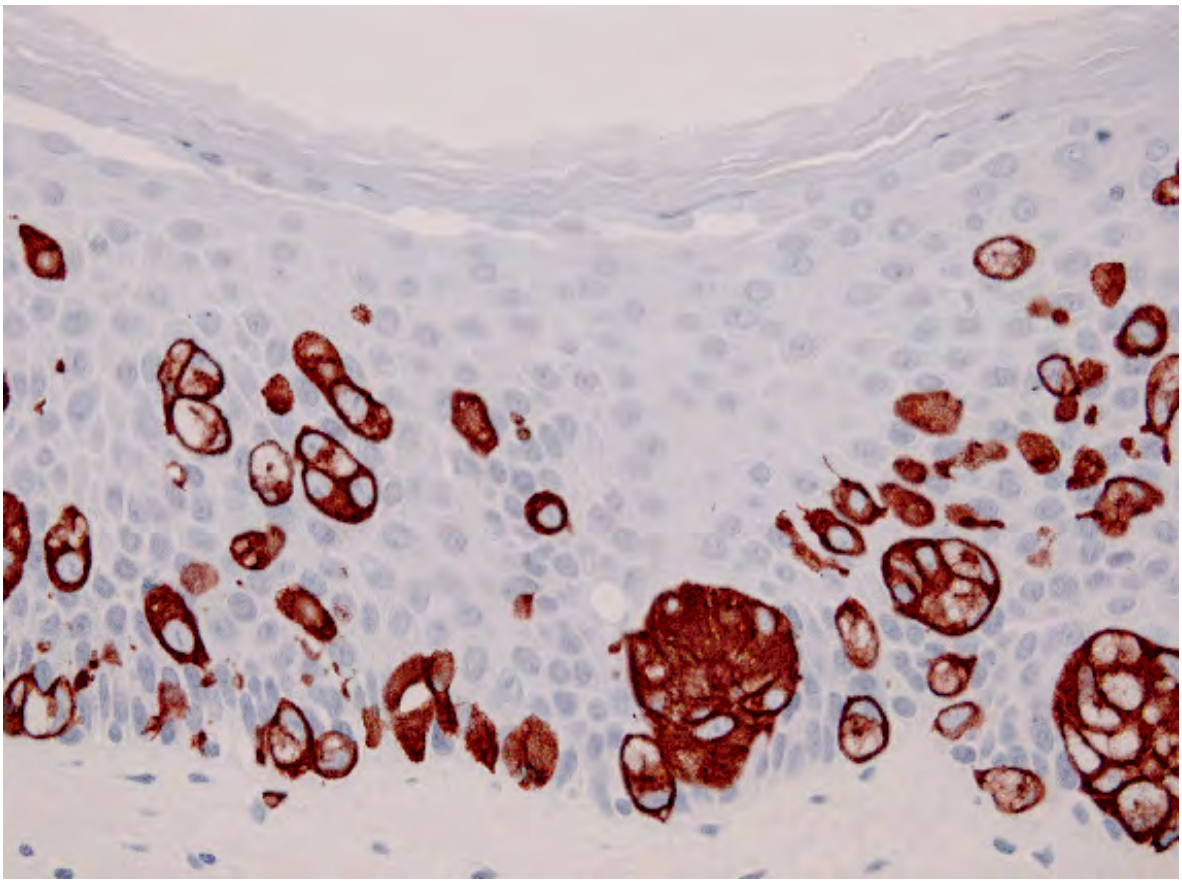

Figure 27.43 Squamous zone: Paget's cells (CK7).

Gender and Aging

There is little information on differences in the anal canal between the two sexes and as a result of aging. The surgical anal canal is a few millimeters shorter in females (4.4 cm

vs. 4.0 cm in males) (37), and the external sphincter is also shorter, particularly its anterior part (40 ,41). With aging, the collagen fiber deposition increases in the internal sphincter (45).

The mucosal surface is often more smooth in the elderly, and the papillae may be more pronounced (Figure 27.5). The underlying connective tissue becomes less stable, which may result in descent of the anal cushions and subsequent squamous metaplasia of the

ATZ (54). The number of lymphoid follicles does not change with age (77).

Specimen Handling

In minor surgical specimens it is often possible to identify the smooth gray-brown squamous zone from the gray-blue, more glistening anal mucosa. The tissue always should be cut and embedded along the longitudinal axis in order to describe the lesions (i.e., AIN) in relation to the different epithelial zones.

Local excisions should be provided by the surgeon with a suture at the proximal end, pinned up on a plate and sectioned in the same way with special attention to resection lines. Larger surgical specimens are rare nowadays where anal carcinoma most often is treated nonsurgically. They should also be pinned up, and multiple sections may be necessary to find or exclude residual tumor tissue. Information on previous radiation therapy should be provided.

Normally most diagnoses can be established without the use of special stains, but occasionally a panel of immunohistochemical reactions is useful (Table 27.4).

Introduction

The embryology, gross morphology, and histology of the normal human liverâ€”the single largest organ in the human bodyâ€”are described in this chapter. It is emphasized that liver biopsy specimens must be processed with special care in order to obtain optimal sections for diagnostic histologic evaluation. In many instances, immunohistologic studies of liver tissue have the potential to yield more information than electron microscopy. In surgical and autopsy liver specimens, nonspecific histologic alterations may be prominent, but they often have little significance. On the other hand, some morphologic changes, particularly in needle biopsy specimens, are frequently subtle but may be of diagnostic importance. The pathologist must be familiar with these histologic variations of and from the normal liver.

Embryology

The liver arises as the hepatic diverticulum from the endodermal lining of the most distal portion of the foregut during the third to fourth week of gestation (1,2,3). In embryos 4 to 5 mm in length,

the hepatic diverticulum differentiates cranially into proliferating hepatic cords and caudally into the gallbladder and extrahepatic bile ducts. The anastomosing cords of hepatic epithelial cells grow into the mesenchyme of the septum transversum. As the hepatic cords extend outward during the fifth week of gestation, they are interpenetrated by the inwardly growing capillary plexus, which arises from the vitelline veins in the outer margins of the septum transversum and forms the primitive hepatic sinusoids.

Scattered mesenchymal cells derived from the septum transversum lie between the endothelial wall of the

sinusoids and the hepatic cords and form the connective tissue elements of the hepatic stroma, as well as the capsule, which is covered by a mesothelial layer. Hematopoietic tissue and Kupffer cells also derive from splanchnic mesenchyme of the septum transversum. Once these structures are established, the liver grows rapidly to fill most of the embryonal abdominal cavity and by nine weeks' gestation accounts for approximately 10% of the total weight of the embryo (4). The bile canaliculi appear in the 10-mm embryo as intercellular spaces between immature hepatocytes (hepatoblasts).

The epithelium of the intrahepatic bile ducts arises from the proximal part of the primitive hepatic cords. This process is largely determined by the progressive development and branching of the portal vein with its surrounding mesenchyme. First, the epithelial layer in direct contact with the mesenchyme around the portal vein transforms into bile ductâ€“type cells. Then a second layer transforms into bile duct epithelial cells, resulting in a circular cleft in the shape of a cylinder around the portal vein and its enveloping mesenchyme (Figure 28.1). This primitive channel duct in the 8-mm embryo (five to six weeks of gestation) is termed the ductal plate (5), which then undergoes gradual remodeling to form the normal anastomosing system of bile ducts in the portal tracts (6,7). The differentiation of intrahepatic ducts is recognized in embryos of 22 to 30 mm. Despite the common

ancestry of hepatic parenchymal cells and ductal epithelium, each cell type is structurally and functionally distinct. The walls of the terminal twigs of the biliary tree, the canals of Hering, which connect bile canaliculi to bile ducts, include both typical hepatocytes and bile duct cells, without intermediate forms.

Functionally, intrahepatic hematopoiesis begins during the sixth week, hepatocyte bile formation by the twelfth week, and excretion of bile into the duodenum by the sixteenth week. The third trimester marks the cessation of hematopoiesis with a concomitant decrease in liver growth so that the liver accounts for approximately 5% of the newborn's body weight.

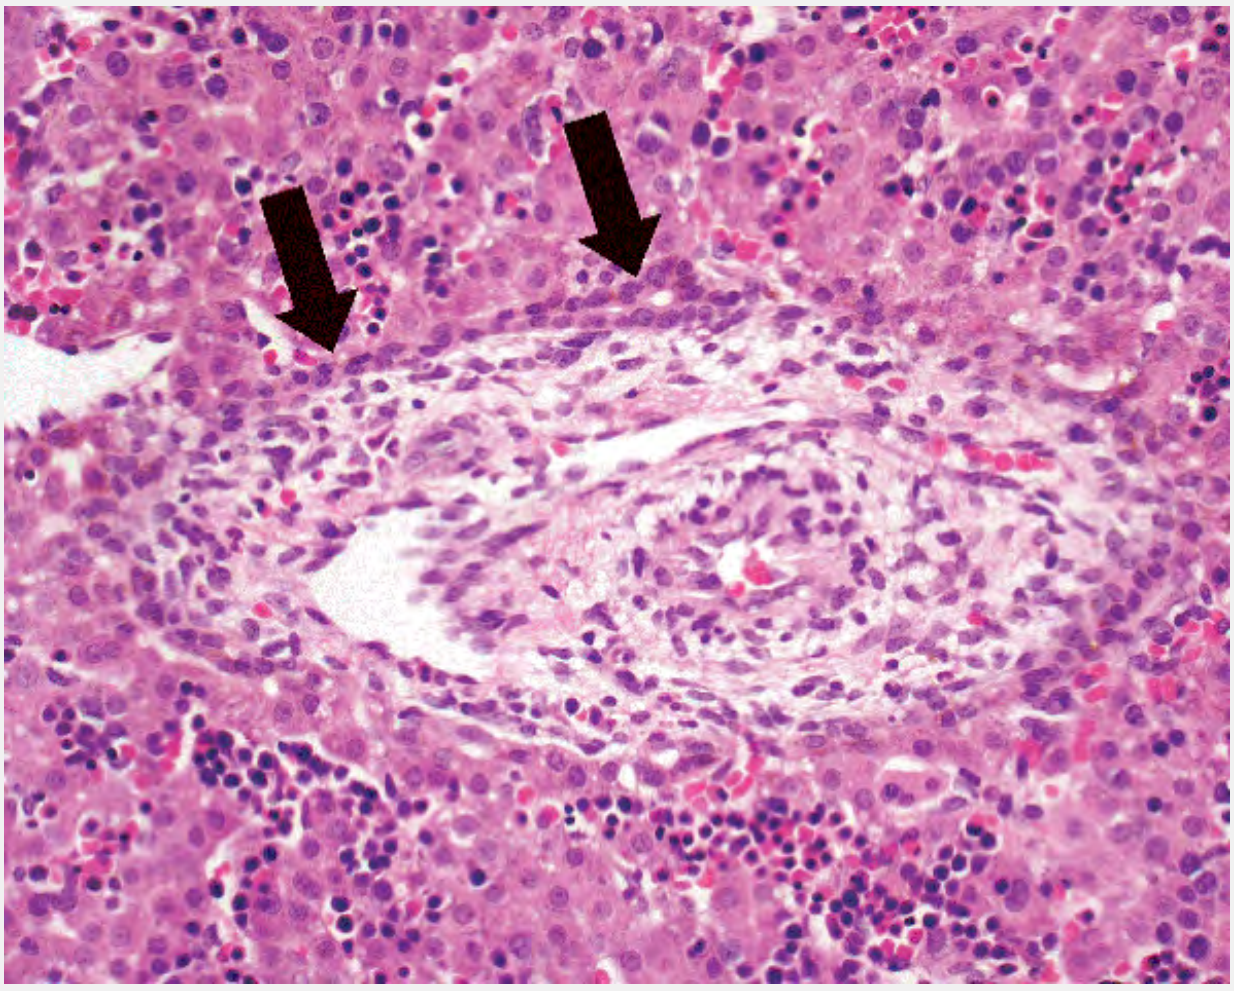

Figure 28.1 Ductal plate (*arrows*) developing around the portal vein mesenchyme in the liver of a 10-week-old embryo. There is extramedullary hematopoiesis in the sinusoids.

Apoptosis

Apoptosis occurs at all stages during fetal growth and development of ductal plates and hepatoblasts. There is a good correlation between the proliferative and the apoptotic activities in the ductal plate, depending on the remodeling process (8). Involution of liver hyperplasia and neoplasia (9,10,11,12) also is controlled by apoptosis, which is induced by transforming growth factor-Î²1 (11,12,13). In these regressing livers or tumors, scattered apoptotic bodies, rather than massive lytic necrosis, are observed. In viral infections, such as cytomegalovirus and herpes hepatitis, apoptosis has been proposed as a mechanism of cell death. In viral hepatitis B, however, it is not clear if cell death is mediated directly by the virus or by the host immune system through the release of cytokines such as tumor necrosis factor-a to the infected cells (14). In normal liver tissue, although rare, individual apoptotic bodies may be seen, which suggests that apoptosis is a physiological process in the liver (15) (Figure 28.2).

Gross Morphology

The liver of an adult weighs 1400 to 1600 g, comprising 2% of the body weight (3,16). It is relatively larger in infancy, representing one-eighteenth of the birth weight, mainly

due to a large left lobe. The liver resides predominantly in the abdominal right upper quadrant and is completely protected by the rib cage. It extends from the right fifth intercostal space in the midclavicular line down to the right costal margin and to the left as

far as the left midclavicular line. It has the appearance of a wedge with the base to the right and measures about 10 cm in vertical span, 12 to 15 cm in thickness, and 15 to 20 cm in its greatest transverse diameter.

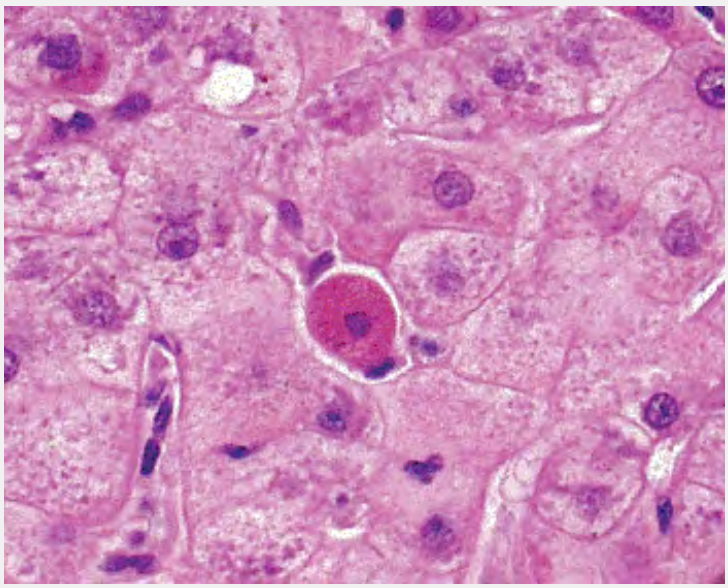

Figure 28.2 An hepatocyte undergoing apoptosis.

It is divided by deep grooves into two large lobesâ€”the right (lateral to falciform ligament) and left (medial to falciform ligament)â€”and two smaller lobesâ€”the caudate and quadrate lobes. This traditional division is only of topographical significance. Functionally, the division into eight segments, which do not correspond to the anatomical division into lobes (17), is more important. Each segment is served by its own vascular pedicle of arterial and portal venous blood supply and branch of the biliary tree. This segmental division is of critical importance, particularly when dissecting small space-occupying lesions from these areas or when removing segments of liver for transplantation. The superior, anterior, and lateral surfaces of the liver are smooth and almost completely covered by

peritoneum, except for a small triangular areaâ€”the â€œbare areaâ€• below the diaphragmâ€”which is surrounded by the reflections of the peritoneum forming the coronary ligaments. A thin layer of fibrous connective tissue, the Glisson's capsule, surrounds the liver and extends into the parenchyma to form extensions that support arterial and biliary structures. Anteriorly, the falciform and round ligaments, which during fetal life conducted the left umbilical vein, connect the liver to the abdominal wall. Through the posterior surface of the liver at the base of the bare area runs the inferior vena cava, to which two to four hepatic veins connect. The fossa of the gallbladder and the round ligament separate the quadrate lobe from the right and left liver lobes, respectively. The fossa of the ductus venosus (i.e., the connection of the left umbilical vein to the vena cava inferior) and the inferior vena cava separate the caudate lobe from the left and right lobes of the liver. The horizontal portal fissure (or porta hepatis), which joins the upper ends of the gallbladder fossa and the groove of the round ligament, contains the branches of the hepatic artery, the portal vein, the hepatic nerve plexus, the hepatic ducts, and lymph vessels.

Anatomy

Blood Supply and Drainage

The liver is nourished by a dual blood supply, approximately three-fourths via the portal vein and the remainder via the hepatic arteries. The portal vein carries venous blood from the alimentary tract, including the pancreas, which is rich in nutrients; whereas the hepatic artery supplies arterial blood from the celiac axis that is rich in oxygen for liver survival.

Venous outflow is provided by the right, middle, and left hepatic veins. The right hepatic vein drains the right lobe, the middle hepatic vein drains primarily the middle portion of the left lobe and a variable portion of the right, and the left hepatic vein provides the

principal drainage of the left lateral lobe. The middle and the left hepatic veins often join together to form a common trunk before entering the vena cava. In addition, there are short venous segments that drain the posterior surface of the liver directly into the inferior vena cava (18).

Bile Ducts

Bile ducts accompany the hepatic artery and portal vein while coursing through the liver. They are nourished by the hepatic arteries via a complex peribiliary plexus of capillaries, which supplies all structures within the portal tracts. Bile is formed in hepatocytes, steadily secreted into bile canaliculi, canals of Hering, and then to the intra- and extrahepatic bile ducts. The extrahepatic biliary tract consists of a gallbladder that ends in the cystic duct. The cystic duct joins the hepatic duct to form the common bile duct, which enters the second portion of the duodenum through its muscular structure, the sphincter of Oddi (19).

Lymphatics

The capsule and the stroma of the liver is rich in lymphatic structures. The lymphatic plexus found in the capsule forms significant anastomoses with the intrahepatic lymphatics. The importance of these anastomoses is evident when hepatic venous pressure is increased; exudation of excess lymph from the capsular plexus forms protein-rich ascitic fluid. The intrahepatic lymphatic system exists as a fine, valved plexus associated with branches of hepatic artery in portal tracts. Hepatic lymph is most likely formed in the interstitial space of Disse. Lymphatic capillaries are not observed within the acini (20,21). Most of the hepatic lymphatics leave the liver at the porta hepatis and drain into hepatic nodes along the hepatic artery and into the celiac nodes. Other important efferent routes are via the falciform ligament and the superior epigastric vessels to the parasternal nodes, from the bare area to posterior

mediastinal nodes, and from the visceral surface to the left gastric nodes.

The liver represents the largest single source of lymph in the body, producing 15 to 20% of the overall total volume (22) and 25 to 50% of the thoracic duct flow (21). Furthermore, hepatic lymph has an unusually high protein content, about 85 to 95% of that in plasma, and a high content of lymphocytes.

Nerve Supply and Innervation

The liver is innervated by two separate but intercommunicating plexuses around the hepatic artery and portal vein and are distributed with their branches (23). They include parasympathetic fibers from both vagi and sympathetic fibers, which receive their preganglionic connections from spinal segments T7 to T10 (24). The hilar plexuses also include afferent visceral and phrenic fibers. Besides their presence around vascular structures in portal tracts, nerve fibers (mostly sympathetic) are present in the parenchyma along the sinusoids. Release of neurotransmitters from the intrasinusoidal fibers modulate hepatocyte and perisinusoidal cell function. It controls in part carbohydrate and lipid metabolism and induces contraction of perisinusoidal cells, thereby regulating intrasinusoidal blood flow (25). However, neural mechanisms may have only a minor regulatory role because limited reinnervation in liver allografts does not seem to impair their function. Denervation probably explains the impaired normal response of the liver to ischemia, sinusoidal dilatation seen in liver allografts, and impaired metabolic function in cirrhosis (26,27).

Histology

The structural organization (16,28,29,30,31) of the liver into parenchymal, interstitial, vascular, and ductal elements is based on

its many functions and its position between the digestive tract and the rest of the body. The functional unit of the liver is represented by the hepatic lobule or rather, as defined by Rappaport (3,32), the hepatic acinus (Figure 28.3). The latter is a regular, three-dimensional structure in which blood flows from a central axis, formed by the terminal portal venule and terminal hepatic arteriole in the portal tract, into the acinar sinusoids and empties into several terminal hepatic venules at the periphery of the acinus (Figure 28.4).

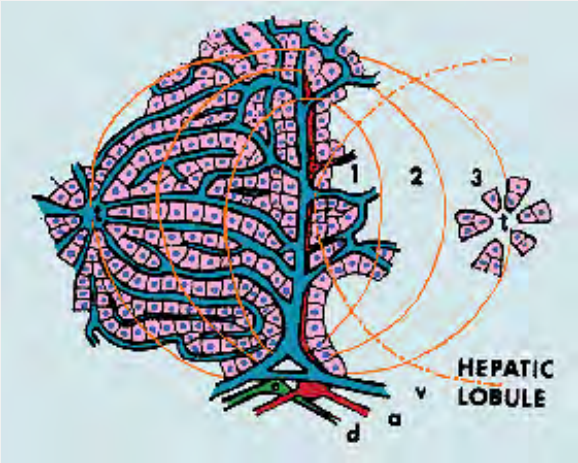

Figure 28.3 Diagram comparing the hepatic acinus with zones 1, 2, and 3 to the hepatic lobule (*dotted line*). Portal tract contains portal venule (*v*), hepatic arteriole (*a*), and hepatic duct (*d*). (*t*, terminal hepatic venule)

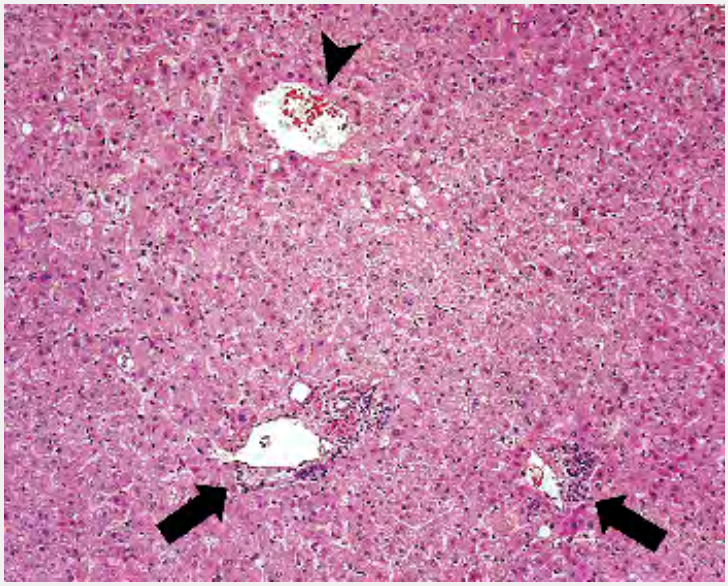

Figure 28.4 Normal human liver showing two portal tracts (*arrows*) and one terminal hepatic venule (*arrowhead*).

In contrast, the hepatic lobule consists of an efferent central vein with cords of hepatocytes radiating to several peripheral portal tracts (33). Therefore, in a two-dimensional view, the acinus occupies parts of several adjacent lobules. The acini measure 560 to 1050 Âµm in length and 300 to 600 Âµm in width. The division of the hepatic parenchyma into the classic lobules, with changes described as being centrilobular, midzonal, and peripheral or periportal, is still used as a convenient landmark. However, Rappaport acinus has now come to be more generally accepted. The acinus is subdivided into zones 1, 2, and 3 with decreasing oxygenation (34). The hepatocytes in zone 1 are nearest to portal tracts and correspond to the peripheral area of the classic lobule. Zone 2 corresponds roughly to the midzonal area of a classic lobule, and zone 3 corresponds to parts of several centrilobular areas.

The terminal vascular branches, which bring substances for nutrition and metabolism into the acinus, run along the terminal bile ducts

that drain the secretory products of the same acinus. The vessels form a vascular plexus around the bile ducts (35). Thus, as a result of the sinusoidal blood flow, structural, secretory, and functional unity is established in the acinus. The oxygen gradient, metabolic heterogeneity, and differential distribution of enzymes across the three zones of the acini (14) explain the zonal distribution of liver damage due to ischemia and toxic substances.

Hepatocytes and Bile Canaliculi

The hepatocytes are arranged in spongelike plates that in the adult are normally one-cell layer thick and are separated

by sinusoids along which blood flows from portal tracts to terminal hepatic venules (Figure 28.5). Surrounding the terminal hepatic venules, the hepatocytes exhibit a more regular radial pattern. Away from the perivenular area, the liver cell plates are arranged less regularly without distinct radial arrangement. In children up to 5 or 6 years of age, the liver cells are arranged in two-cell thick plates (Figure 28.6). In adults, the presence of two-cell thick plates and the formation of rosettes indicates regeneration.

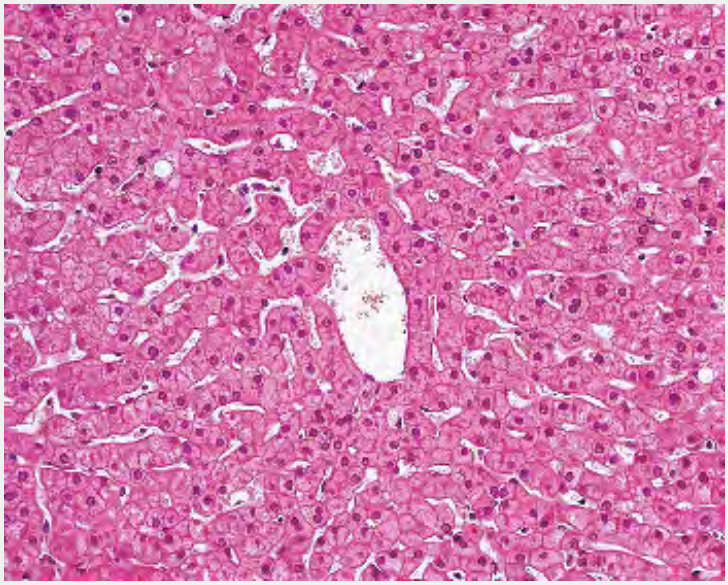

Figure 28.5 Terminal hepatic venule surrounded by converging hepatocyte plates and sinusoids.

The individual hepatocyte is a polygonal epithelial cell approximately 25 Âµm in diameter with a well-defined plasma membrane that is differentiated into three specialized regions or domains: basolateral (70% of total surface area), which faces the sinusoid; bile canalicular (15%), bounding that part of the intercellular space that constitutes the bile canaliculi; and lateral (15%), facing the rest of the intercellular space. Each domain has different molecular, chemical, and antigenic compositions and functions.

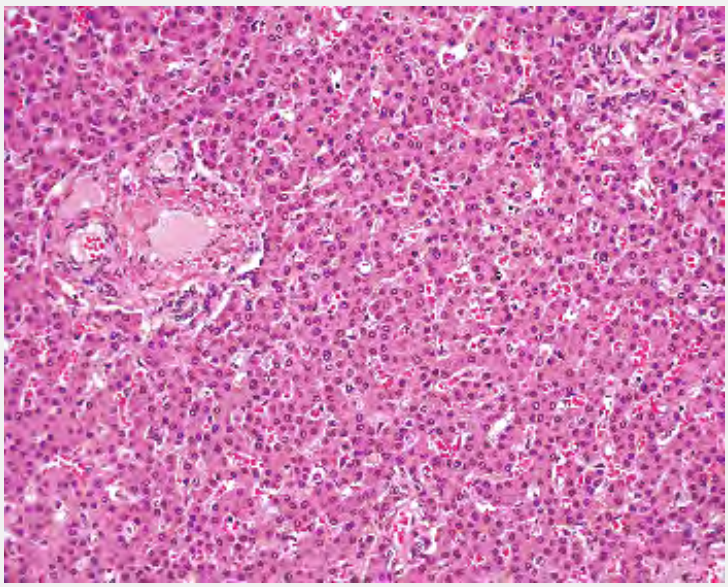

Figure 28.6 Liver of a child showing small uniform hepatocytes that are arranged in two-cell thick plates.

The nucleus is centrally located, round, and contains one or more nucleoli. At birth, all but a few hepatocytes are mononuclear. In

adults, although binucleate forms are not uncommon (up to 25% of cells), mitotic activity is rare. Nuclei vary in size in the adult, and the great majority are diploid (36). Some nuclei are larger than others, indicating polyploidy, particularly in persons over 60 years of age (37) (Figure 28.7). The significance of polyploidy is unknown and is usually more marked in the midzonal area. Since cell size is proportional to cell ploidy, polyploidy does not provide an increased quantity of genetic material per unit volume of cytoplasm. The hepatocytes in the portal limiting plates are smaller than other parenchymal cells with more intense nuclear staining and more basophilic cytoplasm. Nuclear displacement to the sinusoidal pole with hyperchromasia is a cytological indication of regenerative activity.

The abundant cytoplasm is eosinophilic and contains fine basophilic granules representing rough endoplasmic reticulum. Cytoplasmic glycogen is present and after proper fixation is stainable with periodic acid-Schiff (PAS) reagent. On hematoxylin and eosin (H&E) preparations, glycogen gives a fine, reticulated, foamy appearance to the cytoplasm. The quantity and distribution of glycogen show diurnal and diet-related variations. An irregular distribution pattern may sometimes be found in biopsies and is not of diagnostic significance (Figure 28.8). Glycogen accumulation in hepatocyte nuclei around portal tracts produces a vacuolated appearance (Figure 28.9) and is common in adolescents. In adults, such an appearance may be conspicuous in

conditions such as diabetes mellitus, pancreatic carcinoma, and chronic heart failure but is usually of no diagnostic significance.

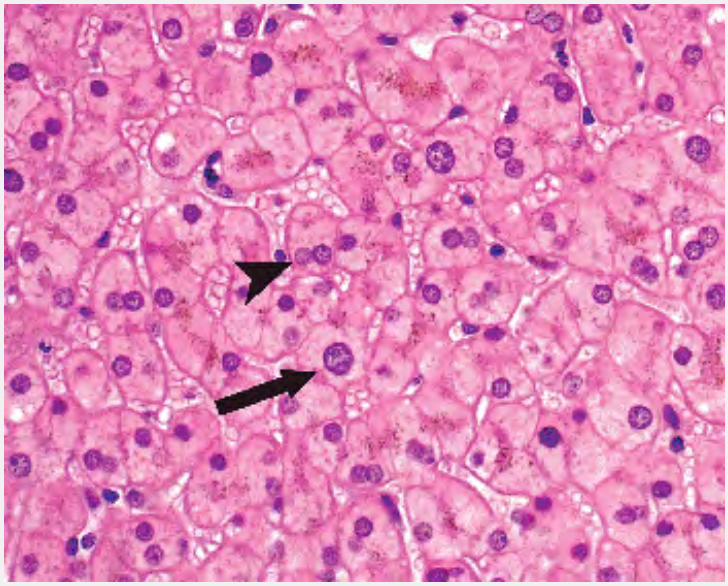

Figure 28.7 Liver of a 65-year-old patient showing significant polyploidy of hepatocyte nuclei (*arrow*) and binucleate forms (*arrowhead*).

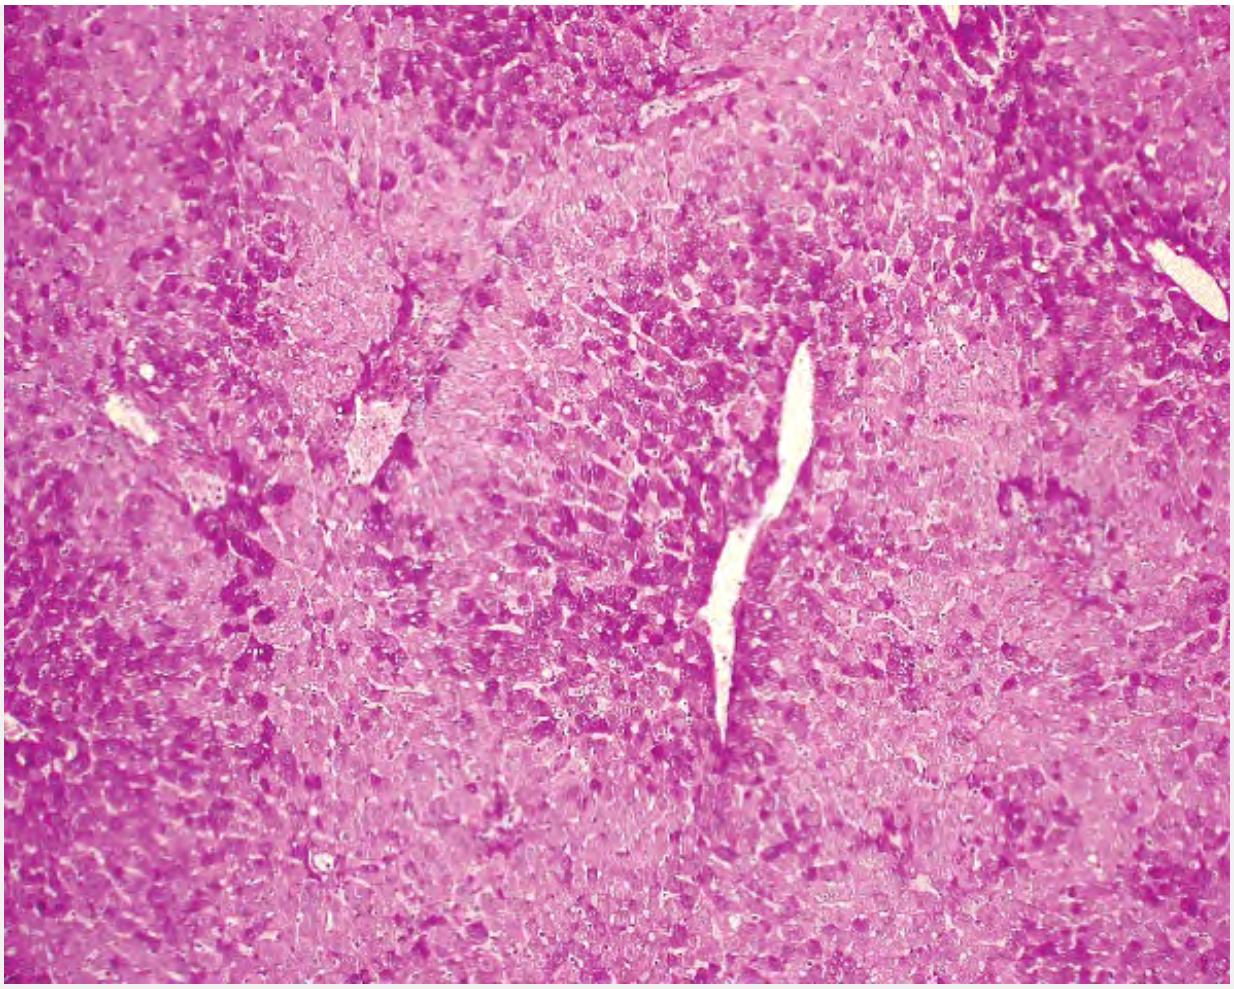

Figure 28.8 Periodic acid-Schiff reaction shows irregular distribution of glycogen (darker color) in the hepatocytes.

A few vacuoles and small quantities of stainable iron are common in normal hepatocytes, particularly in older individuals. Hemosiderin and copper are abundant in the cytoplasm of hepatocytes during the first week of life, then gradually disappear and should be absent at the age of 6 to 9 months.

Lipofuscin, the â€œwear and tearâ€• pigment, is seen in varying quantities as fine, well-delineated, light brown, PAS-positive diastase-resistant, partly acid-fastâ€“positive granules in the

cytoplasm of hepatocytes in zone 3, particularly at the canalicular pole (Figure 28.10). There is a progressive increase of its amount in individual hepatocytes and in the number of cells involved in older individuals. It is rich in oxidized lipids accumulating in secondary lysosomes as a result of autophagy and uptake of exogenous substances. It is not found in recently regenerated hepatocytes. It may be difficult to distinguish lipofuscin from the pigment that accumulates in hepatocytes in large amounts in Dubin-Johnson syndrome.

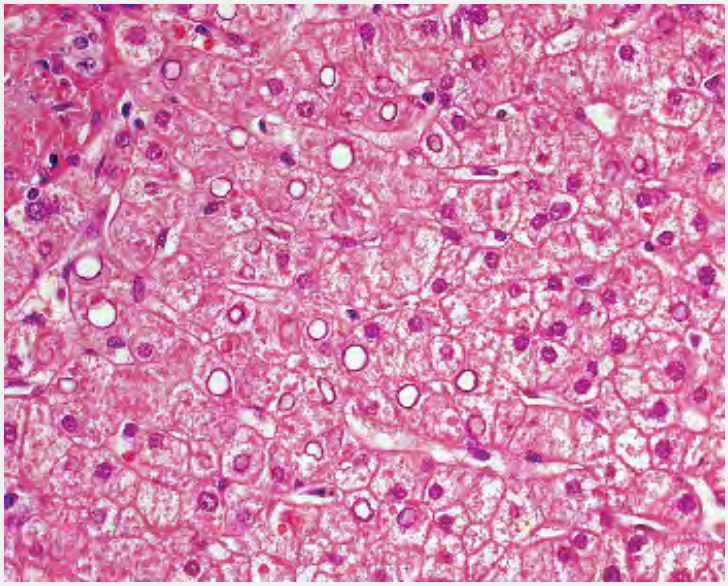

Figure 28.9 Glycogen accumulation in hepatocyte nuclei resulting in clear, empty appearance.

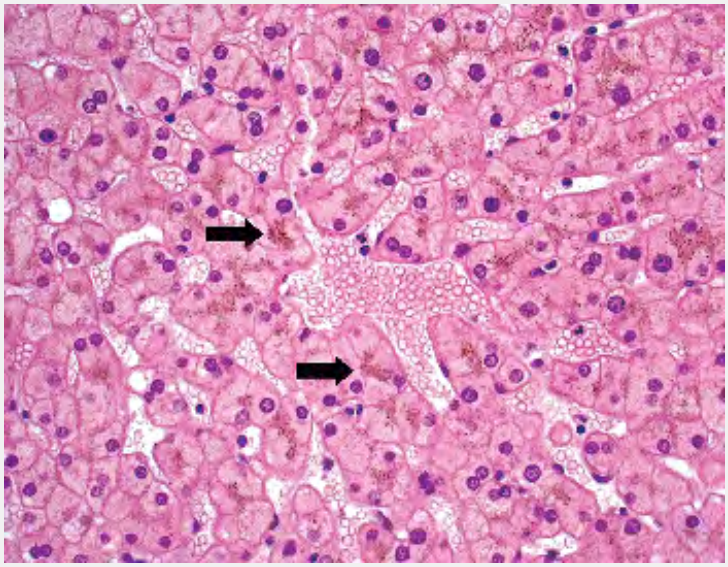

Figure 28.10 Lipofuscin in hepatocytes of zone 3 of the acinus. The finely granular pigment accumulates along the bile canaliculi (*arrows*).

In contrast to lipofuscin, iron and copper are coarser, birefringent, and usually deposited in periportal hepatocytes. Intracellular bile is poorly defined and less granular than the other pigments and often forms thrombi in bile canaliculi in zone 3 (38) (Figure 28.11). Isolated eosinophilic bodies as a result of coagulative necrosis, rare

apoptotic bodies representing normal turnover of hepatocytes (15), and an occasional focal necrosis where chronic inflammatory cells replace a few necrotic hepatocytes are not unusual in otherwise apparently normal livers.

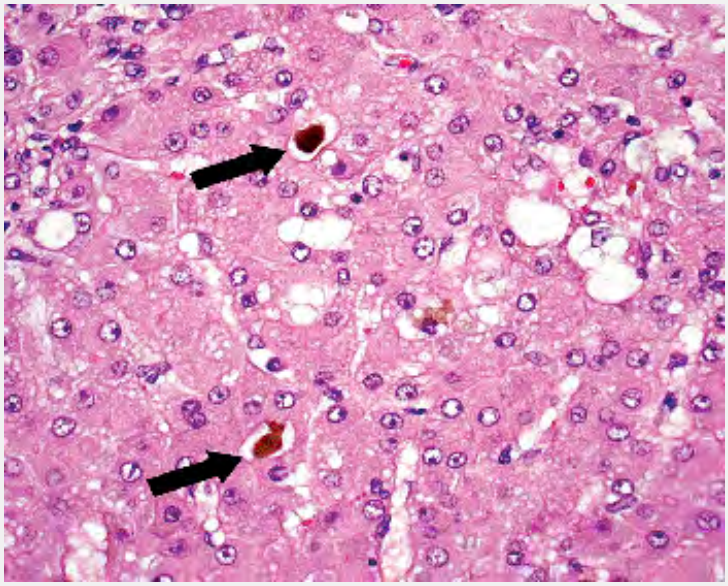

Figure 28.11 Canalicular bile thrombi (*arrows*) in zone 3 of the acinus.

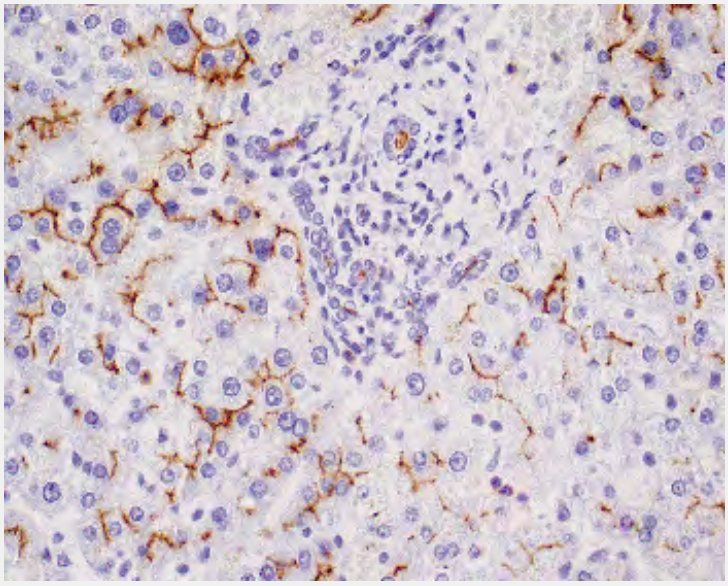

Figure 28.12 CD10 immunostaining delineates the twig-like

structures of bile canaliculi, as well as the lumen of bile ducts and ductules.

The bile canaliculus is an intercellular space with a diameter of approximately 1 Âµm, formed by the apposition of the edges of gutterlike hemicanals on adjacent surfaces of two or three neighboring hepatocytes. Bile canaliculi are not readily recognized under the light microscope unless distended in conditions with parenchymal cholestasis, which is accompanied by hepatocyte rosetting. Bile canaliculi form a chicken wireâ€“like network in the center of the hepatic plates, which can be demonstrated immunohistochemically with polyclonal anticarcinoembryonic antigen (pCEA) or CD10 (Figure 28.12). Bile canaliculi connect to bile ductules via canals of Hering.

Sinusoidal Lining Cells

In normal liver biopsy specimens, sinusoids are slitlike spaces that contain a few blood cells. The periportal sinusoids are more tortuous than the perivenular ones.

Hepatic sinusoids separate cords of hepatocytes and are lined by sinusoidal lining cells supported by reticulin fibers (Figure 28.13). These cells, which include endothelial and Kupffer cells, constitute a coordinated defense system. They are not conspicuous in normal biopsy specimens. The endothelial cells have thin, indistinct cytoplasm and small, elongated, darkly stained nuclei without nucleoli. The sievelike plates of the endothelial cytoplasm and the absence of a structurally defined basement membrane (in contrast to capillaries) facilitate exchange between blood and hepatocytes (20,39,40).

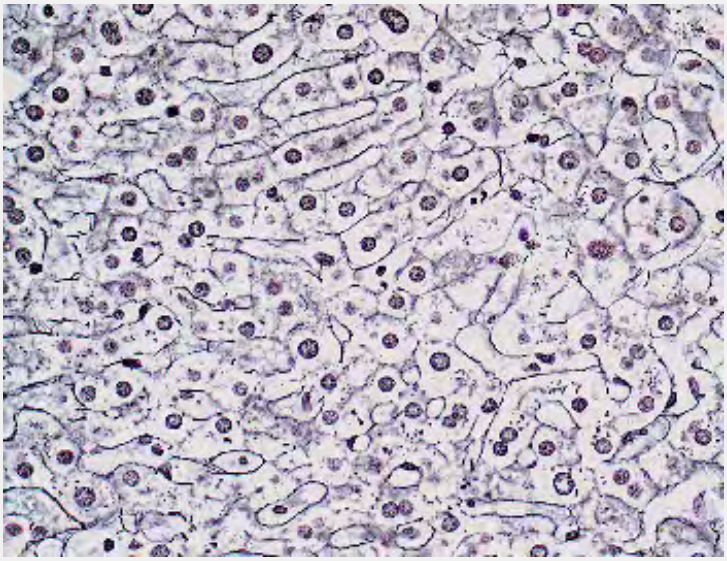

Figure 28.13 Hepatic sinusoids lined by reticulin fibers in a normal liver (reticulin stain).

The Kupffer cells have a bean-shaped nucleus and plump cytoplasm with star-shaped extensions (41). They are more numerous near the portal tracts. They belong to the mononuclear-phagocytic system and are derived in part from the bone marrow. They contain vacuoles and, particularly in the diseased liver, many diastase-resistant PAS (PAS-D)â€“positive lysosomes and phagosomes, as well as acid-fast granular aggregates of ceroid pigment. These cells respond actively to many types of injury by proliferation and enlargement.

Between the endothelial cells and the hepatocytes lies the space of Disse, a zone of rapid intercellular exchange. It contains plasma, scanty connective tissue that constitutes the normal framework of the liver, and perisinusoidal cells such as hepatic stellate cells (Ito cells, interstitial fat-storing cells, or hepatic lipocytes) and pit cells. The connective tissue fibers along the sinusoids represent predominantly collagen type III, which stains black in silver impregnations (reticulin) and forms a regular network radiating from

the center of the lobules. Elastic fibers and basement membranes are absent from normal sinusoids (42,43). The space of Disse is not discernible in well-fixed, normal liver biopsy material; but in postmortem liver, the hepatocytes shrink, pericellular edema develops, and the space becomes more conspicuous (Figure 28.14).

On light microscopy, hepatic stellate cells (44) are difficult to differentiate from sinusoidal lining cells. They are modified resting fibroblasts that can store fat and vitamin A and produce hepatocyte growth factor (45) and collagen. They play a significant role in hepatic fibrogenesis. When loaded with fat, such as in hypervitaminosis A, they may be recognized due to cytoplasmic fat droplets of rather uniform size with scalloping of the elongated nucleus (Figure 28.15). When activated, these cells contain stainable desmin and actin in their cytoplasm (46), justifying their designation as myofibroblasts.

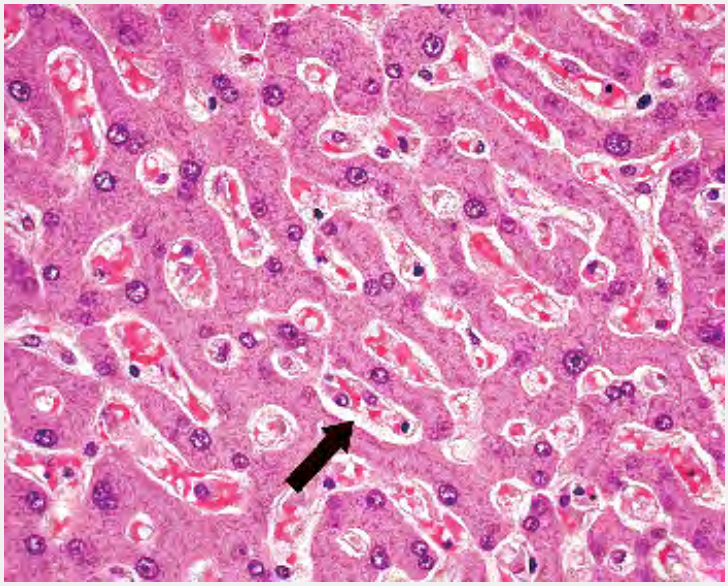

Figure 28.14 Autopsy liver specimen exhibiting dilatation of sinusoids and Disse's space (*arrow*) with prominent sinusoidal lining cells including endothelial and Kupffer cells.

Pit cells (47,48) have not been characterized by light microscopy. Under the electron microscope, they have neurosecretory-like electron-dense granules and rod-cored vesicles. Recent evidence indicates that pit cells are not endocrine cells but correspond to the large granular lymphocytes and have natural killer cell activity (49). Occasional inflammatory cells, lymphocytes, or polymorphonuclear leukocytes may be present in the sinusoids. During the first few weeks after birth, the presence of foci of extramedullary hematopoietic cells in the sinusoids and wall of terminal hepatic venules is a normal feature.

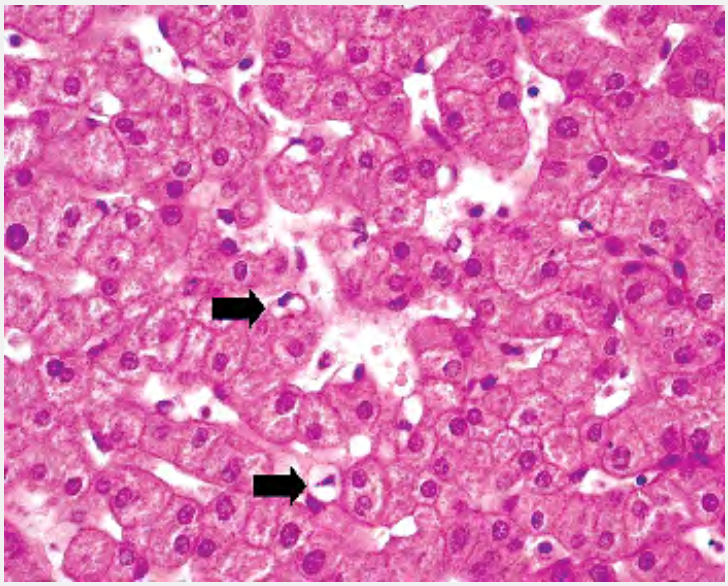

Figure 28.15 Prominent lipocytes in liver biopsy specimen of patient with hypervitaminosis A. The nuclei of the lipocytes are scalloped (*arrows*) due to fat droplets in cytoplasm.

Hepatic Veins

The intrahepatic course of the valveless hepatic veins, which are embedded in a thin sheath of connective tissue, is straight to the inferior vena cava. The smaller branches (or sublobular veins) and the smallest efferent veins (or terminal hepatic venules) are in direct contact with the hepatic parenchyma. There is a defined spatial relationship between the terminal hepatic venules and the branches of the portal vein and hepatic artery in the portal tracts, which interdigitate but do not directly connect in the three-dimensional space.

The distance between two terminal hepatic venules represents the size of an acinus. The terminal hepatic venules have a very thin wall (Figure 28.5) lined by endothelial cells, which is readily demonstrable after staining with trichrome for collagen or Victoria blue for elastic fibers, but they do not have an adventitia around their wall (50).

It has been suggested that perivenular sclerosis in alcoholic patients may be an index of progressive liver injury (50), although this has been disputed subsequently (51). Thickening of the wall of terminal hepatic venules is often part of pericellular fibrosis and central hyalin sclerosis in alcoholic liver disease (51). It may be seen focally in apparently normal individuals, as well as in children up to 2 years of age.

Portal Tracts

Each portal tract contains a bile duct and several bile ductules, a hepatic artery branch, a portal vein branch, and lymphatic channels embedded in connective tissue (Figure 28.16). The amount of connective tissue and the size of the intraportal structures depend on the size of the portal tract.

Nerve fibers, both sympathetic and parasympathetic for innervation of blood vessels and bile ducts, can be seen in large portal tracts. The largest portal tracts are round or triangular, the smaller ones are triangular or branching, and the smallest terminal divisions are round

or oval. The size of a portal tract is approximately three to four times the diameter of the hepatic artery branch. They normally contain a few lymphocytes, macrophages, and mast cells, but no polymorphonuclear leukocytes or plasma cells. The number of inflammatory cells increases with age. However, their density varies from one portal tract to the next. The connective tissue consists mainly of collagen type I, which is seen as thick, deep blue fibers on the trichrome stain (Figure 28.17). Newly formed collagen type III appears as fine, light blue fibers. In the subcapsular region of the liver, the portal tracts contain more and denser connective tissue. Irregular extensions of fibrous tissue from Glisson's capsule into the parenchyma, sometimes connecting adjacent portal tracts, must not be interpreted as cirrhosis in wedge or superficial biopsy specimens of subcapsular parenchyma (52).

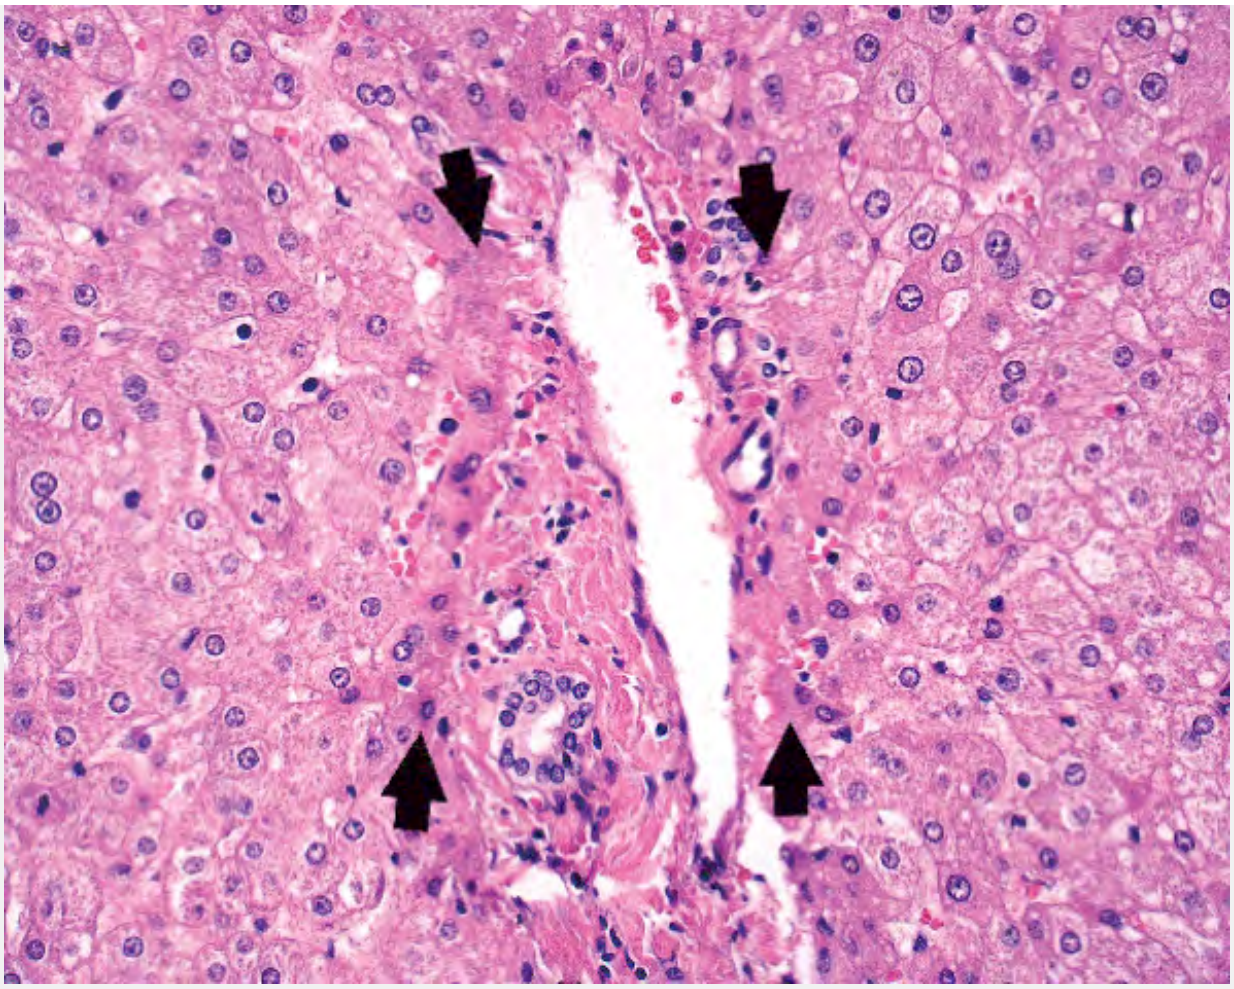

Figure 28.16 Normal portal tract with bile duct, hepatic arteriole, portal venule, and clearly defined limiting plate (*arrows*).

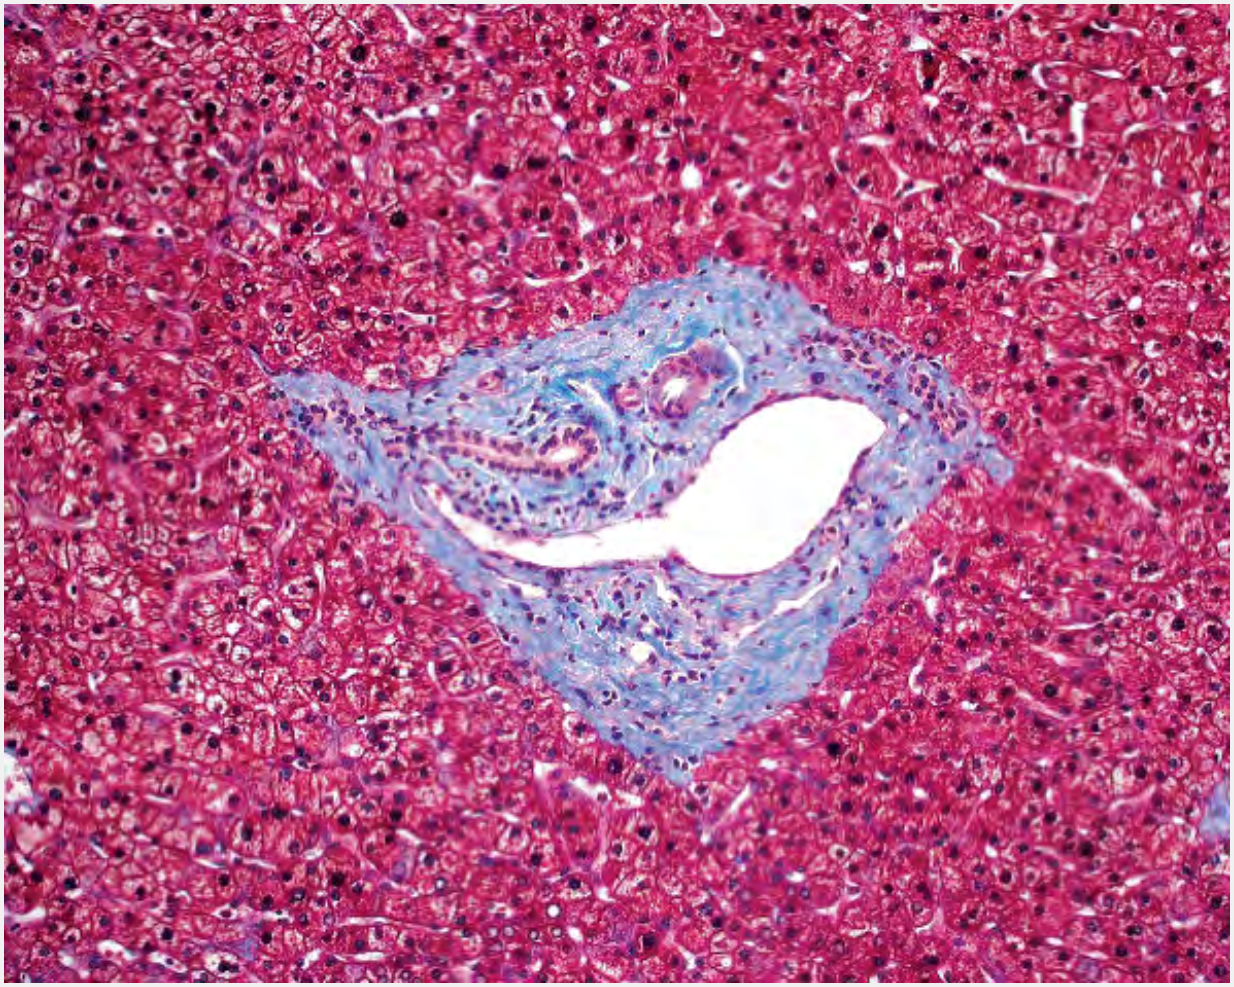

Figure 28.17 The connective tissue of portal tracts consists of mainly collagen type I, which appears as thick, deep blue fibers on trichrome stain.

Bile Ducts

The larger intrahepatic or septal bile ducts are lined by tall columnar epithelial cells measuring about 10 mm in diameter with basally situated, pale, oval nuclei and light eosinophilic cytoplasm (53,54) (Figure 28.18). They have an internal diameter greater than 100 Âµm and a distinct basement membrane stainable with PAS-D.

Lymphocytes may occasionally be present within the lining epithelium. The larger bile ducts are located in the central part of the portal tracts and have more periductal fibrous tissue than the smaller ones. The collagen fibers are arranged in an irregular and circumferentialâ€”but not concentricâ€”manner, as may be seen in chronic biliary tract diseases such as primary sclerosing cholangitis and as a sequela of chronic cholecystitis.

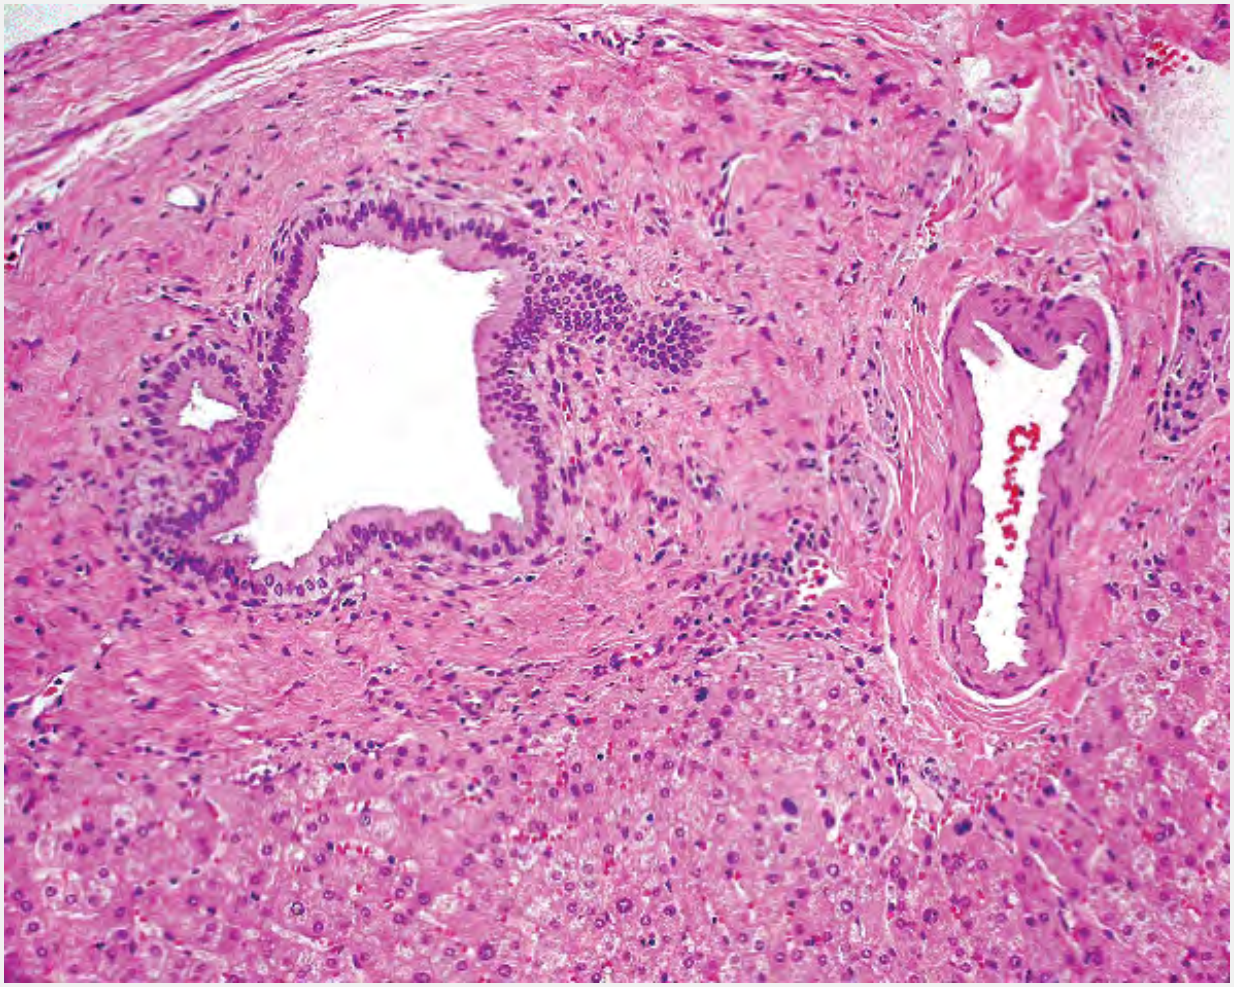

Figure 28.18 A large portal tract containing an artery and a bile duct lined by columnar epithelial cells.

The smaller or interlobular bile ducts are lined by cuboidal or low columnar epithelium. They have a basement membrane and a small amount of periductal connective tissue. One or more interlobular ducts may be present in a portal tract. Bile ducts are always accompanied by a portal vein and a hepatic artery, the latter having approximately the same diameter as the bile duct (external caliber ratio of bile duct to artery is 0.7:0.8) (54) (Figure 28.19). The bile ducts are connected to the bile canaliculi by bile ductules and canals of Hering.

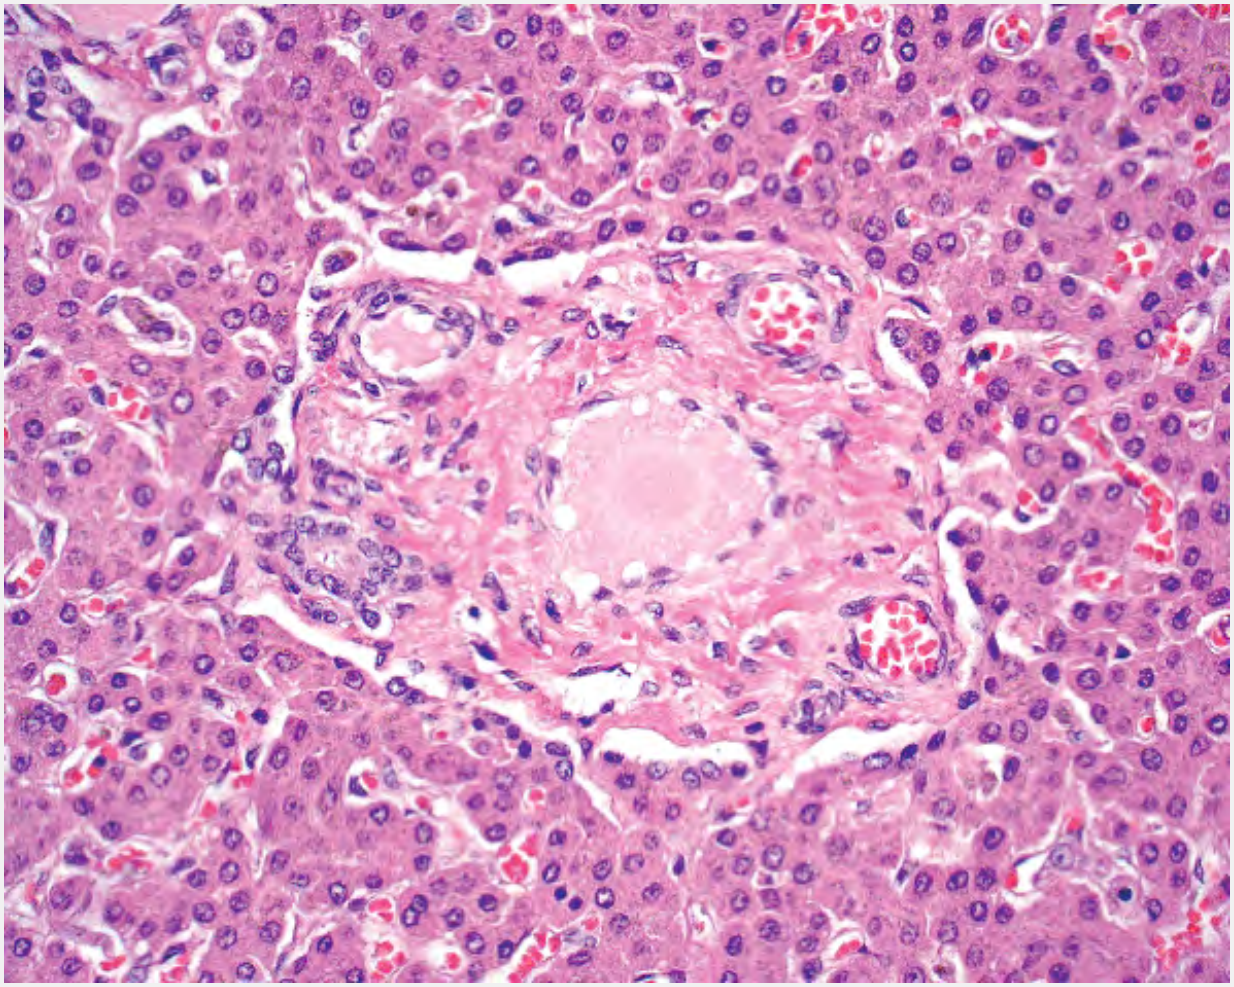

Figure 28.19 Normal portal tract in a newborn, with bile ducts and their corresponding hepatic arterioles of approximately the

same diameter.

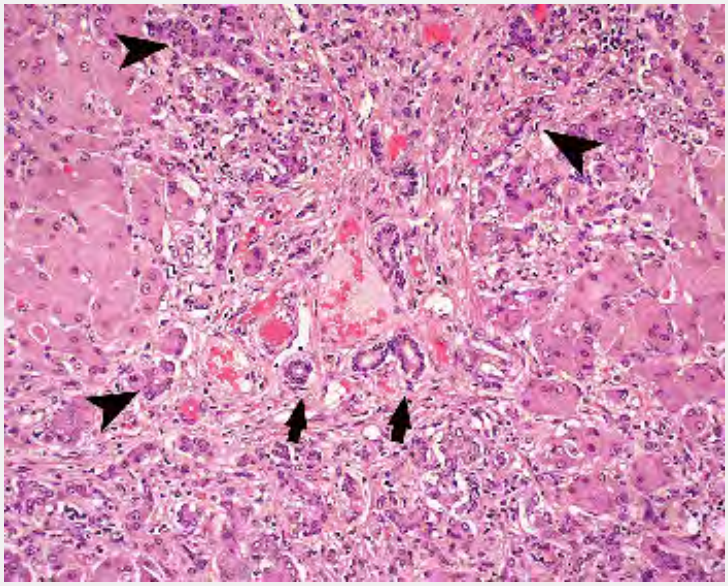

Figure 28.20 Bile ductules (*arrowheads*) are located in the peripheral zone of the portal tract and are smaller than the bile ducts (*arrows*).

Bile ductules are located in the peripheral zone of the portal tracts and are smaller (lumen of less than 20 Âµm) than the interlobular bile ducts (Figure 28.20). They have a basement membrane, are lined by cuboidal cholangiocytes, and are accompanied by a portal vein but not by a hepatic artery branch. Bile ductules may be observed at the edge of the portal tract stroma or may transverse the limiting plate, in which case it will have an â€œintralobularâ€• as well as an â€œintraportalâ€• segment. Ductular reaction, or proliferation of bile ductules, occurs in a variety of chronic liver diseases and can be so extensive as to raise the question of adenocarcinoma (55). Proliferating bile ductules should be

differentiated from ductular hepatocytes, which are seen in zone 1 of the liver acini in massive hepatic necrosis (56). Canals of Hering, which are the physiologic link between hepatocyte canaliculi and the biliary tree, are not discernible on routine sections of normal liver. They are lined partly by cholangiocytes and partly by hepatocytesâ€”not by cells of intermediate morphology, which are not identified in normal livers (57). They can be demonstrated by staining for high-molecular weight cytokeratin polypeptides (CK7, CK19), which are prominent in all cells of ductal origin (Figure 28.21).

Portal Vein and Hepatic Artery

The lymphatic vessels in portal tracts drain the spaces of Disse. The lymph flows in the same direction as the bile, opposite to that of the blood. The hepatic artery branches are intimately related to the corresponding portal veins. They may show thickening and hyalinization of the wall in older persons, although these changes are usually milder than in other organs. The terminal hepatic arterioles regulate the parenchymal blood supply with their muscular sphincter (58), whereas the portal venous supply is controlled by mesenteric venous blood flow.

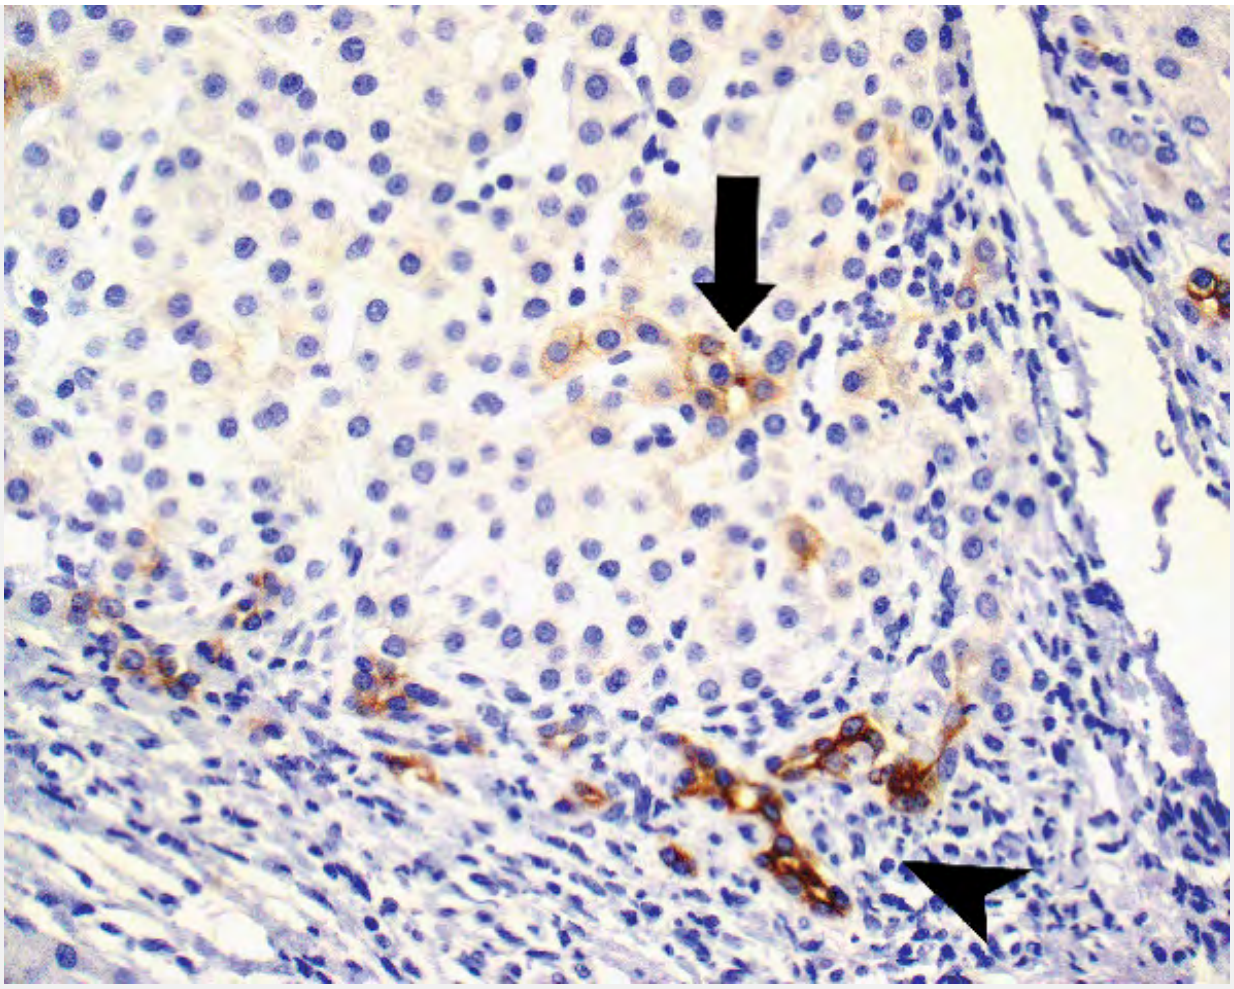

Figure 28.21 Proliferating bile ductules and hepatocytes undergoing ductular metaplasia *(arrow)* in chronic cholestasis are stained brown with anti-CK7.

The portal veins are the largest vessels in the portal tracts and produce venules that empty into periportal sinusoids. In contrast to hepatocytes around the terminal hepatic venules, the hepatocytes bordering the portal tracts are joined together and form a distinct row called the limiting plate (59). Destruction of this limiting plate by necroinflammation and/or apoptosis is a hallmark of chronic hepatitis (piecemeal necrosis/interface hepatitis) (Figure 28.22).

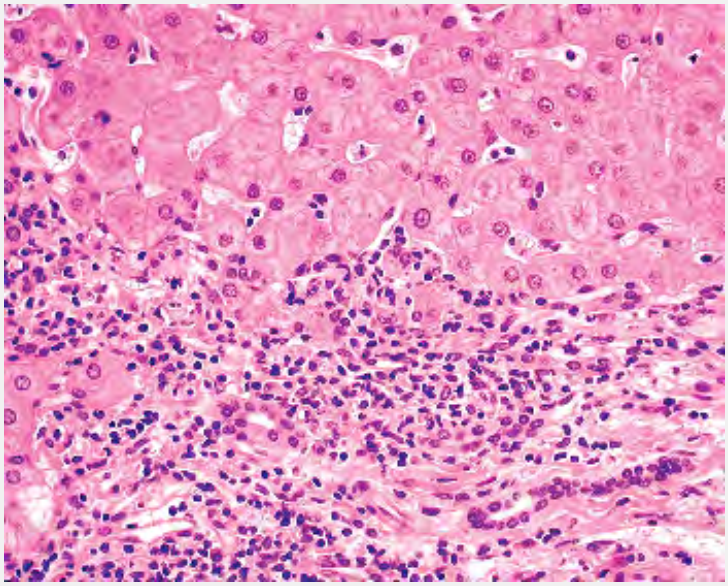

Figure 28.22 Liver from a patient with chronic hepatitis showing destruction of the limiting plate by extension of inflammatory cells from the portal tract into the periportal parenchyma with necrosis/apoptosis of hepatocytes (piecemeal necrosis/interface hepatitis).

Extracellular Matrix

Both interstitial and basement membrane collagens are present in the liver and play an important role, not only as structural elements but also in hepatic function (60). Collagen Iâ€"the main component of the dense, birefringent connective tissue fibersâ€"is seen mainly in portal tracts and walls of hepatic veins and rarely in the normal parenchyma, whereas collagen III and IV are present along the sinusoids (5). Collagen I can be demonstrated with connective tissue stains; collagen III can be seen with silver impregnation for reticulin. Collagen II, characteristic of cartilage, is absent from the liver. Collagens IV and V, the basement membrane collagens, and laminin

are seen in the basement membrane of vessels, bile ducts, and bile ductules but (except for some collagen IV) not along the sinusoids of normal human liver (42,60). Distribution of elastic fibers in the liver, as demonstrated by orcein, resorcin, or Victoria blue stains, seems to follow that of collagen I (43). Fibronectin, an extracellular matrix glycoprotein, is present diffusely along the sinusoidal surface of hepatocytes and in portal tracts together with the other collagens (61). All components of the extracellular matrix are visualized best by immunohistochemical staining using specific antibodies.

Methodology

Specimen Handling

At the time of the biopsy procedure, the needle liver biopsy specimen is immediately examined for adequacy. It should be at least 1.5 cm in total length; otherwise, another pass is recommended. Adequate size of the specimen minimizes sampling error.

After the biopsy procedure (62,63), the liver specimen should be handled as little as possible and with utmost care to avoid squeezing and drying artifacts. If the case so indicates, small pieces of liver tissue may be frozen for histochemistry, immunohistochemistry, chemical analysis or fixed in glutaraldehyde for electron microscopy. If required, cultures should be taken. Then the tissue should be transferred quickly into the appropriate fixative solution, usually 10% buffered formalin. Needle biopsy specimens may be arranged on a piece of card to prevent distortion and fragmentation. At this stage, the gross appearance of the liver specimen is noted. Particular attention should be paid to fragmentation, which suggests cirrhosis, and to the number, size, shape, and color of the fragments. Tumors or granulomas, for example, can be recognized as white areas in an otherwise reddish brown tissue. Gray-black discoloration is seen in Dubin-Johnson syndrome, rusty brown in hemochromatosis, green in cholestasis, and yellow in steatosis or in older individuals from the

lipofuscin deposition.

Needle biopsy specimens are fixed for at least three hours at room temperature, whereas wedge biopsy specimens, after sectioning into 2-mm thick slices, need longer fixation. Formalin penetrates most tissues at about 0.5 mm per hour at room temperature. In order to avoid shrinkage and hardening of the tissue, it is important to process liver specimens separately from other tissues and on a more rapid schedule in the automated tissue processor. Rush liver biopsy specimens are manually processed to shorten the time schedule to meet the needs of critically ill patients. More than 10 consecutive sections, 3 to 5 Âµm in thickness, can be cut without artifact from well-embedded specimens. Usually paraffin is used for embedding, but plastic embedding may be used to obtain thinner sections.

Special Stains

The tissue is routinely stained with H&E. Masson's trichrome, Sirius red, or chromotrope-aniline blue stains are used for fibrous tissue; Victoria blue or orcein is used for hepatitis B surface antigen (HBsAg), elastic fibers, lipofuscin, ceroid, and copper-binding protein; PAS with diastase (PAS-D) is used for glycoproteins, including Î±1-antitrypsin inclusions (Figure 28.23), ceroid in macrophages (Figure 28.24), basement membranes of bile ducts, cytoplasmic inclusions of cytomegalovirus, and *Mycobacterium avium-intracellulare*. Stains for reticulin and iron are also important. If it is not possible to perform all these stains, at a minimum a special stain for connective tissue, such as Masson's trichrome, and/or reticulin should be obtained in order to assess the lobular architecture and to facilitate the diagnosis of cirrhosis.

It should be emphasized that an adequate and properly processed liver specimen without artifacts is an important

prerequisite for the accurate evaluation by an experienced histopathologist, who should be supplied with all relevant clinical and

laboratory data.

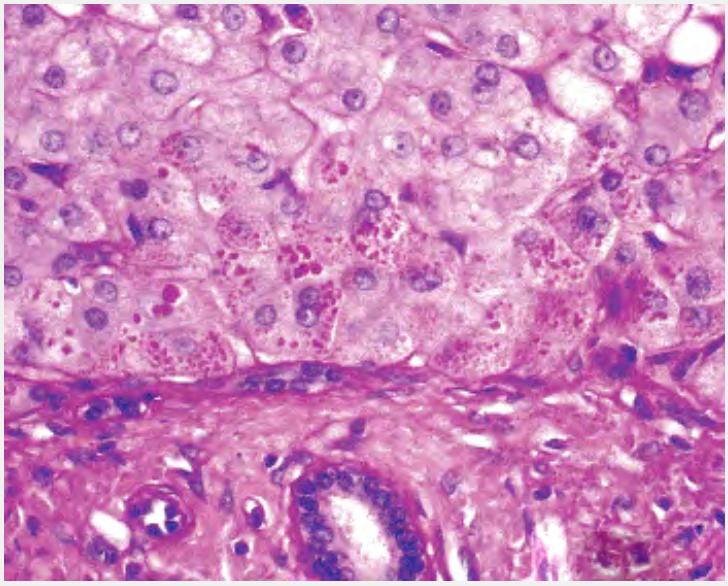

Figure 28.23 Alpha-1-antitrypsin granules and globules in periportal hepatocytes (PAS-D).

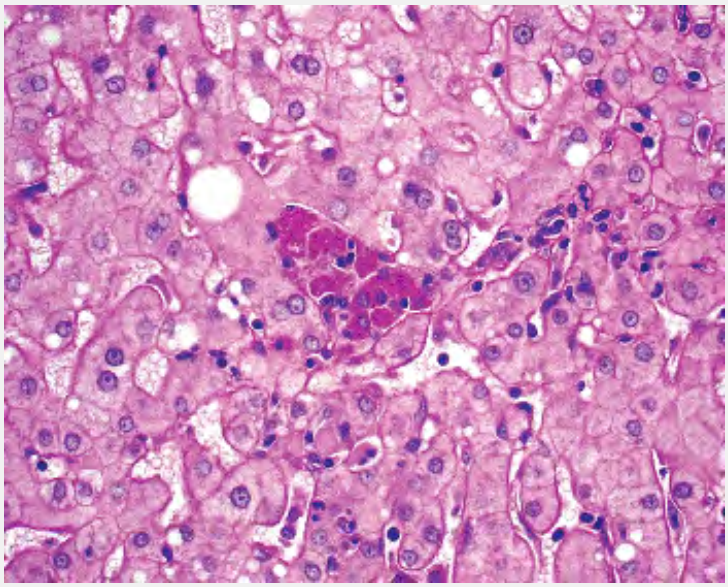

Figure 28.24 Ceroid pigment in macrophages as an indicator of previous hepatocyte injury/necrosis (PAS-D).

Microscopic examination should conform to a routine and include all tissue fragments and all structures of the liver (architecture, portal triads, limiting plate, hepatocytes, sinusoidal cells, and terminal hepatic venules). We usually start with careful examination of zone 3 of the acinus because many changes are found here (congestion, fat, necrosis, cholestasis, pigments, endophlebitis) and then move to the remainder of the parenchyma and portal tracts. Sampling error, particularly in focally or irregularly distributed disease processes, always must be taken into consideration. Squeezing of tissue during the biopsy procedure results in distortion of cells and elongation of nuclei, which makes cytologic evaluation of the specimen difficult (for other artifacts, see section In the Liver at Autopsy below).

Immunohistologic Studies

Recent progress in immunology, particularly the development of monoclonal antibodies and of highly sensitive immunohistochemical staining procedures (peroxidase-antiperoxidase and avidin-biotin-peroxidase complex methods), has made it possible to demonstrate many antigens in routinely processed (i.e., formalin-fixed and paraffin-embedded) tissue sections. Blocking of biotin is often required prior to the application of primary antibodies because hepatocytes contain large amount of endogenous biotin, which can give a false positive reaction; such a false positive is even more pronounced with the use of antigen retrievals (64,65).

Cytokeratins (CK) are the intermediate filaments of epithelial cells and are present in hepatocytes and, in greater amounts, in the bile duct epithelium. Different as well as similar cytokeratins are expressed by hepatocytes and bile ducts. Embryonal hepatocytes contain CK8, CK18, and CK19. The expression of CK19 in hepatocytes

dissappears by the tenth week of gestation (66). Mature hepatocytes in the normal liver contain only CK8 and CK18 and thus stain diffusely with keratin CAM 5.2. Cytokeratin staining of hepatocytes is usually more intense in the acinar zone 1. Most hepatocytes also stain with keratin 35Î²H11, which reacts with CK8 only (67). Hepatocytes do not stain with vimentin, epithelial membrane antigen, CK7, and CK19. HepPar1 stains hepatocytes in a diffuse, granular, cytoplasmic pattern (68,69) (Figure 28.25). Normal hepatocytes do not stain with AFP, but hepatocytes in cirrhotic nodules may occasionally show focal positive staining (70).

Cytokeratin polypeptides may be altered in specific liver diseases such as alcoholic hepatitis with formation of Mallory hyalins (67). Mallory hyalins are composed of heterogenous cytokeratin filament and usually react strongly with antibody to CK18, 34Î²E12, and CAM 5.2 antibodies and with antibody to ubiquitin (71,72). They also react occasionally with CK7 and CK19.

Bile canaliculi can be demonstrated using pCEA and CD10 (73) (Figure 28.12).

Sinusoidal endothelial cells show phenotypic differences with vascular endothelium. Normally, they do not bind the lectin ulex europaeus; they do not express factor VIIIâ€“related antigen or contain other molecules found in vascular endothelium, such as CD34 and CD31. They, however, assume these phenotypic properties in chronic liver diseases and in hepatocellular carcinoma (74,75,76).

Several markers of neural/neuroectodermal differentiation have been found in hepatic stellate cells. These are

synaptophysin, glial fibrillary acidic protein (GFAP), and neural cell adhesion molecule (N-CAM), which can be used to identify resting stellate cells (77,78,79). When activated, these cells show expression of vimentin, desmin, and smooth muscle actin, which suggests myofibroblastic differentiation (46).

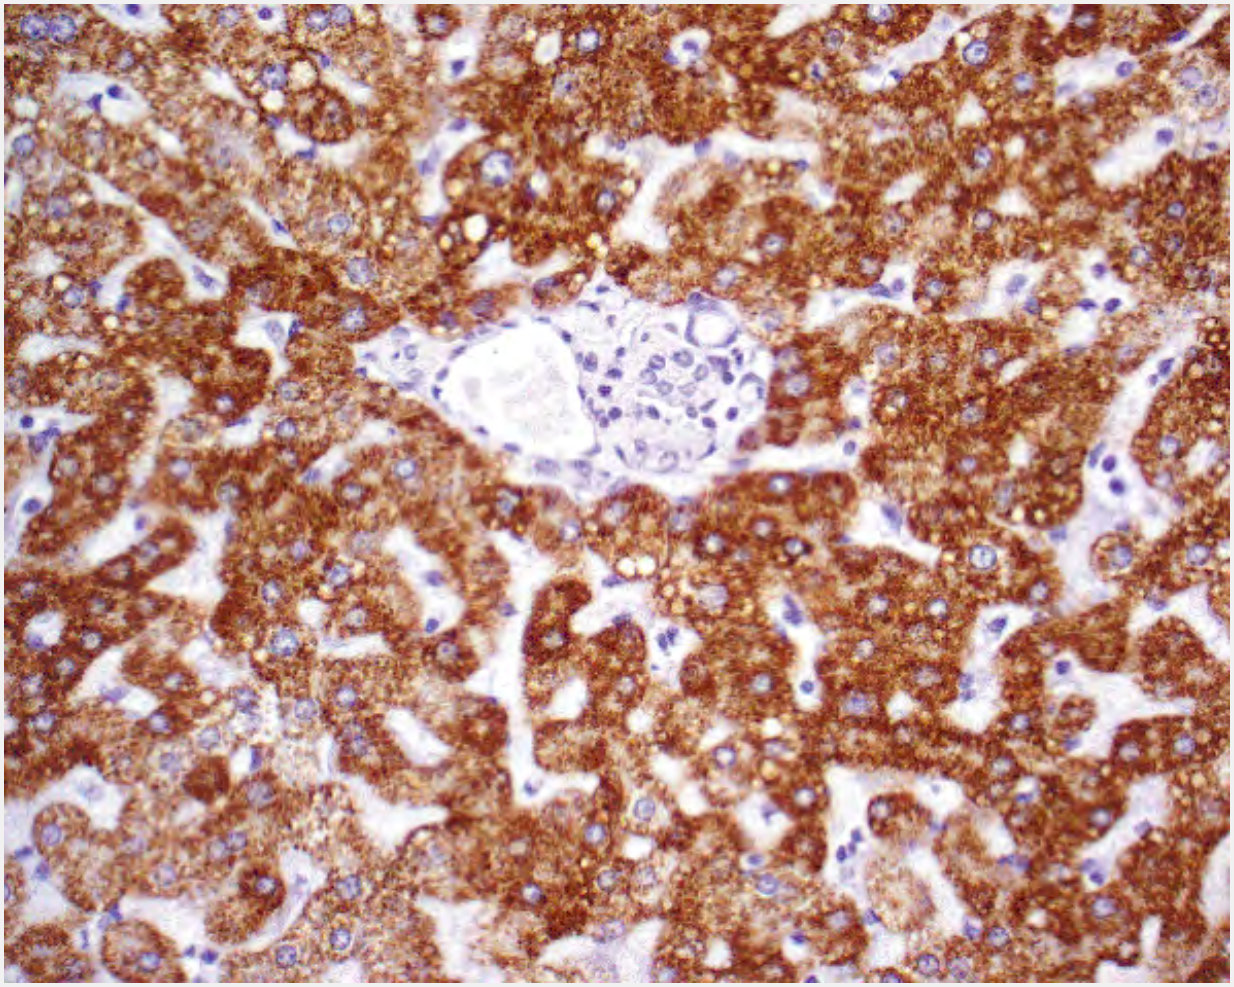

Figure 28.25 Granular staining of hepatocytes using HepPar1 antibody excludes other cells and all structures in the portal tract.

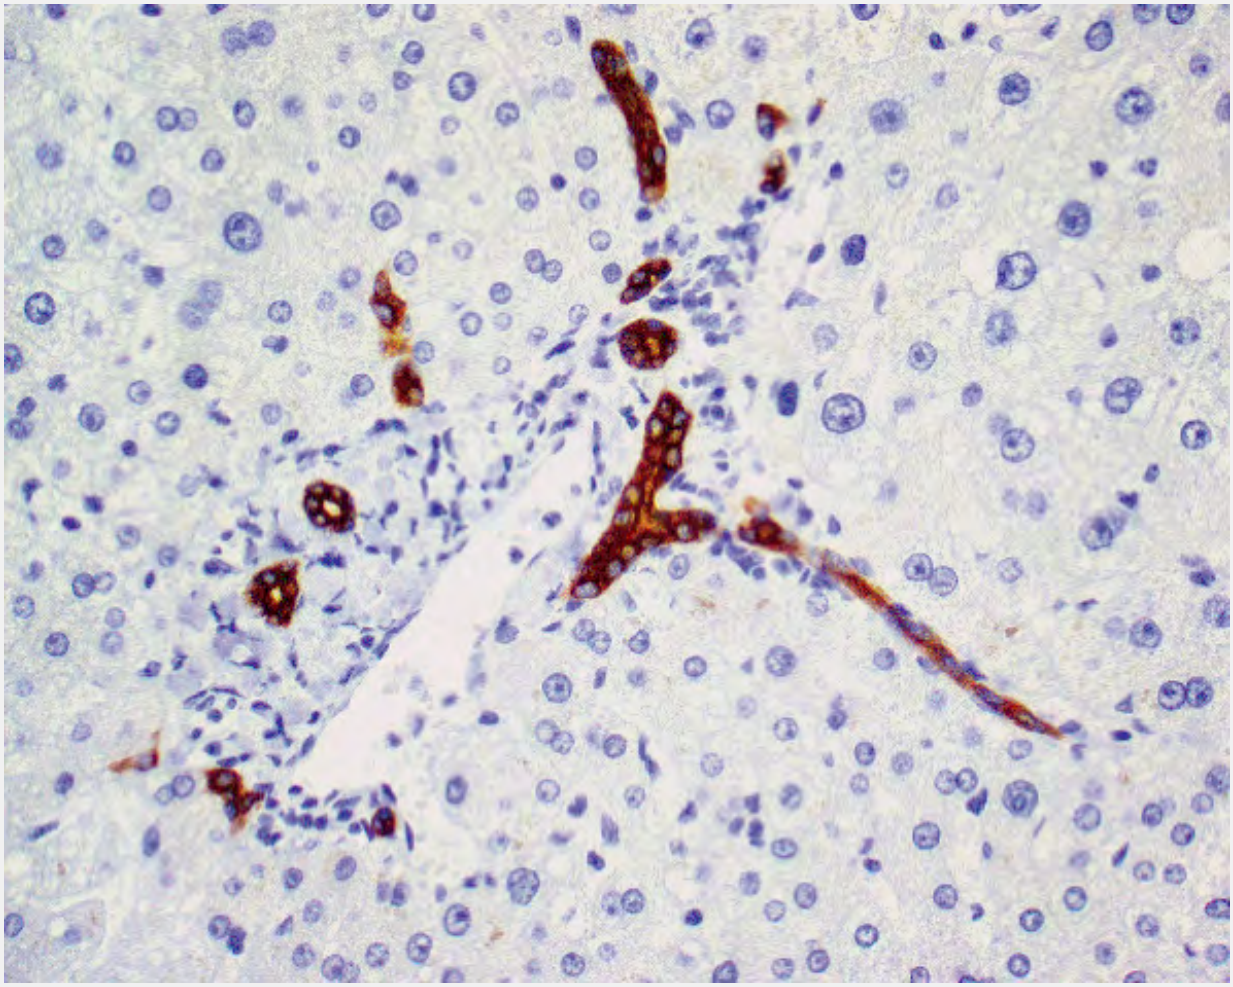

Figure 28.26 Cytokeratin 7 immunostaining of bile duct and bile ductules.

Bile ducts and ductules are readily revealed by immunostaining for bile ductâ€“type CK7 and CK19 (80) (Figure 28.26). Cytokeratin 7 immunostaining is useful to evaluate the presence or loss of bile ducts, such as in cholestatic liver diseases and chronic rejection in liver transplantation. Bile ducts also stain with CK8, CK18, AE1/AE3, 35Î²H11, and 34Î²E12 antibodies (67). Some hepatocytes in the periphery of cirrhotic nodules may react with keratin AE1/AE3, CK7, and CK19 antibodies, thus suggesting biliary differentiation (81,82)

(Figure 28.21).

Detection of the following antigens is useful in the diagnostic evaluation of liver diseases: Î±1-antitrypsin in PAS-Dâ€“positive intracytoplasmic globules in periportal hepatocytes of patients with Î±1-antitrypsin deficiency (Figure 28.18); Î±-fetoprotein in hepatocellular carcinoma; and CEA, CK7, and Lewis blood group antigens in bile duct carcinoma, although CEA is also expressed in some hepatocellular and many other metastatic carcinomas (83,84).

The presence or absence and distribution pattern of viral antigens are helpful in the diagnostic and prognostic evaluation of viral hepatitis, particularly hepatitis B surface (Figure 28.27) and core antigens (Figure 28.28) in hepatitis B virus (HBV) or in dual HBV and HCV (hepatitis C virus) infection. The detection of hepatitis A, C, and delta (D) antigens and of herpesvirus antigens (cytomegalovirus, herpes simplex virus, and Epstein-Barr virus) confirms the cause of acute or chronic hepatitis (85). Since the cloning and sequencing of the HCV genome in 1989, there have been a number of studies for the detection of HCV antigens in the liver. However, the reports are conflicting (86,87,88). The detection rate of positive cases varied, which may be related to tissue sampling and differences in sensitivity of various methods and specificity and/or to avidity of the antibodies. Immunohistochemical studies on frozen sections appeared to demonstrate HCV antigens more reliably than on formalin-fixed, paraffin-embedded sections.

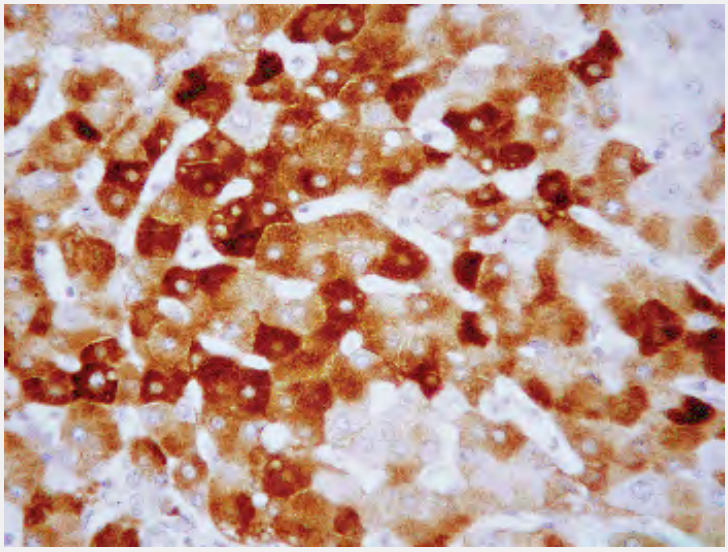

Figure 28.27 Immunostaining of hepatitis B surface antigen (HBsAg) in cytoplasm of ground-glass hepatocytes in an asymptomatic HBV carrier.

The expression of the various components of extracellular matrix in the diseased liver is currently under intensive investigation. It is clear that development of additional monoclonal antibodies to other antigens will further expand the usefulness of immunohistologic stainings to the diagnostic hepatopathologist.

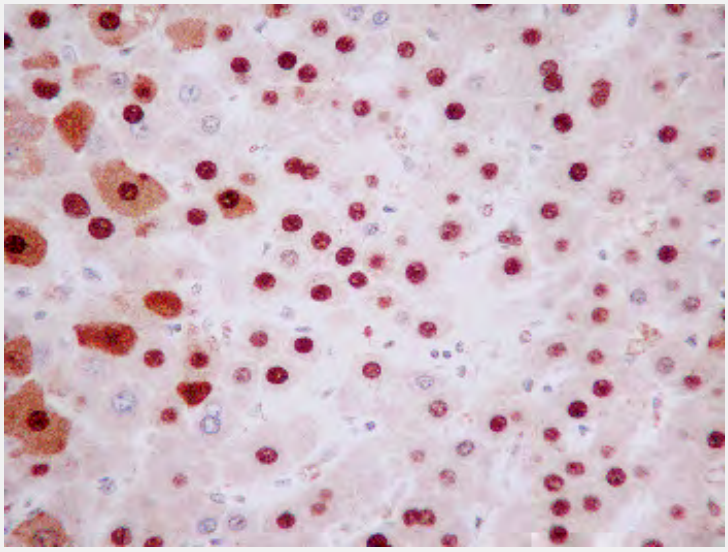

Figure 28.28 Immunostaining of hepatitis B core antigen (HBcAg) in numerous nuclei and cytoplasm of hepatocytes of an immunosuppressed patient with high viral replication.

Molecular Studies

In situ hybridization for the detection of DNA or RNA may be performed on formalin-fixed, paraffin-embedded tissue sections. In situ hybridization for albumin mRNA is highly specific for normal hepatocytes and hepatocellular tumors (69).

The detection of viral sequences such as those of Epstein-Barr virus and more recently of HCV by in situ hybridization appear to be more sensitive than by immunohistochemical methods (89,90,91). The sensitivity, especially in HCV infection, in which the number of virus in the liver is low, can be further increased by in situ polymerase chain reaction (92).

Aging Changes

There are several changes in the liver related to aging. These are commonly seen in individuals 60 years of age and older. There is more variation in the size of the hepatocytes and their nuclei, similar to that seen in patients on methotrexate, due to increased polyploid cells (93). With aging and atrophy of liver cell cords there may be apparent dilatation of sinusoids. More abundant lipofuscin deposition is present in the centrilobular hepatocytes, and sometimes there are some iron pigments in the periportal hepatocytes. The portal tracts contain denser collagen and may exhibit a higher number of mononuclear inflammatory cells than in younger subjects. The arteries may have thickened walls (Figure 28.29), even in normotensive individuals. These histologic changes of aging need to be kept in mind because they are often present in viable donors for which frozen sections are requested and should not be interpreted as pathologic. These aging-related findings are accompanied by alteration in the metabolic function of the liver, including the metabolism of toxins and drugs (94), and therefore may increase the susceptibility of the liver to hypovolemia and decrease its capacity for regeneration.

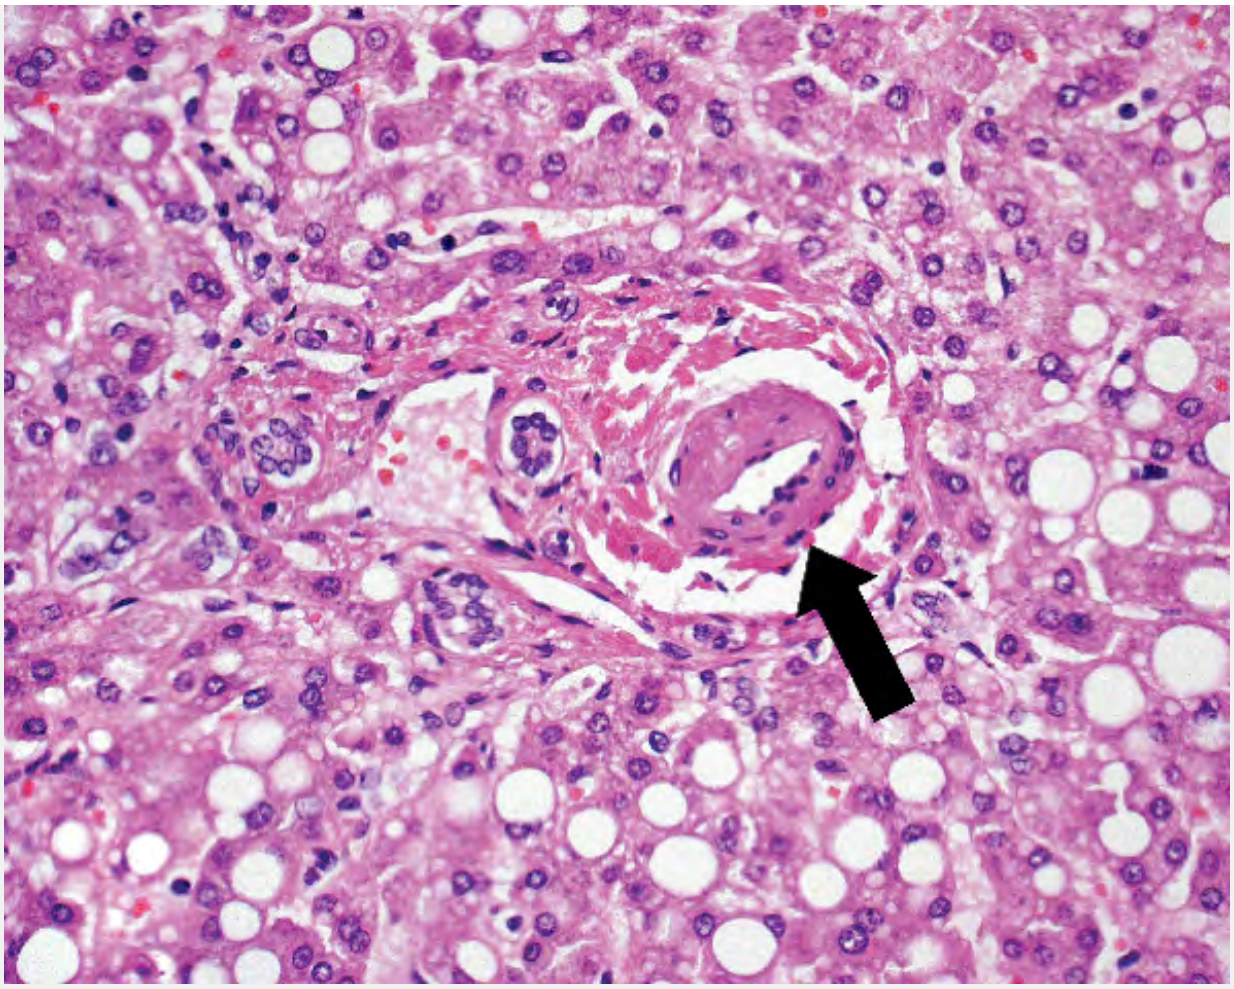

Figure 28.29 Thickened hepatic arteriole in an older individual (*arrow*).

Frequent Histologic Changes of Little Significance

In the Liver at Autopsy

Liver tissue obtained at autopsy often shows changes that are not usually seen in liver biopsy specimens and therefore may cause difficulties in the evaluation. Agonal loss of glycogen from

hepatocytes causes increased density and eosinophilia of the cytoplasm. Poor fixation results in irregular staining of hepatocytes, particularly in the center of the specimen. This may result in striking differences in the appearance of liver cells in the peripheral versus the central part of the tissue.

Agonal necrosis, particularly of hepatocytes in zone 3 in patients with shock or heart failure, may not be reflected in elevated aminotransferase levels (Figure 28.30). Its terminal nature is recognized from the lack of any inflammatory response. Autolysis of hepatocytes, particularly in hepatitis and cholestasis resulting in loss of cellular detail and prominent sinusoidal lining cells, is often more pronounced than in other tissues because the liver is rich in proteolytic enzymes. Loss of inflammatory cells by autolysis may make the diagnosis of hepatitis in postmortem specimens difficult (95). Trichrome stain assists greatly in the identification of portal tracts and central venules (and thus the lobular architecture) and, by demonstrating the fibrous septa, the chronicity of the condition.

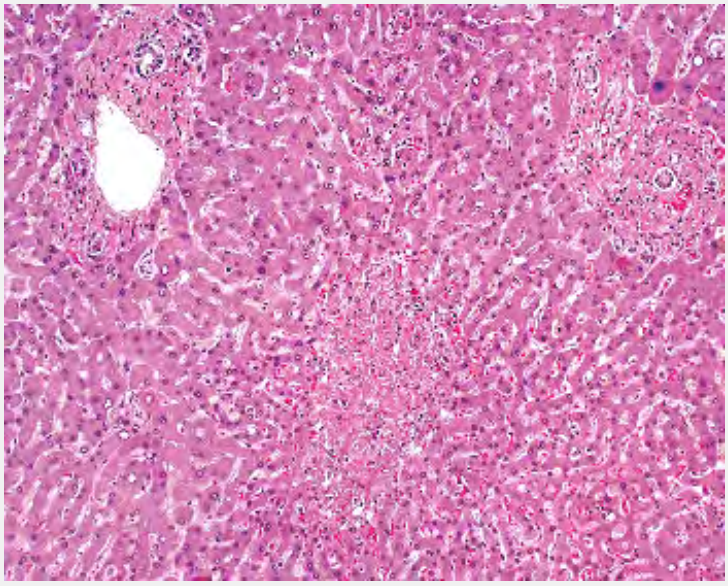

Figure 28.30 Agonal necrosis in zone 3 hepatocytes of autopsy liver without inflammatory cells.

Dilatation of the sinusoidal and perisinusoidal spaces is of little significance in postmortem liver tissues (Figure 28.14) as opposed to similar changes in well-preserved biopsy specimens. Focal accumulation of lymphocytes in scattered portal tracts is frequently seen in autopsy livers and does not justify the diagnosis of chronic hepatitis. Large tissue sections obtained at autopsy often include many large triangular portal tracts with abundant connective tissue that can be distinguished from true portal fibrosis by evaluation of the size of the intraportal structures. Increased fibrous tissue in portal tracts and parenchyma is a normal phenomenon in older individuals.

In Surgical Liver Biopsy Specimens

Surgical biopsy specimens may have several features not seen in needle biopsy specimens that may cause diagnostic difficulties. If the surgeon removes a small, superficial wedge of liver tissue from the inferior margin, the triangular tissue fragment is covered on two sides by the Glisson's capsule. The fibrous connections between the superficial portal tracts and the capsule may imitate cirrhosis (31) (Figure 28.31). However, these changes usually do not extend more than 2 mm into the liver parenchyma.

In biopsy specimens removed at the end of a long surgical procedure, clusters of polymorphonuclear neutrophils are seen in or under the capsule, in sinusoids, around terminal hepatic venules, in portal tracts, and in areas of small focal necroses resembling microabscesses, probably as a result of minor trauma (96) (Figure 28.32). This characteristic lesion must be distinguished from inflammatory liver diseases such as cholangitis. Other

â€œinnocentâ€• hepatic lesions include focal steatosis involving small groups of hepatocytes, fat granulomas from mineral oil deposition in perivenular areas and in portal tracts; undefined pigmentation, and unexplained mitoses of hepatocytes that normally have a life span of many years.

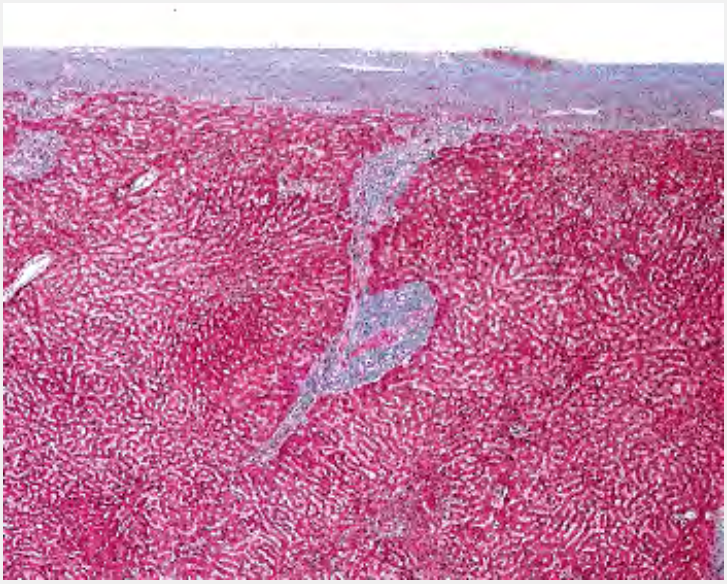

Figure 28.31 Surgical liver biopsy specimen showing fibrous connections between the capsule and superficial portal tracts, imitating the picture of cirrhosis (trichrome stain).

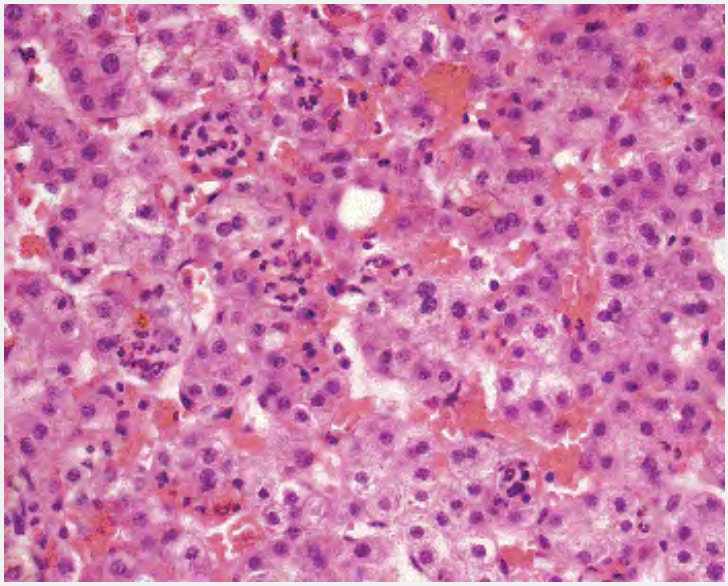

Figure 28.32 Surgical liver biopsy specimen showing clusters of polymorphonuclear neutrophils in sinusoids resembling microabscesses (surgical hepatitis).

Minor but Significant Hepatic Alterations

Nonspecific Reactive Hepatitis

This poorly defined histologic change represents a reaction of the liver to a variety of extrahepatic, particularly febrile, and gastrointestinal diseases. Nonspecific reactive hepatitis must be differentiated from primary liver diseases such as mild chronic hepatitis and residual stages of acute viral hepatitis. The alterations consist of activation of sinusoidal lining cells with prominent Kupffer cells, foci of isolated hepatocyte necrosis with accumulation of macrophages and other inflammatory cells, and mild infiltration of some portal tracts by mononuclear cells, without piecemeal necrosis or interface hepatitis (Figures 28.33,28.34). Scattered hepatocytes

also may contain microvesicular or macrovesicular fat droplets.

Nonspecific reactive hepatitis with steatosis, increased variation in size and staining quality of hepatocyte nuclei, sinusoidal dilatation, and poorly developed granulomas are seen in livers of patients with acquired immunodeficiency syndrome (AIDS) (97,98). The granulomas are poorly formed and may be difficult to recognize, but special stains may show the a large number of microorganisms such as *M. avium-intracellulare.* Although patients with AIDS are often infected with cytomegalovirus, the characteristic intranuclear and cytoplasmic inclusions are

sometimes not detected in the liver. Instead, focal aggregates of polymorphonuclear leukocytes (so-called microabscesses) may be seen in the lobules at the sites of the degenerated infected hepatocytes or sinusoidal lining cells (98,99) (Figure 28.35).

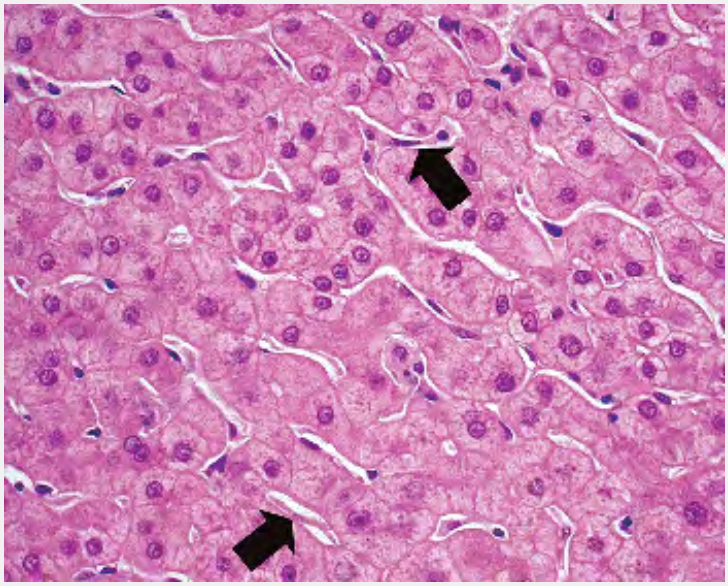

Figure 28.33 Nonspecific reactive hepatitis characterized by activation of sinusoidal lining cells (*arrows*).

Vicinity of Space-Occupying Lesions

Nonspecific reactive changes are also seen in patients with space-occupying lesions in the liver (100). Although the biopsy specimen may not include the neoplasm, the abscess, or the cyst, a characteristic histologic triad is often observed in the adjacent liver. These changes consist of proliferated and distorted bile ductules with irregular and even atypical epithelium accompanied by neutrophils in edematous portal tracts, and focal sinusoidal dilatation and congestion (Figure 28.36). In contrast to large bile duct obstruction and other biliary tract diseases such as primary sclerosing cholangitis, cholestasis is usually absent. In addition, the liver cell plates may be compressed and distorted with atrophy of hepatocytes. These histologic changes are the result of focal obstruction of blood and bile flow by the expanding mass. They may be subtle and are usually focal

with involvement of small portal tracts. The described triad is characteristic for the vicinity of a space-occupying lesion, and its recognition in a liver specimen should lead to continued search for a neoplasm, cyst, or abscess.

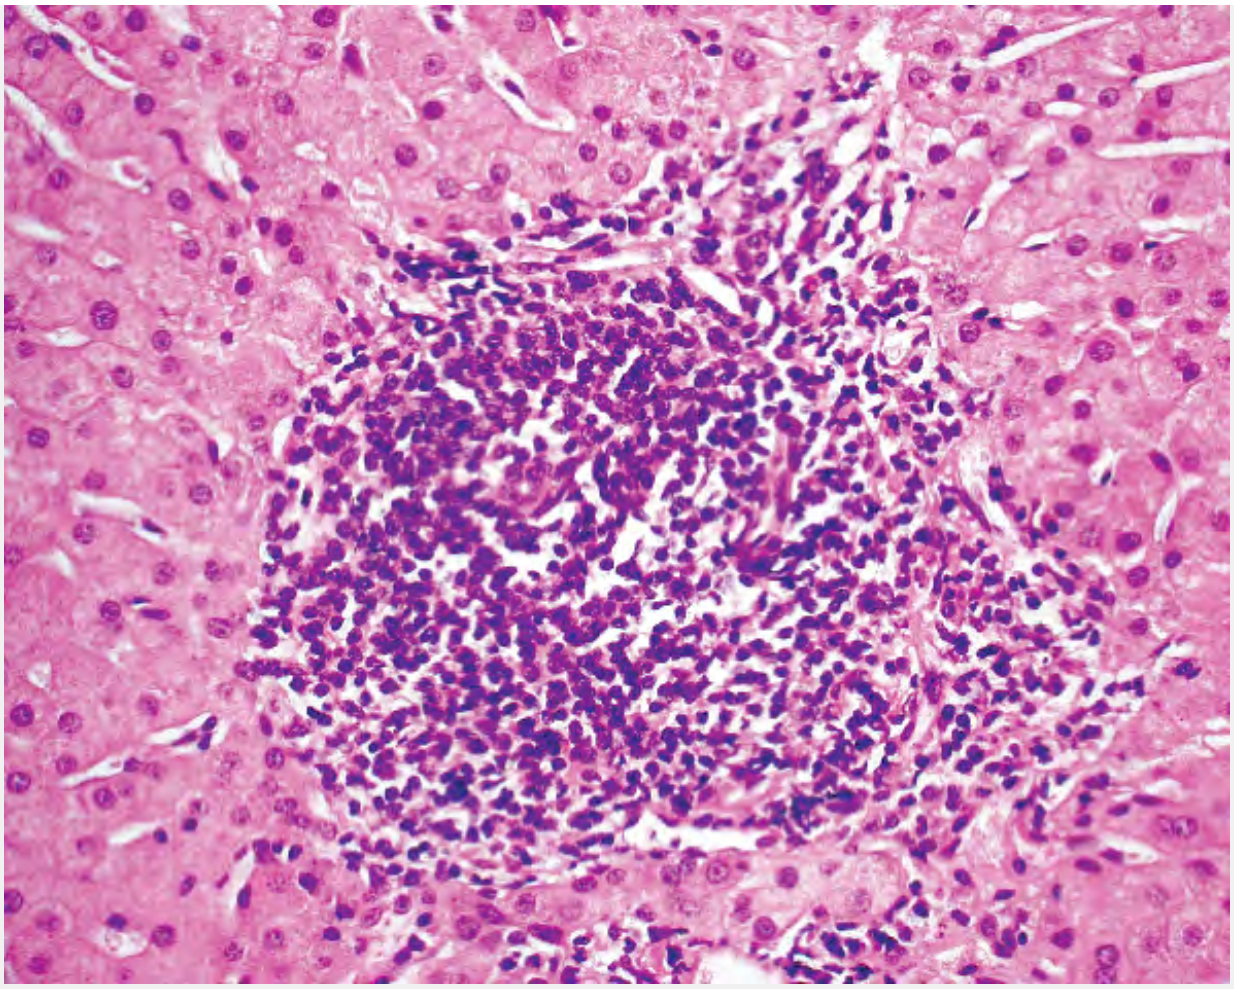

Figure 28.34 Dense lymphocytic aggregate in a portal tract with chronic hepatitis C.

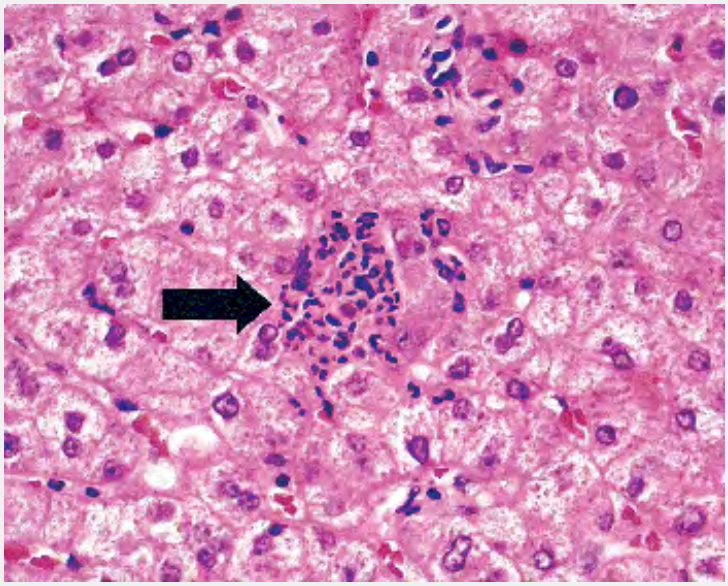

Figure 28.35 Aggregates of polymorphonuclear leukocytes in sinusoid adjacent to a cytomegalovirus-infected cell (*arrow*).

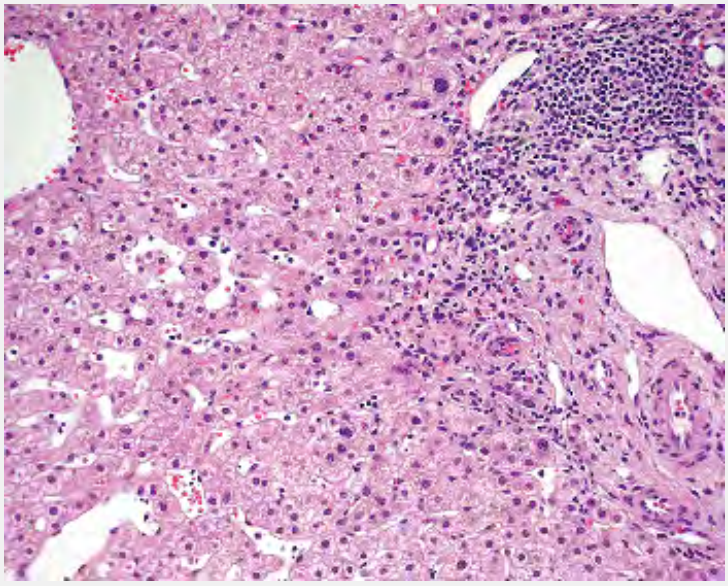

Figure 28.36 Liver biopsy specimen of patient with metastatic

carcinoma showing dilatation of sinusoids in zone 2, as well as proliferation of bile ductules and infiltration of portal tract by neutrophils. The specimen did not contain metastatic carcinoma, but the histologic changes are consistent with the vicinity of a space-occupying lesion.

Sinusoidal Dilatation

Acute or chronic venous congestion with dilatation of sinusoids in Rappaport acinus zone 3 and of terminal hepatic venules is frequently seen at autopsy but also in biopsy specimens; it is usually a consequence of right-sided congestive heart failure, whereas irregular necrosis of hepatocytes in zone 3 is often caused by left-sided heart failure or shock (101). In more severe and chronic cases, there is also atrophy of hepatocytes with increased lipofuscin accumulation and scattered small droplet fat vacuoles, enlargement of Kupffer cells containing ceroid pigment, focal cholestasis, and progressive fibrosis in the periphery of the acinus (rather than concentric around the central venules). Engorgement of sinusoids around terminal hepatic venules is also observed in patients with Budd-Chiari syndrome, veno-occlusive disease, sepsis, malignant tumors, so-called collagen diseases, granulomatous diseases, Crohn's disease, and in patients with AIDS (97,102,103,104).

In contrast, dilatation of sinusoids in Rappaport acinus zone 1 has been observed in pregnancy, in renal transplant patients, after exposure to anabolic/androgenic or contraceptive steroids (105,106,107), and near space-occupying lesions (100). After exposure to vinyl chloride, thorotrast, arsenicals, and oral contraceptives, sinusoidal dilatation may be accompanied by hepatocellular and sinusoidal cell hypertrophy, hyperplasia, and dysplasia, increased reticulin fibers along sinusoids, and portal fibrosis (106,107,108).

Acknowledgments

The late Dr. Hans Popper reviewed the manuscript and offered invaluable constructive criticism. The late Dr. Michael Gerber was the senior author of this chapter in the earlier editions. The authors thank Pamela Ramali for revising illustrations in this chapter.

Gallbladder and Extrahepatic Biliary System

Edward B. Stelow

Seung-Mo Hong

Henry F. Frierson Jr.

Introduction

The gallbladder is one of the most common surgical pathology specimens. It is most often resected because of stones or inflammatory disease and is only rarely resected because of neoplasia. Somewhat uncommonly, grossly and microscopically â€œnormalâ€• gallbladders are removed incidentally during surgery for other reasons (e.g., liver transplantation). At most institutions, these specimens are rarely seen. The situation is quite different with the extrahepatic bile ducts and ampullae of Vater. These sites are infrequently sampled by biopsy only when neoplasia is suspected, especially cholangiocarcinoma or ampullary adenocarcinoma. The distal common bile duct and ampulla can be studied in the occasional pancreatoduodenectomy specimen but will often be abnormal due to the effects of an ampullary or periampullary neoplasm. The remaining extrahepatic bile duct is rarely resected. The complete biliary system and ampulla can be only studied with autopsy

material; however, due in some part to the toxicity of bile, significant autolysis is usually present in these specimens.

This chapter discusses the gross anatomy, physiology, histology, immunohistochemistry, and ultrastructure of the normal gallbladder, extrahepatic bile ducts, ampulla of Vater, and minor papilla.

Gallbladder

Gross Anatomy

The gallbladder is a piriform bladder that is attached to the extrahepatic biliary system via the cystic duct and rests in a shallow depression located on the inferior surface of the posterior right lobe of the liver. It measures up to 10 cm long and 3 to 4 cm wide in normal adults, and its wall is approximately 1 to 2 mm thick, varying due to the degree of muscular contraction. The serosal surface of the liver extends to cover the gallbladder, while interlobular connective tissue of the liver merges with the subserosal connective tissue of the gallbladder. The gallbladder is anatomically divided into a blindly ending fundus, a large central body, and a narrow neck that joins the cystic duct. The tapered area of the body that joins the neck is considered the infundibulum. It is here that a peritoneal fold, the cholecystoduodenal ligament, attaches the gallbladder to the first portion of the duodenum. Hartmann's pouch, a small bulge at the infundibulum, is probably not normal and may result from chronic inflammation or stone impaction (1). The neck is somewhat serpentine, measures 5 to 7 mm long, and narrows as it connects with the cystic duct (2).

Physiology

The gallbladder concentrates, stores, and releases bile. Approximately 800 to 1000 mL of bile flow daily into the gallbladder

from the liver (3). Its filling results from complex neural and hormonal stimulations that result in its relaxation and the contraction and closing of the sphincter of Oddi. When the sphincter is closed, the intraluminal pressure of the bile ducts will increase as bile is continuously produced by the liver; bile will then flow into the gallbladder. When relaxed the gallbladder can store only 40 to 70 mL of bile and retains a constant intraluminal pressure (3). A much larger volume, however, is handled as the gallbladder concentrates bile via a sodium-coupled transport of chloride, mediated by sodium potassium-ATPase (NaK-ATPase) (4). The active transport of electrolyte into the lateral intercellular space creates an osmotic gradient, and water ultimately flows through the basement membrane into the capillaries of the lamina propria. The gallbladder also has a secretory role, liberating mucosubstances from the surface epithelial cells and neck mucous glands.

Contraction of the gallbladder is also mediated by complex neural and humoral mechanisms and occurs both after and between meals (5). Cholecystokinin, released from the mucosa of the proximal duodenum after fatty meals, is the most important hormone that promotes gallbladder contraction (6). Motilin aids in interdigestive gallbladder contraction, which occurs in tandem with giant migratory complexes of the intestines every two hours or so (5,7). Other peptides including pancreatic polypeptide and somatostatin may affect gallbladder motility (5,7,8,9). The vagal system may also play a role both directly and indirectly in gallbladder contraction (10). The complicated balance of humoral and neural mechanisms involved in the working of the gallbladder is sometimes disrupted and many disease states have been implicated in the development of gallbladder dysmotility. Dysmotility may, in turn, result in gallbladder pathology (11).

Blood Supply and Lymphatic Drainage

The arterial supply of the gallbladder varies both in its anatomy and

in its relationship to the extrahepatic biliary system. The cystic artery supplies the gallbladder and usually arises from the proximal portion of the right hepatic artery. Indeed, 72% of all cystic arteries in a study by Moosman and Collier (12) arose from the right hepatic artery, whereas 13% arose from the superior mesenteric artery; the remainder originated from the common hepatic artery, left hepatic artery, gastroduodenal artery, celiac artery, or aorta. Most commonly, the artery is located superior to the cystic duct (Figure 29.1). In Moosman and Collier's study, 70% of all cystic arteries coursed to the right of the common hepatic duct, and 17% traveled anterior to the common hepatic duct; the remainder of the cystic arteries passed posterior to

the common hepatic duct, anterior or posterior to the common bile duct, to the right and inferior to the cystic duct, or posterior to both hepatic ducts. The cystic artery branches to form superficial channels that lie over the gallbladder serosa and deep channels that lie between the gallbladder and its hepatic bed (2). One of the more common anatomic variations noted is the double cystic artery. In their study of the extrahepatic biliary tree in 250 cadavers, Moosman and Collier noted a double cystic artery in 14% of their cases. Michels found double cystic arteries in one-quarter of 200 cadavers (13).

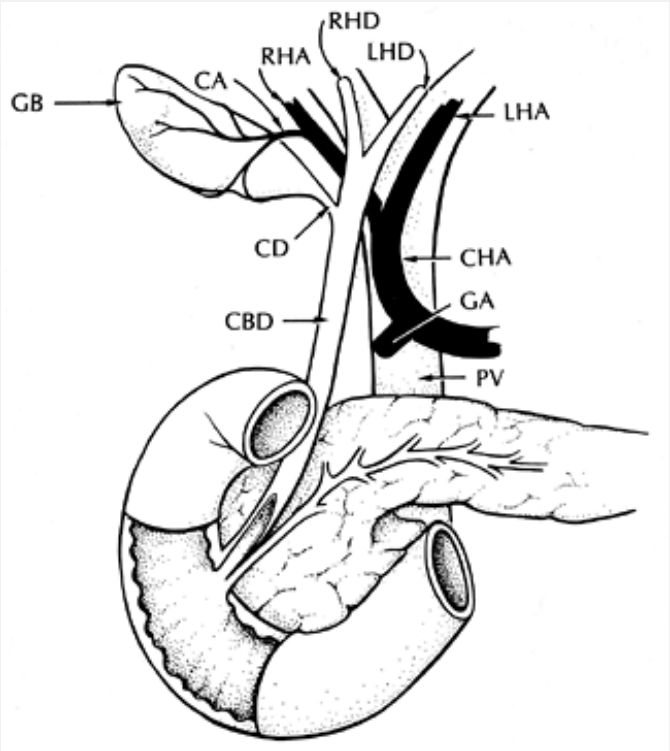

Figure 29.1 Although variations are common, this diagram depicts the â€œusualâ€• relationships of the extrahepatic bile ducts, portal vein, and branches of the common hepatic artery. (*PV,* portal vein; *GA,* gastroduodenal artery; *CHA,* common hepatic artery; *LHA,* left hepatic artery; *LHD,* left hepatic duct; *RHD,* right hepatic duct; *RHA,* right hepatic artery; *GB,* gallbladder; *CA,* cystic artery; *CD,* cystic duct; *CBD,* common bile duct)

A single large cystic vein does not exist (2). The venous drainage consists, in part, of small venous channels on the hepatic side of the gallbladder that lead directly into the liver. Other small veins flow toward the cystic duct and merge with channels from the common bile duct before terminating in the portal venous system.

The lymphatic system of the gallbladder has been investigated by

anatomic and physiologic studies and by studies of gallbladder malignancy (14,15). The lymphatics of the gallbladder drain first into lymph nodes at the gallbladder neck or cystic duct. Following this, drainage may proceed to retropancreatic, celiac, or mesenteric lymph nodes. These pathways appear to all converge at abdominal aortic lymph nodes located at the superior mesenteric artery (14). In a study in which dye was injected directly into lymphatic vessels of the gallbladder, the dye flowed initially into the cystic node and pericholedochal nodes, then into lymph nodes posterior to the pancreas, portal vein, and common hepatic artery, and finally into interaortocaval nodes near the left renal vein (15). Ascending lymph flow to the hepatic hilum does not usually occur; however, retrograde flow to the hepatic hilum may occur when there is blockage of lymphatic channels by cancer, inflammation, or surgical ligation (15).

Nerve Supply

Nerve branches from the left trunk of the vagus join the hepatic plexus. The hepatic plexus then supplies the gallbladder with sympathetic, parasympathetic, and possibly afferent nerve fibers (2). Vagal stimulation, both directly and indirectly, may then stimulate interdigestive periodic contractions of gallbladder smooth muscle (10). Neuropeptide Y nerve fibers, which may also participate in gallbladder smooth muscle contraction, are found in all layers of the gallbladder. They form a particularly dense network in the lamina propria, running near the epithelium and paralleling the muscle bundles (16).

Histology

The layers of the gallbladder include the mucosa (surface epithelium and lamina propria), smooth muscle, perimuscular subserosal connective tissue, and serosa. A muscularis mucosae and submucosa are not present. The luminal folds are lined by a single layer of

columnar epithelium and have cores of lamina propria. The height and width of the folds are variable, and branching is characteristic (Figure 29.2). The columnar epithelial cells have lightly eosinophilic cytoplasm with occasional small apical vacuoles (Figure 29.3). Nuclei are aligned at the cell base or slightly more centrally. They are oval and uniform and have fine chromatin and smooth membranes. Nucleoli are absent or very small and inconspicuous. Occasional columnar cells are

narrow with dark eosinophilic cytoplasm (1). These cells, dignified with the appellation â€œpencil-likeâ€• cells, appear to be little more than contracted columnar cells, although they reportedly have a few ultrastructural and enzymatic properties that differ from those of the usual columnar cells. Basal cells are inconspicuous and have nuclei that lie just above and parallel to the basement membrane.

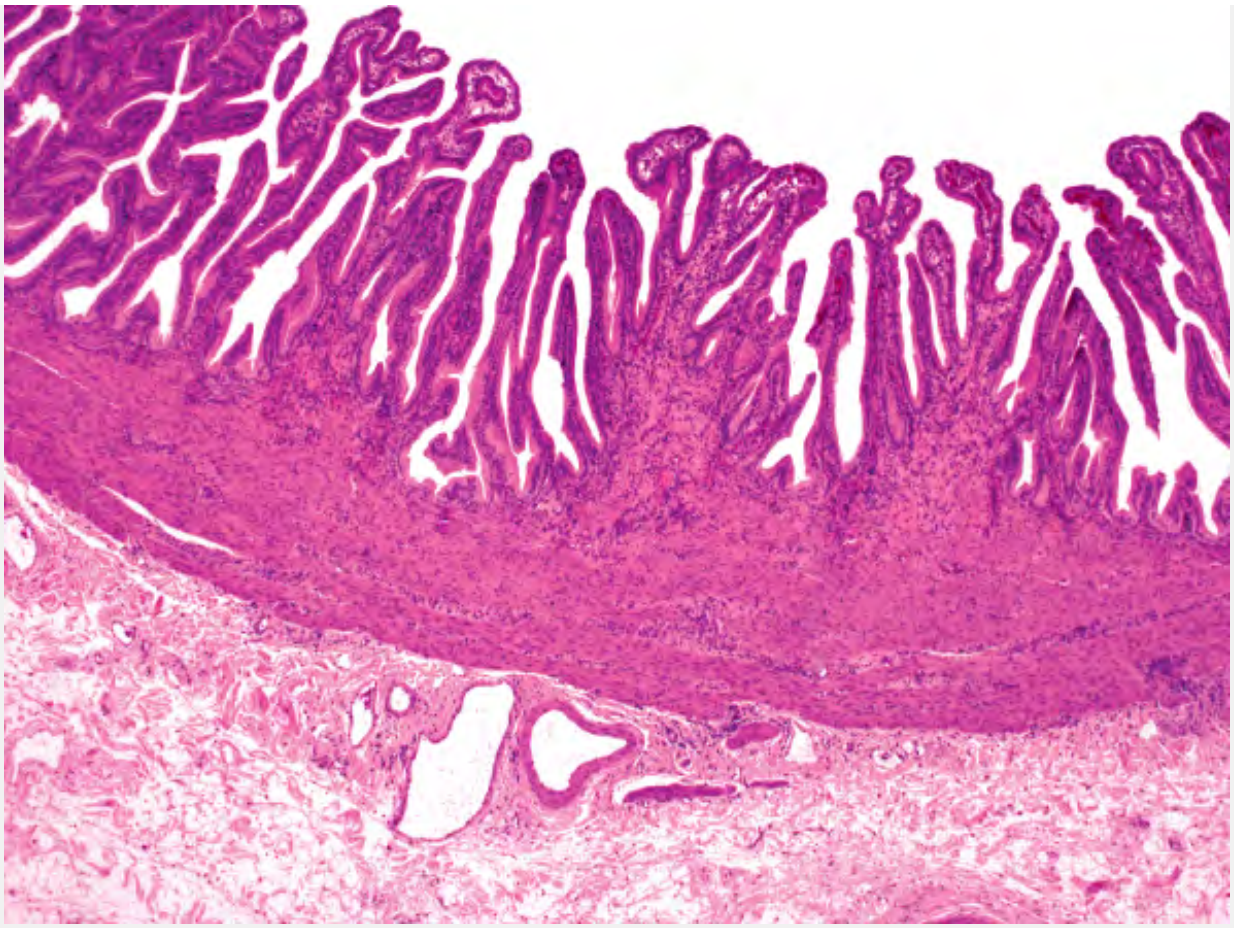

Figure 29.2 The luminal folds of the gallbladder vary in height and contain a delicate core of lamina propria above the bundles of smooth muscle.

Figure 29.3 The gallbladder is lined by a single layer of tall columnar cells with basally oriented nuclei.

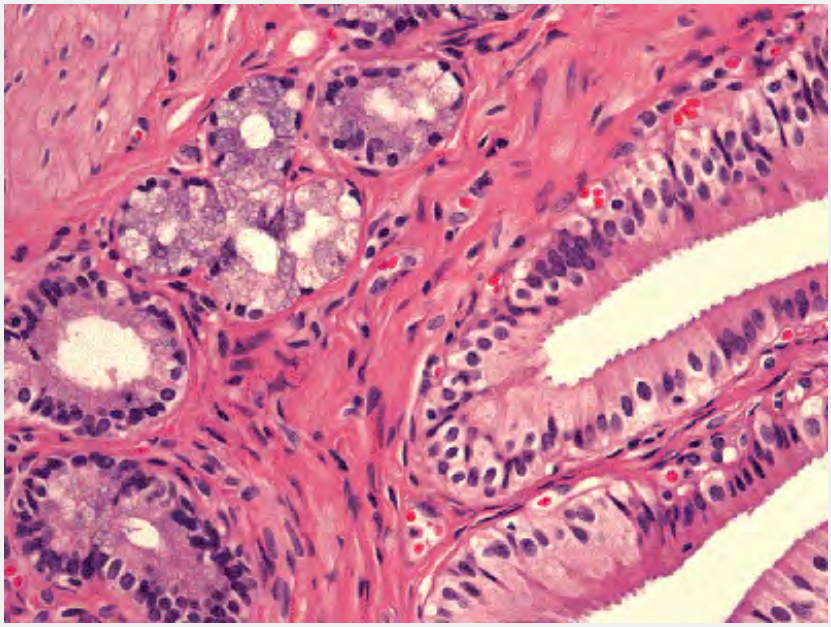

Figure 29.4 Mucous glands are present only in the neck of the normal gallbladder.

Tubuloalveolar mucous glands are located only in the neck of the gallbladder (17). They have cuboid or low columnar cells with abundant clear to lightly basophilic cytoplasm and round, basally oriented nuclei (Figure 29.4). Their lectin-binding profile is dissimilar to that of the surface epithelial cells (18). The neck mucous glands also differ morphologically and histochemically from the antral-type metaplastic glands found in the fundus, body, or neck of chronically inflamed gallbladders or those that contain gallstones (17). Rare endocrine cells can be found here but are otherwise absent in the normal gallbladder (19,20). Gastric metaplasia (foveolar-type epithelium or antral-type glands) and â€œintestinalâ€• metaplasia (absorptive cells with prominent brush borders, endocrine cells, goblet cells, and Paneth's cells) are not observed in the normal gallbladder but commonly occur in chronic cholecystitis and cholelithiasis (1,17,21,22,23,24,25). Squamous metaplasia, rarely

found in diseased gallbladders, is also absent in normal gallbladders (1). Melanocytes are not found in the normal epithelial lining. However, a few small lymphocytes often are seen between the surface columnar cells.

Gallbladder epithelial cells contain chiefly sulfated acid mucin with very small quantities of nonsulfated acid mucin (17). In contrast, metaplastic cells (goblet cells, superficial gastric-type cells, antral-type glands) contain nonsulfated acid mucin and neutral mucin but little sulfated acid mucin. By immunohistochemistry, the epithelial cells express MUC5AC and MUC6, akin to gastric epithelium; however, pepsinogens I and II, present in pyloric gland metaplasia, are not seen in normal gallbladder epithelium (24,26). Lysozyme is also absent in the normal columnar cells but may be found in metaplastic glands (27). Alpha-1-antitrypsin and Î±1-antichymotrypsin are present in both normal and metaplastic epithelia (27).

Immunohistochemical staining for carcinoembryonic antigen (CEA) (polyclonal; unabsorbed) of normal gallbladders shows focal weak staining along the apices of some lining cells (28). In contrast to the results using monoclonal antibodies to CEA, inflamed epithelium usually shows immunostaining with polyclonal antisera (29). Absorption of at least one polyclonal antibody with human liver powder abolishes the immunoreactivity because there is removal of the CEA-related glycoproteins nonspecific cross-reacting antigen (NCA) and biliary glycoprotein (BGP) (29). The surface epithelium and neck mucous glands are strongly immunoreactive for epithelial membrane antigen and low-molecular weight keratin (CAM 5.2 antibody). The CAM 5.2 antibody also stains some smooth muscle fibers in the gallbladder wall. Normal gallbladder epithelium also reacts with antibody directed against cytokeratin (CK)7 and does not react with antibody directed against CK20 (Figure 29.5) (30). Because endocrine cells are not found in the normal epithelium of the fundus or body, immunohistochemical staining for neuron-specific enolase and chromogranin A is absent (19). A few argentaffin

(enterochromaffin) cells are present in the mucous glands of the neck; these cells are readily detected by an antibody to chromogranin A (19). Normal gallbladder mucosa lacks immunoreactivity for estrogen receptor, whereas in 6 of 31 cases of cholelithiasis, a few immunoreactive cells were observed chiefly in metaplastic mucous glands (pseudopyloric glands) (31). Adhesion molecules expressed by normal gallbladder epithelial cells include Î±-catenin, Î²-catenin, Î³-catenin, CD44, CD99, and E-cadherin (32).

The lamina propria contains loose connective tissue, elastic fibers, nerve fibers, small blood vessels, and lymphatic

channels. Mast cells and macrophages may be seen in small numbers, and it has been noted that these cells are more numerous in normal or minimally inflamed gallbladders than in those with overt chronic cholecystitis (Figure 29.6) (33). Polymorphonuclear leukocytes normally are not present in the lamina propria, but small numbers of lymphocytes and plasma cells are usual. Plasma cells that contain immunoglobulin (Ig)A occur chiefly in the lamina propria, whereas IgM-containing cells are more frequent in the smooth muscle layer (34). A few IgG-containing plasma cells also may be present.

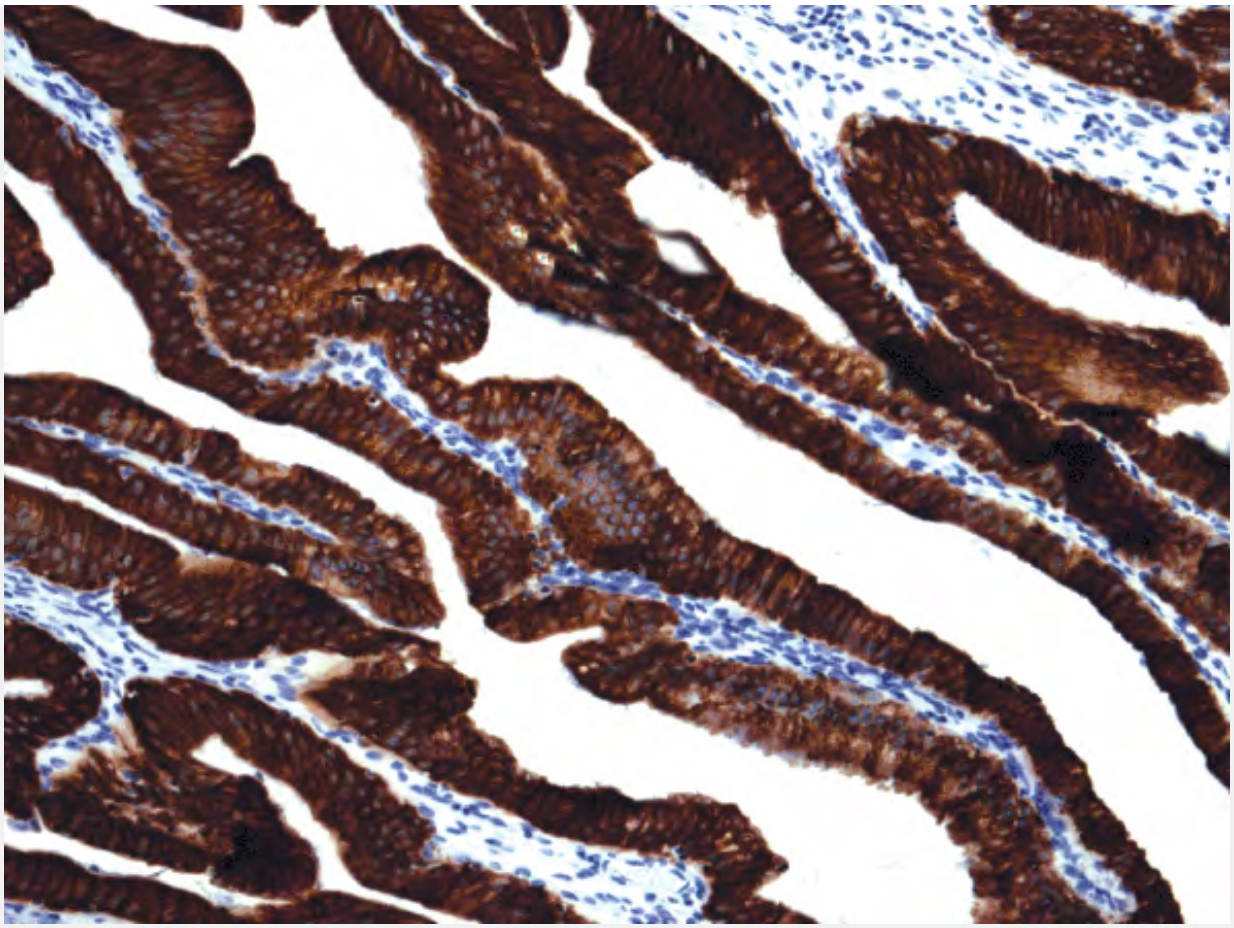

Figure 29.5 The epithelial lining of the gallbladder reacts strongly with antibodies directed against cytokeratin 7 (immunoperoxidase technique).

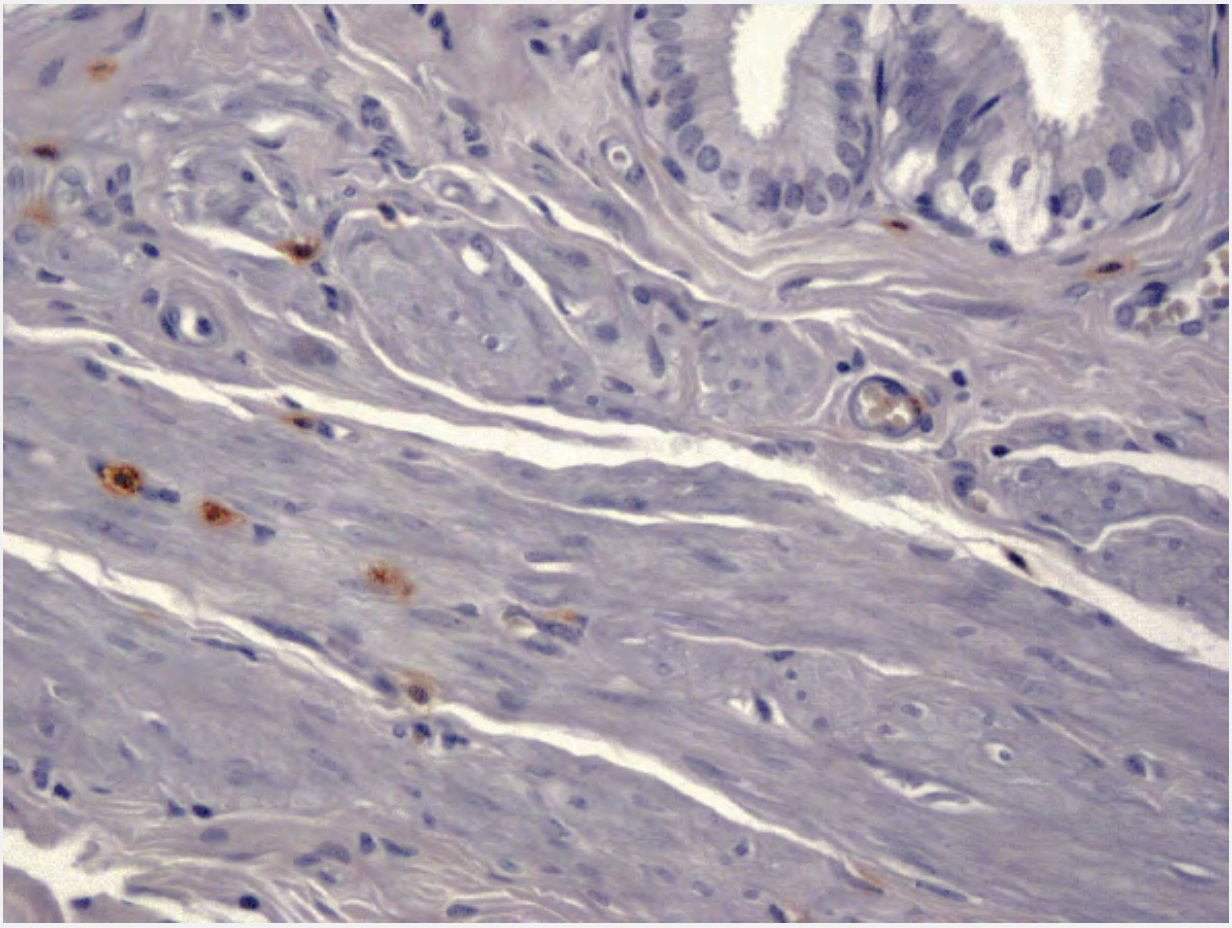

Figure 29.6 Occasional mast cells are identified within the gallbladder by kit-immunostaining. No interstitial cells of Cajal were identified (immunoperoxidase technique).

The smooth muscle consists of loosely arranged bundles of circular, longitudinal, and oblique fibers that do not form well-developed layers like they do in the luminal gut. Fibrovascular connective tissue focally separates the muscle bundles. The muscle fibers sometimes extend high into the lamina propria to just beneath the epithelial basement membrane. The thickness of the muscle layer is quite variable, which may simply reflect variable contractile states of the specimen. Ganglion cells are found in the lamina propria, between

smooth muscle bundles, and in the subserosal connective tissue (Figure 29.7). We have been unable to identify interstitial cells of Cajal, although they have been rarely noted by other authors, and rare gastrointestinal stromal tumors of the gallbladder have been reported (1,35).

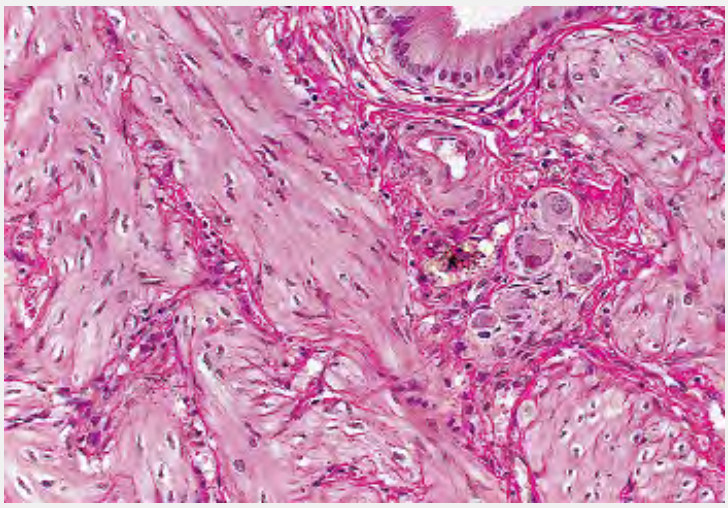

Figure 29.7 Ganglion cells are readily seen in the connective tissue layers of the gallbladder.

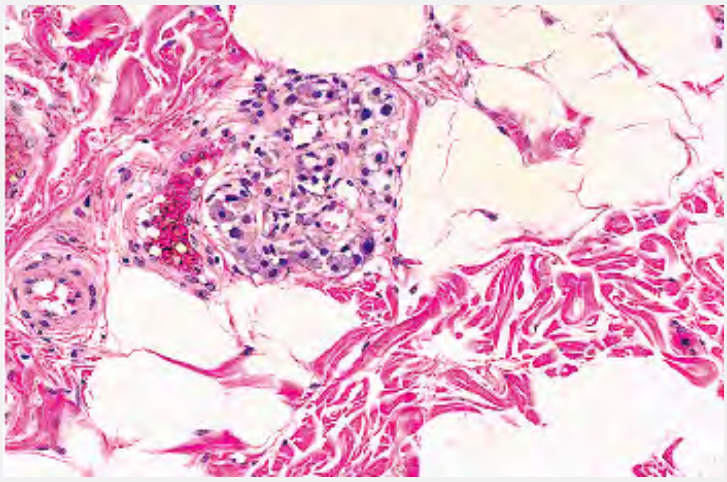

Figure 29.8 Paraganglia are located in the subserosal connective tissue of the normal gallbladder.

The subserosal tissue contains loose collagen fibers, fibroblasts, elastic fibers, adipocytes, blood vessels, nerves, and lymphatics. Small aggregates of lymphocytes may occur around vessels. Uncommonly, a lymph node is found in the subserosal connective tissue (36). Paraganglia, infrequently seen in routine sections, are found adjacent to blood vessels and small nerves (Figure 29.8). Examining serial blocks and subserial sections of gallbladders, the investigators of one study found one to five paraganglia in the subserosal tissue of nine of ten cholecystectomy specimens (37).

Rokitansky-Aschoff sinuses represent herniations of epithelium into the lamina propria, smooth muscle, or subserosal connective tissue (Figure 29.9). Although these

are commonly considered a feature of chronic cholecystitis, they are often present in histologically normal gallbladders, albeit more superficially. In a series of 125 cholecystectomy specimens that were inflamed or contained gallstones, 86% had Rokitansky-Aschoff sinuses, almost 90% of which penetrated into or through the smooth muscle (38). The sinuses were also observed in 42% of 112 normal gallbladders examined at autopsy (39). When present in normal gallbladders, they were generally confined to the lamina propria, with infrequent penetration of the smooth muscle. The sinuses are not found in gallbladders from fetuses, but a few superficial outpouchings may be observed in organs from infants (40). The diameters of the sinuses are variable, and flask-shaped formations are usual. Although the exact mechanism for their formation is unknown, herniation of the epithelium may result from overdistension (with increased intraluminal pressure) and extreme contractions of the gallbladder, with subsequent weakening of its wall (40).

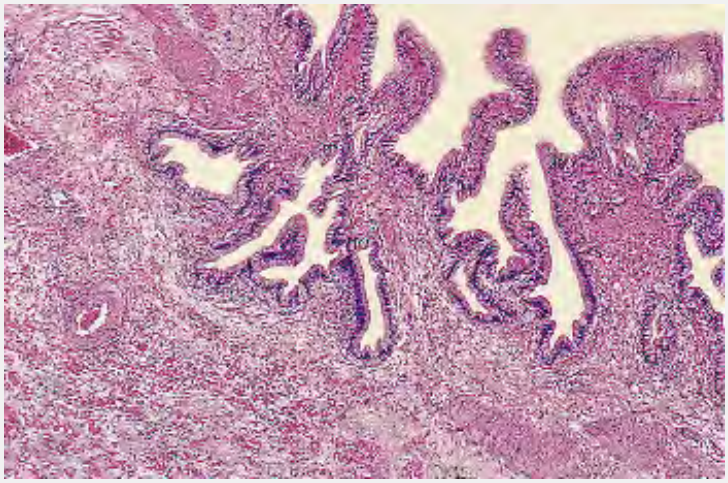

Figure 29.9 Rokitansky-Aschoff sinuses occur in the normal gallbladder but uncommonly penetrate through the smooth muscle bundles.

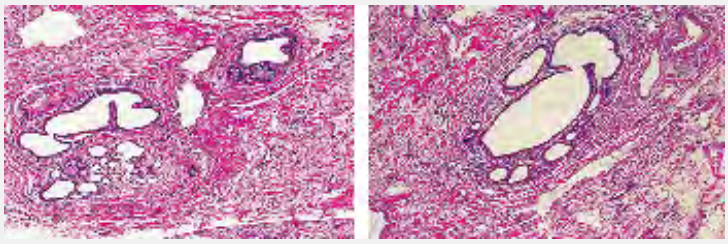

Figure 29.10 Luschka's ducts consist of groups of small ducts having lumina of various caliber. They are surrounded by condensed connective tissue.

Luschka's ducts are small, usually microscopic, bile ducts that lie in

the subserosal connective tissue, most commonly on the hepatic side of the gallbladder (Figure 29.10). Occasionally, a few ducts are present in the subserosal connective tissue on the peritoneal side. The ducts have been found in 10 to 12% of routine sections from cholecystectomy specimens, occurring in both normal and diseased organs (39,40). They have been observed in gallbladders from infants, adolescents, and adults and may represent embryonic remnants. Reports of their drainage site are varied. Most have argued that they communicate with intrahepatic bile ducts; however, some have argued that those beneath the serosa possibly drain into the peritoneal cavity, and others, rarely, have suggested that they may drain into the gallbladder lumen, especially within its neck (38,40,41).

The ducts are solitary or multiple but are usually present in small groups surrounded by a distinctive ring of connective tissue and may be adjacent to blood vessels. In serial sections, they sometimes are seen as a system of anastomosing channels. The diameters of their lumina vary from several microns up to a few millimeters. The ducts are lined by cells similar to those of the intrahepatic bile ducts. In some instances, small foci of hepatic parenchyma are located adjacent to the ducts (40). Luschka's ducts are distinct from Rokitansky-Aschoff sinuses, and the two should not communicate. It should be noted that the term *Luschka's duct* has been used somewhat indiscriminately and has been used to refer to entities ranging from Rokitansky-Aschoff sinuses to true accessory ducts.

At surgery and by cholangiography, larger accessory ducts (up to several millimeters long) sometimes are seen in the gallbladder bed. They may be mistaken grossly for small veins or thin strands of fibrous tissue (42). If these ducts are not ligated during surgery, a bile leak may develop, which typically ceases spontaneously. In one study, 9% of 204 patients with randomly selected cholecystectomies had bile leaks from the drain tube; some of these were considered to be due to a divided subvesical duct (43). Although these ducts lie in the gallbladder wall, they usually do not drain into the lumen of the

fundus but communicate with the cystic or hepatic ducts (44,45). In a study of 20 autopsy dissections from patients without biliary disease, six subvesical ducts were found, five of which were placed centrally in the gallbladder bed and one in the lateral peritoneal reflection (43). Five led to the right hepatic duct, and one entered the common hepatic duct.

Ectopic hepatic, pancreatic, adrenal, gastric, and thyroid tissues have been reported in the gallbladder (46,47,48,49). Ectopic hepatic and adrenal tissues are typically incidental findings, whereas ectopic pancreatic or gastric tissues may lead to symptoms related to their secretions (46).

Ultrastructure

The surface columnar cells measure 15 to 25 Âµm in height and 2.5 to 7.0 Âµm in width and rest on a basement membrane (50). These cells have numerous apical microvilli with filamentous glycocalyx and core rootlets (Figure 29.11). The microvilli are shorter and more variable in size and density than those of the intestinal epithelium. Pinocytotic vesicles are formed from the intervillous portions of the cell membrane. The lateral cell membranes are straight at the apex and connected by junctional complexes. Below this boundary, the cell membranes have complex interdigitations that surround lateral intercellular spaces (Figure 29.11). The diameter of the intercellular space varies, depending on the state of fluid transport (51). It is collapsed when there is no water transport but is distended during influx of electrolytes and water. The nuclei are oval, have prominent euchromatin, and occasional small nucleoli. The cytoplasm contains rough endoplasmic reticulum, mitochondria, glycogen, filaments, Golgi apparatus, mucous granules, vesicles, and lysosomes.

Pencil cells have slender outlines, narrow nuclei, and dense cytoplasm that is packed with organelles. At the base of the pencil cell, cytoplasmic extensions project into the basement membrane,

unlike that for the typical columnar cell (52). However, microvilli and lateral membrane interdigitations are similar for the pencil cell.

The basal cell measures 10 to 15 Âµm in diameter, has an irregular nucleus, and has cytoplasmic organelles that include rough and smooth endoplasmic reticulum, mitochondria, vacuoles, and ring-shaped osmiophilic inclusions (50,52). They have a cytoplasmic extension that runs parallel to the basement membrane, changes direction to run perpendicularly, and then branches toward the lumen (50). The branches are variable in length, delicate, and complex. Throughout the lining epithelium, there are intraepithelial nerve endings that originate from the nerve submucosal plexus and are associated with the small basal cells (50).

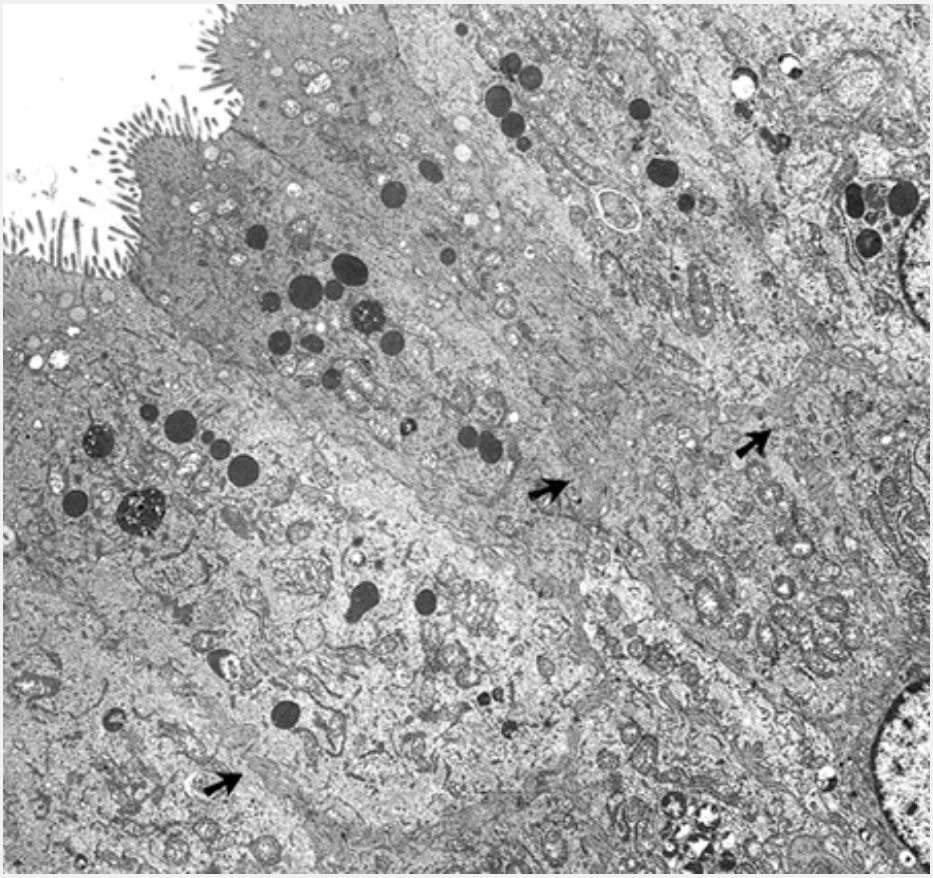

Figure 29.11 Ultrastructurally, the apical portion of the

columnar cells of the gallbladder contains abundant microvilli with core rootlets, mitochondria, Golgi apparatus, mucous granules, lysosomes, and a few strands of rough endoplasmic reticulum. The lateral cell membranes form complex interdigitations (*arrows*).

Capillaries are found just below the epithelial basement membrane, and their lumina change in size according to the state of fluid transport. The epithelial cells of the glands in the gallbladder neck have a few short microvilli, relatively even lateral membranes, rare secretory granules, and round nuclei (53).

Cystic Duct

The cystic duct is located at the right free edge of the lesser omentum and usually joins the right lateral portion of the common hepatic duct approximately 2 cm distal to the union of the right and left hepatic ducts. In one study, the mean length of the cystic duct was 30 mm and ranged in size from 4 to 65 mm (12). The mean collapsed diameter was 4 mm. Connection and drainage into the common hepatic duct varies. Anatomic studies have found that most cystic ducts drain laterally at an acute angle into the common bile duct (12). In some cases, it may form an angular junction with either the anterior or posterior aspect of the common hepatic duct. A short cystic duct parallel to the common hepatic duct may be present, and a long cystic duct has been rarely noted. Rarely, the cystic duct may spiral and join the common hepatic duct anteriorly or posteriorly. In a cholangiographic study involving large numbers of patients, however, the cystic duct drained laterally at an acute angle into the common bile duct in only 17% of the cases, whereas in 35% it drained in a spiral form, in 41% posteriorly, and in 7% it first ran parallel to the common hepatic duct (54). In rare instances, the cystic duct may join the right and left hepatic ducts, forming a trifurcation. The cystic duct usually passes inferiorly to the cystic

artery and to the right of the right hepatic artery.

The lining of the cystic duct is pleated, and in some areas there are short folds of varying width and height. The surface cells are identical microscopically and immunohistochemically to those of the gallbladder (55). Groups of mucous glands are embedded in the dense, collagenous lamina propria. Lectin-binding patterns of the lining cells are similar to those for the surface epithelial cells of the gallbladder body and neck, and the lectin-binding profiles for the mucous glands of the cystic duct are indistinguishable from those of the glands at the gallbladder neck (18). Enterochromaffin

cells containing serotonin have been described in cystic ducts from patients with pancreaticobiliary disease (56). In this same group of patients, a few intramural gland cells have shown immunoreactivity for somatostatin.

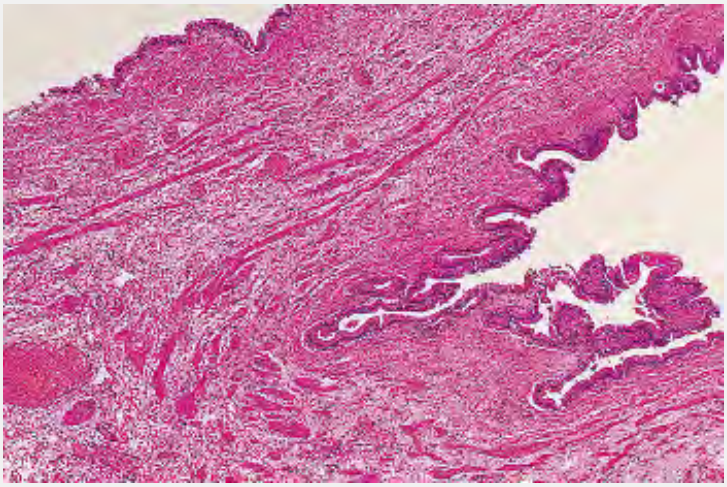

Figure 29.12 The stroma of the spiral valve of Heister contains thin strands of smooth muscle fibers.

The connective tissue of the large, oblique folds, grossly visible in the cystic duct at the junction with the gallbladder neck, contains

thin groups of smooth muscle fibers (spiral valve of Heister) (Figure 29.12). The smooth muscle is believed to prevent both overdistention and collapse of the cystic duct when it is subjected to changes in pressure (2). Abundant collagen and some elastic fibers, nerve fibers, and ganglion cells are intermixed with the smooth muscle. Nerve fibers showing immunoreactivity for vasoactive intestinal peptide (VIP) and other peptides have been described in the wall (9,56). The loose subserosal connective tissue contains adipose tissue, nerves with occasional ganglion cells, large blood vessels, and lymphatic channels. Lymphocytes and plasma cells are sparse or absent.

Right and Left Hepatic Ducts, Common Hepatic Duct, and Common Bile Duct

Gross Anatomy

The right and left hepatic ducts, common hepatic duct, and common bile duct are embedded between the serous layers of the hepatoduodenal ligament (the right free border of the lesser omentum). The hepatic ducts emerge from the liver and, in most instances, unite in the hilum approximately 1 cm from the liver to form the common hepatic duct. In 10 to 30% of cases, two large segmental ducts drain the right hepatic lobe and join separately with the left hepatic duct, common hepatic duct, or cystic duct; it is incorrect to label one of these ducts the right hepatic duct and the other as â€œaccessoryâ€• (57). In a dissection of 100 autopsy specimens, the mean length of the right hepatic duct was 0.8 cm (range: 0.2â€“2.5 cm) and that of the left hepatic duct 1.0 cm (range: 0.2â€“3.5 cm) (58). The usual diameter of each hepatic duct was 3 to 4 mm, and the length of the common hepatic duct ranged from 0.8 to 5.2 cm (mean: 2.0 cm) (58). Its diameter ranged from 0.4 to 2.5 cm (59). The diameter of the common hepatic duct and its number of elastic fibers increase with age (59). The common bile

duct, resulting from the union of the cystic duct and common hepatic duct, can be divided into supraduodenal, retroduodenal, pancreatic, and intraduodenal segments. It is usually about 1 mm thick and 5 cm long, but its length is quite variable (range: 1.5â€“9.0 cm) (58). The diameter at its midpoint ranges from 0.4 to 1.3 cm (mean: 0.66 cm), and its lumen narrows approximately 50% after entering the duodenal window (58,60). In an autopsy study of 100 selected subjects who ranged in age from 15 to 102 years, lacked a history of biliary tract disease, and had completely intact biliary tracts, the outer diameters of the upper portions of the common bile ducts ranged from 0.4 to 1.2 cm (mean: 0.74 cm) (61). The outer diameters increased with age but were not related to body weight or length (61). The pits in the surface epithelium (sacculi of Beale) are conspicuous in the extraduodenal portion of the common bile duct and the hepatic ducts. At approximately 2 mm from the duodenal wall, the wall of the common bile duct thickens (due to an increase in muscle), resulting in the abrupt narrowing of the duct's lumen.

Arterial Supply, Venous Drainage, and Relationship to Bile Ducts

The common hepatic artery arises from the celiac trunk and divides into right and left hepatic branches (Figure 29.1). Variations in the origins of the right and left hepatic arteries and their relationships to the extrahepatic bile ducts are typical (62). In one study, almost 42% of 200 cadavers had â€œaberrantâ€• hepatic arteries (13). Most often, the right hepatic artery is dorsal to the common hepatic duct and right hepatic duct. The common hepatic and left hepatic arteries lie to the left of the extrahepatic bile ducts and ventral to the portal vein. The gastroduodenal artery lies to the left of the common bile duct, and a branch, the superior pancreaticoduodenal, traverses the duct either dorsally or ventrally (2).

The extrahepatic bile ducts are supplied by numerous arteries. The major arteries that supply branches to the common hepatic duct and

the common bile duct include the retroduodenal, right and left hepatic, posterior superior and anterior superior pancreaticoduodenal, common hepatic, cystic, gastroduodenal, and retroportal arteries (63). The most important branches travel along the lateral borders of the common bile duct (64).

The portal vein, formed by the union of the splenic and superior mesenteric veins, lies dorsal to the bile ducts (Figure 29.1).

The mean length is 6.4 cm (range: 4.8â€“8.8 cm) and its mean diameter is 0.9 cm (range: 0.64â€“1.21 cm) (65). Venous channels that drain the superior portion of the common bile duct enter the liver directly, and those from the inferior portion lead to the portal vein.

Lymphatic Drainage

Lymphatic channels from the common bile duct drain into lymph nodes located along the hepatoduodenal ligament or within the posterior pancreaticoduodenal area. Drainage then proceeds to lymph nodes at the superior mesenteric artery, aorta, and common hepatic duct (66,67).

Nerve Supply

The nerve supply to the cystic and hepatic ducts derives from the anterior portion of the hepatic plexus, whereas nerves that supply the common bile duct arise from the posterior segment of the hepatic plexus. The nerve of the common bile duct, lying dorsally, is the right portion of the posterior hepatic plexus. Smaller branches from the posterior hepatic plexus travel inferiorly along the common bile duct and accompany the duct to the major duodenal papilla (2). Neuropeptide Yâ€“containing nerve fibers have the same pattern of distribution in the common bile duct as in the gallbladder (16).

Histology

The extrahepatic bile ducts, serving as conduits for the flow of bile, are lined by a single layer of tall columnar cells surrounded by a dense connective tissue layer (Figure 29.13). The surface of the epithelium is relatively flat or pleated. The columnar cells have basally oriented nuclei that are oval and uniform. Nucleoli are absent or very small. Goblet cells are absent in normal epithelium. The epithelium dips into the stroma to form shallow depressions or deeper pitsâ€”the sacculi of Beale. In some sections, the deeper sacculi appear isolated from the surface epithelium, but deeper sections will often show their connections. Surrounding the sacculi are unevenly distributed lobules of glands that empty into the sacculi (Figure 29.14). These glands have been termed diverticula, crypts, parietal sacculi, deep glands, biliary glands, periductal glands, and extrahepatic peribiliary glands (68). When located in the more peripheral connective tissue, the glands are encircled by condensed stroma. The peribiliary tubular glands are branched or, occasionally, simple (68). Although they are found in all parts of the extrahepatic bile duct system, they are less frequent in the central portion of the common bile duct and in the intrapancreatic portion than around the bile duct at the ampulla. They are lined by low-columnar or cuboid cells, many of which are filled with mucin (Figure 29.14). With inflammation and fibrosis, the sacculi and glands may be distorted, mimicking well-differentiated

adenocarcinoma with desmoplastic stroma. In small biopsy specimens and especially frozen sections, the distinction between adenocarcinoma and distorted benign glands may be impossible. The lack of a lobular arrangement and the presence of marked nuclear atypia and perineural invasion are diagnostic of adenocarcinoma (69). Hence, a haphazard growth pattern and cells whose nuclei vary in size and have irregular nuclear membranes are characteristic of adenocarcinoma. Benign glands of the extrahepatic bile ducts have not been reported to invade nerves.

Figure 29.13 Intrapancreatic segment of common bile duct. The extrahepatic bile ducts are lined by a single layer of tall columnar cells overlying dense, collagenous connective tissue. In segments of the common bile duct away from the duodenum, a few small groups of smooth muscle fibers are sometimes found in the outer half of the wall.

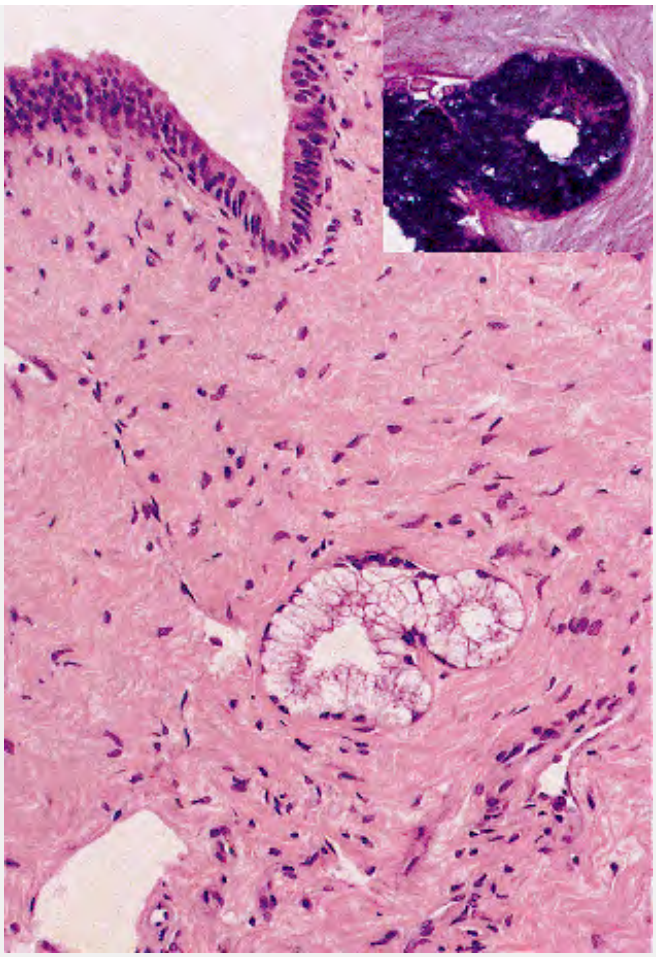

Figure 29.14 Glands embedded in the subepithelial collagenous stroma of the extrahepatic bile ducts typically contain cells with mucin-filled cytoplasm. (Inset: Alcian blueâ€“periodic acid-Schiff (PAS) stain from the same field).

The surface epithelial cells contain smaller quantities of mucin than the cells that line the gallbladder (70). The former also contain sulfated acid mucin, whereas metaplastic and dysplastic cells primarily contain nonsulfated acid mucin and smaller quantities of sulfated and neutral mucins. The normal lining epithelium stains similarly to that of the gallbladder for epithelial membrane antigen and low-molecular weight keratin (CAM 5.2 antibody). Cytokeratin 7

is consistently expressed in normal epithelium, while CK20 expression depends on the condition of the epithelial cells. In normal cells, expression of CK20 is usually absent; however, it may be expressed when metaplasia, hyperplasia, or carcinoma are present (30,71). Carcinoembryonic antigen immunoreactivity may be absent (using absorbed polyclonal antibody) or appear as focal weak staining along the apices of some cells (using unabsorbed polyclonal antibody) (72). Cytoplasmic staining using either polyclonal or monoclonal anti-CEA antibodies is typically absent (73). Immunoreactivity for lysozyme has been found in the cytoplasm of the cells in the glands, whereas staining of the surface epithelial cells is absent or very weak (72). In addition, cells of the peribiliary glands are usually immunoreactive for pancreatic and salivary Î±-amylase, trypsin, and lipase (68). The surface epithelium of the common bile duct also shows immunoreactivity for these enzymes.

Gastric metaplasia and intestinal metaplasia are sometimes found in inflamed and fibrotic extrahepatic bile ducts that may also harbor carcinoma (23,70,74). Scattered endocrine cells, including cells immunoreactive for chromogranin and somatostatin, can be observed between mucin-containing cells in normal as well as diseased biliary epithelium (56,74,75,76).

The stroma directly beneath the surface epithelium is dense and contains abundant collagen and elastic fibers and some small vessels (Figure 29.13). Lymphocytes are sparse. Pancreatic acini and ducts may be seen in the wall of the intrapancreatic portion of the common bile duct (77). Small pancreatic ducts sometimes empty into this segment of the duct. The peripheral stroma of the common bile duct is less dense than the inner connective tissue and contains large blood vessels, lymphatics, nerves and ganglion cells, elastic fibers, and smooth muscle fibers. This stroma merges with the connective tissue of the hepatoduodenal ligament. The distribution of smooth muscle fibers varies throughout the bile duct. Scattered muscle fibers or no muscle fibers are present of the upper one-third of the bile duct, whereas a continuous or interrupted pattern of thick smooth

muscle bundles is present throughout the lower one-third of the bile duct (Figure 29.15) (78). The muscle fibers are more frequently longitudinal and are intermixed with collagen and elastic fibers. Nerve fibers showing immunoreactivity for VIP are present beneath the epithelium and in muscle fibers (76).

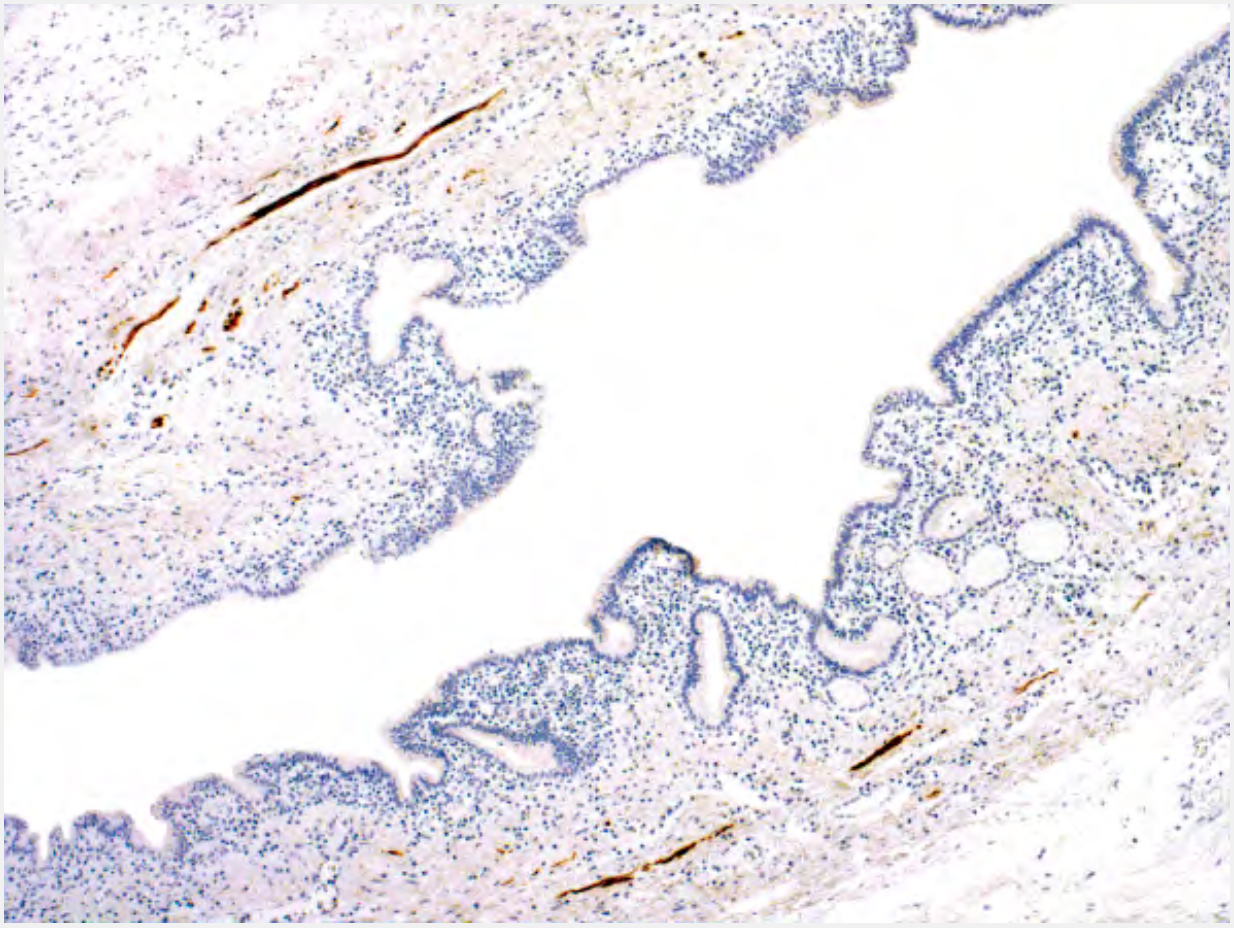

Figure 29.15 Occasional strands of smooth muscle are demonstrated in the upper portion of the common bile duct reacting with antibodies directed against desmin (immunoperoxidase technique).

Vaterian System and Minor Papilla

Gross Anatomy

The Vaterian system is composed of the segments of the common bile duct and major pancreatic duct (occurring either separately or as a common channel) at the duodenum, major papilla, and the sphincteric musculature. It also includes the extraduodenal portion of the common bile duct and major pancreatic duct that join to form a common channel outside the duodenal wall (58). It is a complex structural unit composed of a highly developed mucosa, musculature, and nerve supply that regulates the flow of bile and pancreatic secretions. Its sphincteric function (sphincter of Oddi) is a part of the overall gastrointestinal motility system and is subject to regulation by myogenic, neural, and gastrointestinal hormonal elements (9,79).

The major pancreatic duct of Wirsung drains many small channels in its course from the tail of the pancreas to the duodenal ostium. It typically inserts into the duodenal window caudal or a little lateral to the common bile duct. Its lumen narrows at the duodenal wall. The minor duct of Santorini, usually present, joins the major pancreatic duct at

a variety of angles and locations within the pancreas. Uncommonly, the duct of Wirsung is smaller than the duct of Santorini, and the latter may be the chief conduit for drainage of the pancreas (80). The duct of Santorini leads into the minor papilla but also may end blindly in 10 to 20% of cases (80,81). The luminal pressure of the major pancreatic duct is nearly always higher than that for the common bile duct except when the gallbladder empties (82).

The relationship of the common bile duct and duct of Wirsung at the papilla is complex and variable. The ducts may have separate openings into the duodenum, an interposed septum, or a common channel (sometimes forming an ampulla) (Figure 29.16). The

ampulla, defined strictly, is a dilated, juglike conduit resulting from the union of the common bile duct and major pancreatic duct. In various studies of the pancreaticoduodenal junction, the frequency for separate openings into the duodenal lumen ranged from 12 to 54% and for a common channel from 46 to 88% (57,80,81,83,84,85,86,87). In most studies, more than two-thirds of the patients had a common channel. In a detailed gross and radiographic study, DiMagno et al. (83) examined 390 pancreaticoduodenal specimens at autopsy and found that 74% of the patients had a common channel, 19% had separate openings for the pancreatic duct and common bile duct, and 7% had an interposed septum. Twenty-five percent of their specimens had a well-defined ampulla, 18% had a long common channel (defined as a channel greater than 3 mm long in the absence of an ampulla), and 31% had a short common channel (defined as a channel less than 3 mm in length) (83). For those specimens with an interposed septum, the two ducts emptied together at the ostium of the papilla. For the ducts that opened separately into the duodenal lumen, their ostia were located from 1 mm to several centimeters apart. On occasion, the ducts will unite before the duodenal wall is breached, forming an extended common channel. In one study, the length of the extended common channel ranged from 0.9 to 3.3 cm (mean: 2.2 cm) (88). This lengthy common channel occurred in 13.8% of patients with carcinoma of the biliary tract (18 of 130 cases) and in those with congenital biliary dilatation (four of four cases) but was absent in a control group of 30 cases (88). This confluence of the pancreatic and bile ducts outside of the duodenal wall has been increasingly described in association with congenital dilatation of the bile duct, choledochal cyst, and cholangiocarcinoma (89,90).

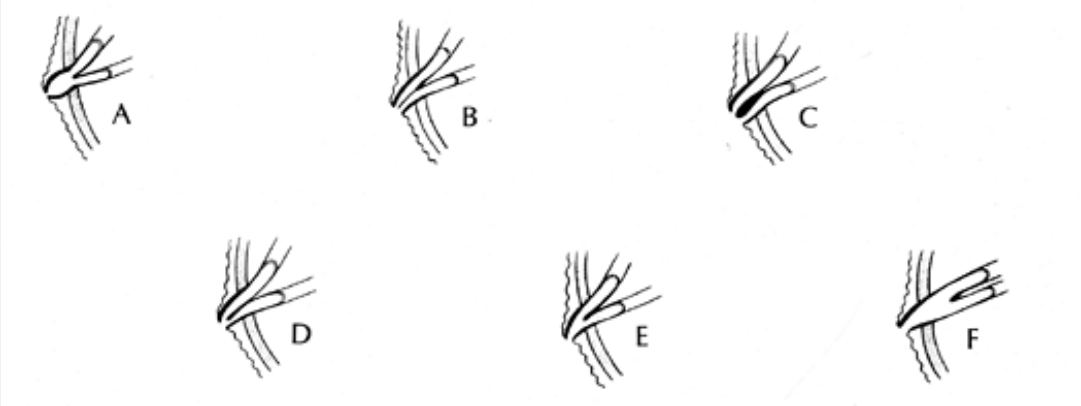

Figure 29.16 Relationship of the common bile duct and duct of Wirsung at the major papilla. (*A,* ampulla; *B,* interposed septum; *C,* separate openings; *D,* short common channel; *E,* long common channel; *F,* extended common channel)

The major papilla, a cylindrical protuberance housing the terminations of the common bile duct and major pancreatic duct or a common channel, is situated medially at the midportion of the second part of the duodenum. It is usually completely or partially covered by a triangular fold of duodenal mucosa; a longitudinal mucosal fold projects from the caudal portion of its base, forming a frenulum, which was absent in about one-quarter of the cases in one study (91). In one series, the papilla had a mean length of 11.7 mm and a mean width of 5.2 mm (85). Rarely, the major papilla is located at or just below the level of the duodenal mucosa or is absent. Mucosal reduplications (valves of Santorini) at the ostium of the major papilla consist of columnar-shaped protrusions and traverse leaflike flaps of ductal mucosa (92,93). In one study, the columnar-shaped projections that arose from the terminal common bile duct numbered one to four per specimen and ranged from 1 to 5 mm in length (93). They were found in approximately one-third of adults but were not observed in fetuses. Leaflike flaps were present in the caudal wall of

the common channel in over 90% of fetuses and adults and were separated by small cul-de-sacs of varying size and depth. The flaps sometimes extended into the major pancreatic duct. In cases in which a common channel was absent, the leaflike flaps were found only at the orifice of the duct of Wirsung. It was postulated by the authors that the flaps may flatten during the flow of pancreatic juice into the duodenum; when the cul-de-sacs are filled, the ostium is blocked and regurgitation is prevented (93).

The sphincter of Oddi consists of the intrinsic circular and longitudinal musculature of the Vaterian system. It is embryologically and functionally distinct from the musculature of the duodenal wall. However, the muscle fibers from the duodenal wall aid in anchoring the Vaterian system in place in the duodenal window. In a study of the structure of the dense connective tissue around the major duodenal

papilla, the papilla and duodenal wall were noted to form both a morphologic and a functional unit (94). Connective tissue fibers spread from the papilla orifice to the circular duodenal musculature and cross at different angles from the orifice to the distal common bile duct. The arrangement and amount of muscle bundles that form the sphincter are highly complex and variable. Important fibers are those around the intrapancreatic (near the duodenal wall) and intraduodenal portions of the common bile duct (sphincter choledochus) (95). In one study, accumulation of circular muscle fibers extended up the common bile duct to a mean distance of 13.6 mm from the pore of the papilla (91). Smooth muscle fibers are also present in the wall of the common channel, around the duct of Wirsung, and near the ostium of the papilla. It is controversial whether the smooth muscle bundles around the pancreatic duct above the common channel have important sphincteric function, but the finding of a sustained pancreatic duct high-pressure zone with phasic contractions after sphincterotomy may be evidence that the sphincter of Oddi extends above the common channel to include

portions of the pancreatic duct (95,96,97). Muscle fibers have been found to extend up the pancreatic duct a mean of 7.3 mm from the papillary pore (91). The tunica muscularis of the duodenum may not have a primary role in managing the flow of bile and pancreatic juice at the choledochoduodenal junction.

The sphincter of Oddi serves to inhibit the flow of bile into the duodenum, pumps bile into the duodenum when necessary, and likely precludes the entry of duodenal contents into the common bile duct or major pancreatic duct (79). Manometric studies have shown that the control of the flow of bile during fasting results from the phasic contractions of the sphincter of Oddi (98). These contractions result in the liberation of small volumes of bile. The flow of pancreatic juice is also regulated. The contractions are in addition to the steady basal pressure of the sphincter of Oddi, which is several mm Hg higher than that for the common bile and pancreatic ducts (99). The high-pressure zone measures 4 to 6 mm long, and the phasic contractions may be antegrade, retrograde, or simultaneous (97). Cholecystokinin has been found to inhibit the phasic contractions of the sphincter and decrease the basal pressure, allowing the flow of large quantities of bile into the duodenum (98). Manometric and contractility studies of the effects of various hormones on the sphincter of Oddi in humans and animals have been summarized (79,97). Glucagon-like cholecystokinin decreases sphincteric pressure, whereas gastrin and secretin elevate basal pressure (97). The phasic contractions and basal tone of the sphincter can be increased or decreased by exogenous drugs. For instance, most narcotics increase sphincteric pressure, whereas atropine decreases it (97).

The minor papilla is nearly always present but may be difficult to locate grossly (81). Its size is variable. It is usually situated 2 cm proximal to the major papilla (81,100).

Vascular and Nerve Supply and Lymphatic Drainage

The intraduodenal portion of the common bile duct is supplied by vessels from the anterior and posterior superior pancreaticoduodenal arteries (2). Venous drainage occurs via small veins that lead to the portal vein. The fine venous architecture of the major papilla has been described in detail (101). Lymphatic drainage is variable, but generally lymphatics from the pancreaticoduodenal junction drain into the anterior and posterior pancreaticoduodenal lymph nodes and then to the nodes at the inferior pancreaticoduodenal artery (102). The Vaterian system is innervated extrinsically by parasympathetic nerve fibers in the vagal nerve and by sympathetic nerve fibers in the splanchnic nerves (9,79). Although little is known regarding the role of these nerve fibers in regulating the motility of the sphincter of Oddi, some evidence indicates that its motility is inhibited by vagal activation (79,103). Three separate ganglia cell groups provide intrinsic innervation. These are found at the base of the papilla in the duodenal wall, within the musculature of the papilla, and within the submucosa (79). This intrinsic innervation appears to provide tonic inhibition and is similar to that for other gastrointestinal sphincters, including the lower esophageal, pyloric, and internal anal sphincters.

Histology

The epithelial lining of the duct of Wirsung is identical to that of the common bile duct. The cytoplasm of the columnar cells also contains sulfated acid mucin (104). The epithelium may undergo hyperplastic, metaplastic, or dysplastic changes. Surrounding the normal epithelium is a dense fibrous layer with abundant collagen and elastic fibers. A few ganglion cells may be seen in the outer half of the fibrous wall. Small pancreatic ducts draining acini traverse the dense fibrous layer. At the orifice of the papilla, the epithelium of Wirsung's duct is thrown into folds (mucosal reduplications) that have cores of fibrovascular stroma. Goblet cells are found interspersed between the columnar lining cells within the papilla. Numerous small accessory pancreatic ducts drain into the ductal lumen near the ostium, and

pancreatic acini are sometimes present just beneath the lining of the duct (Figure 29.17). A few lymphocytes may be seen within the ductal epithelium, and lymphocytes, plasma cells, and mast cells sparsely populate the fibrovascular cores. Circular smooth muscle bundles are present around the duct as it penetrates the duodenal wall (100).

The epithelium of the terminal portion of the common bile duct and common channel (if present) covers long, slender papillary fronds, or valvules, that in some respects resemble the fimbriae of the fallopian tube (Figure 29.18). They correspond to the mucosal reduplications seen

grossly. These papillary formations are considerably larger than the duodenal villi, which are few or absent at the surface of the papilla. The valvules may branch and sometimes project beyond the ostium of the papilla, with shorter fronds at the periphery and longer ones centrally (60,105,106). The columnar lining cells have eosinophilic cytoplasm and basal nuclei. Interspersed goblet cells are more numerous near the ostium. The stroma forming the cores of the fronds contains a few lymphocytes, mast cells, and plasma cells. Muscle fibers, present at the base of the fronds, are occasionally found in the stroma of the fronds. The smooth muscle, forming the sphincter choledochus, becomes apparent in the wall of the duct several millimeters before the duct enters the duodenal window. About 5 mm from the duodenal wall, longitudinal muscle fibers are present around two-thirds of the common bile duct; at 2 mm from the duodenal musculature, circular muscle fibers increase and completely surround the duct (100). These intrinsic muscle fibers are separated from the muscularis propria of the duodenum by connective tissue and, at times, pancreatic tissue (100). Variable amounts of circular and longitudinal muscle fibers also surround the common channel. Before forming a common channel, the common bile duct is set apart from the pancreatic duct by a septum that eventually loses its muscle fibers, becoming a thin connective tissue

membrane (100). Interspersed between areas of smooth muscle around the common bile duct or common channel are collagen, elastic fibers, small nerves, and ganglion cells. When the common bile duct and duct of Wirsung are separate within the papilla, they are distinguishable by light microscopy because the common bile duct is larger, has more prominent fronds, a greater amount of enveloping smooth muscle, and bile in its lumen.

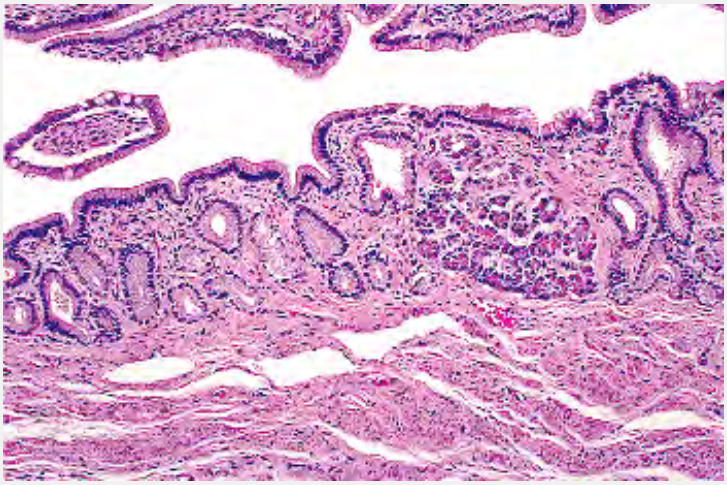

Figure 29.17 The duct of Wirsung at the papilla of Vater is lined by a single layer of tall columnar cells with occasional interspersed goblet cells. Accessory pancreatic ducts and acini are also observed.

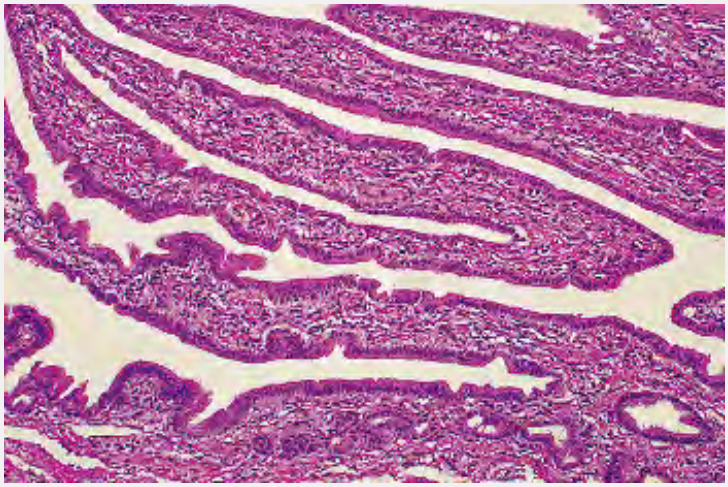

Figure 29.18 Near the ostium of the major papilla, the epithelium of the common bile duct lines prominent papillary fronds (valvules).

A bewildering assortment of glands and ducts of various caliber surround the common bile duct at the papilla. Frequently, it is only possible to distinguish mucous glands from the terminations of accessory pancreatic ducts by studying serial sections (77). Mucous glands drain into the shallow or deep recesses between the papillary fronds (Figure 29.19). The number of these glands and their distribution are variable. Glands near the surface of the papilla may be distended with mucus, and some may even represent dilated accessory pancreatic ducts (105). The number and distribution of accessory pancreatic ducts within the major papilla are also inconstant. These small accessory pancreatic channels, having been studied in serial sections and by camera lucida drawings, empty into the common bile duct (Figure 29.20), duct of Wirsung, common channel, surface of papilla, or through the duodenal mucosa near the papilla (77,107). They are sometimes numerous and may cause obstruction of the common bile duct, duct of Wirsung, or common channel. In such instances, a diagnosis of accessory duct hyperplasia

appropriate (105). In an autopsy study, accessory pancreatic ducts were absent in only two of 100 major papillae (107). The ducts drain small lobules of pancreatic acini located within or, more often, near the papilla. In one study, pancreatic acini were found in 8% of 145 major papillae, whereas pancreatic islets were not seen in any of the major papillae (108). The ducts appear as packets of multiple lumens of small caliber encircled by a cellular fibrovascular stroma (Figure 29.21). Within a group of ducts, the larger central duct is surrounded by smaller branches. Groups of ducts are sometimes seen penetrating the duodenal smooth muscle. Small groups of heterotopic pancreatic acini and ducts also occur in the submucosa of the duodenum away from the major papilla (Figure 29.22).

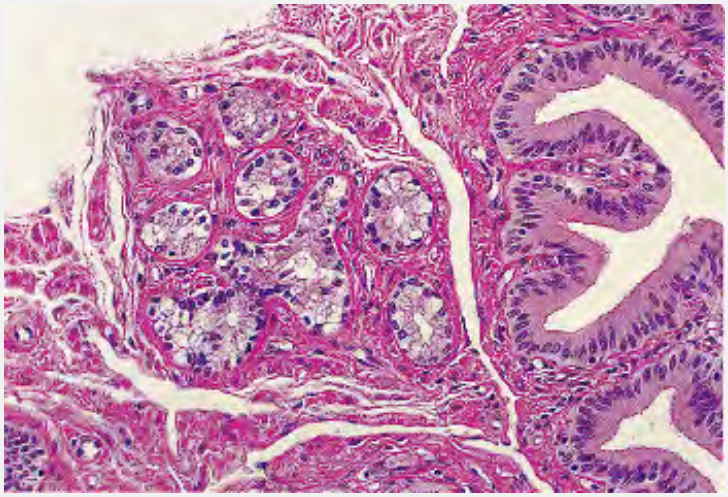

Figure 29.19 Mucous glands are present around the common bile duct at the papilla and drain into recesses between the papillary fronds.

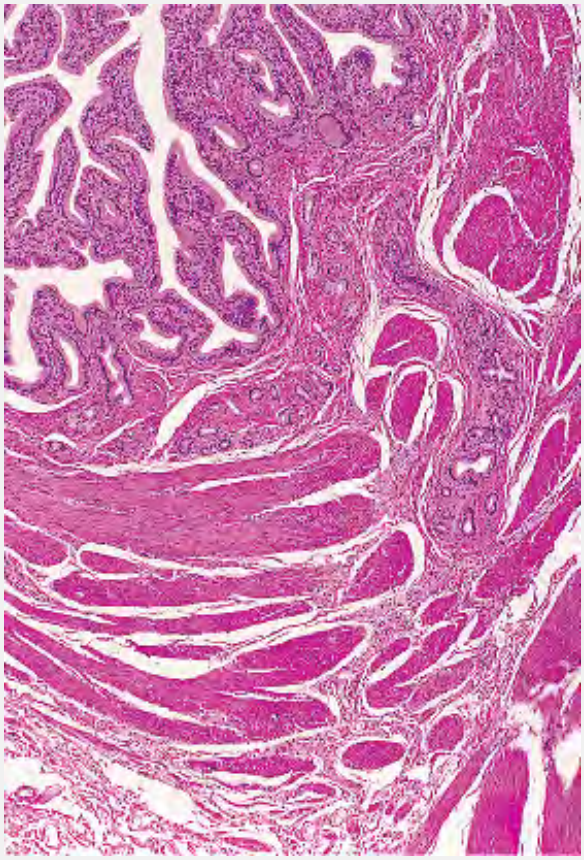

Figure 29.20 Accessory pancreatic ducts pierce the large smooth muscle bundles to empty into the lumen of the common bile duct.

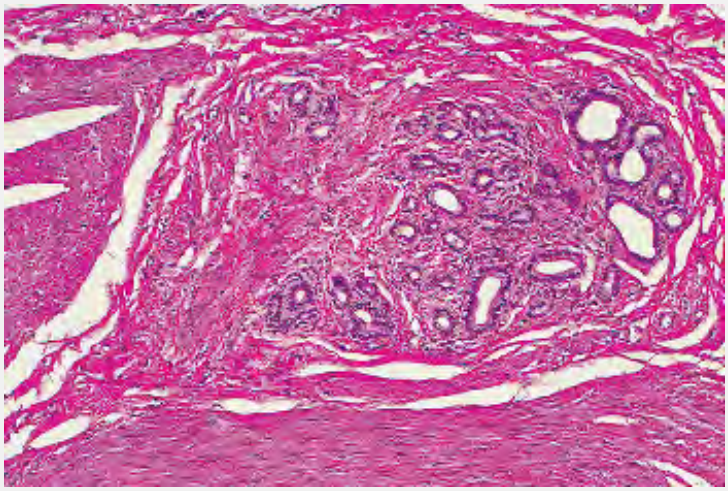

Figure 29.21 Accessory pancreatic ducts that penetrate the smooth muscle bundles at the choledochoduodenal junction are surrounded by a fibrovascular stroma.

Immunohistochemically, the cells lining the common bile duct and the duct of Wirsung at the papilla are positive for low-molecular weight keratin (CAM 5.2 antibody), CK7, and epithelial membrane antigen (EMA). There may be linear apical staining for CEA (unabsorbed polyclonal antibody). The adjacent mucous glands and accessory pancreatic ducts have the same immunoreactivity for keratin and EMA. A few scattered cells lining the large ducts within the pancreas are positive for neuron-specific enolase, chromogranin A, insulin, and glucagon (109). Chromogranin-positive cells are sometimes located in the lining epithelium of the duct of Wirsung and common bile duct within the papilla. Mucous glands and accessory pancreatic ducts also contain scattered cells immunoreactive for neuron-specific enolase and chromogranin A (Figure 29.23). In patients with pancreaticobiliary disease, a few cells lining the lumen of the papilla and in adjacent mucous glands have been found to be immunoreactive for somatostatin (56). Although usually absent, endocrine cell micronests may be scattered singly or are grouped in

the stroma adjacent to pancreatic ducts, ductules, or accessory

glands but not around the common bile duct (108). They have been found in about 3% of major papillae. They consist of round, oval, trabecular, or ribbonlike groups of cells that immunohistochemically are distinct from those of pancreatic islets. They are typically scattered, rarely nodular, and immunohistochemically stain for somatostatin and pancreatic polypepide. It is unclear whether they are a normal finding or represent a metaplastic or hyperplastic condition. The functional role of these endocrine cells in the papilla of Vater is unknown.

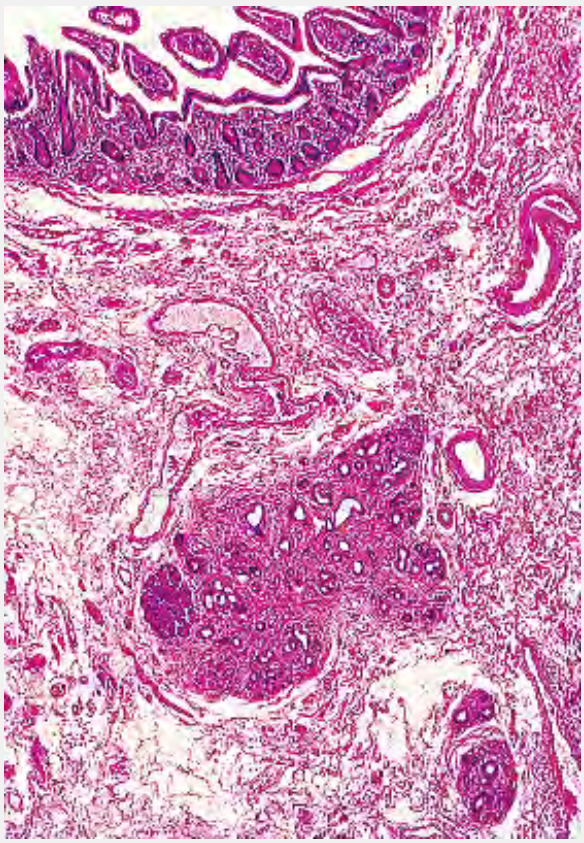

Figure 29.22 Groups of heterotopic pancreatic ducts and acini may be seen in the submucosa of the duodenum away from the papilla of Vater.

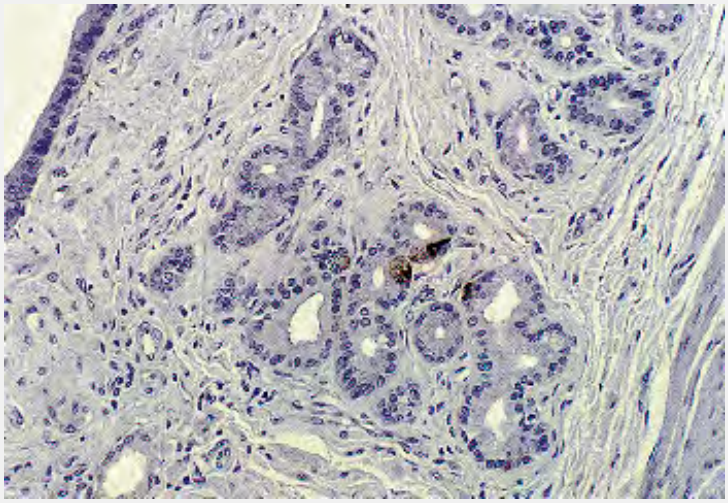

Figure 29.23 Some of the small ducts around the duct of Wirsung at the major papilla contain a few cells that are immunoreactive for chromogranin A (immunoperoxidase technique).

At the minor papilla, the pancreatic duct of Santorini contains papillary fronds that are lined by simple columnar epithelium with some goblet cells (Figures 29.24,29.25). Small pancreatic ducts open into the lumen of the duct of Santorini at the minor papilla or separately into the duodenum (81). Small lobules of pancreatic acini may be present within the connective tissue of the minor papilla and were seen in 77% of 167 minor papillae in a study by Noda et al. (108), who noted that 14% of the papillae also contained well-formed pancreatic islets. Atrophic or poorly formed islets are present uncommonly. Smooth muscle bundles separated by collagen, small nerves, and ganglion cells surround the duct. The bundles of muscle occasionally are continuous with those of the muscularis mucosae of the duodenum, but in many instances continuity between the groups of muscle fibers is lacking (81). The lining epithelial cells and those

of the small pancreatic ducts stain strongly for low-molecular weight keratin (CAM 5.2 antibody), CK7 and weakly for CEA (unabsorbed polyclonal antibody). A few cells within small ducts and some that line the lumen of the duct of Santorini are flask-shaped and immunoreactive for neuron-specific enolase and chromogranin A (Figure 29.26). Small groups of neuroendocrine cells may extend below the epithelial lining (Figure 29.27). In the above-mentioned study of 167 minor papillae, 16% contained endocrine micronests, which were

predominantly scattered and rarely nodular (108). They were usually immunoreactive for somatostatin and pancreatic polypeptide and lacked staining for insulin and glucagon. It is possible that some of these micronests represent metaplasia/hyperplasia or neoplasia.

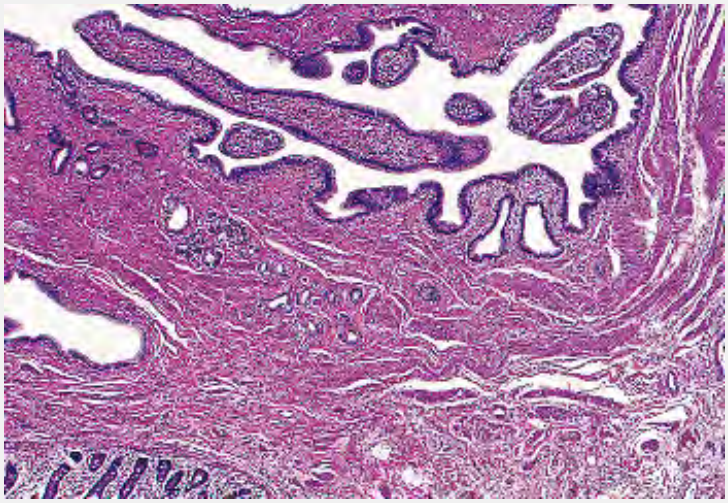

Figure 29.24 The duct of Santorini at the minor papilla contains papillary fronds and is surrounded by muscle bundles.

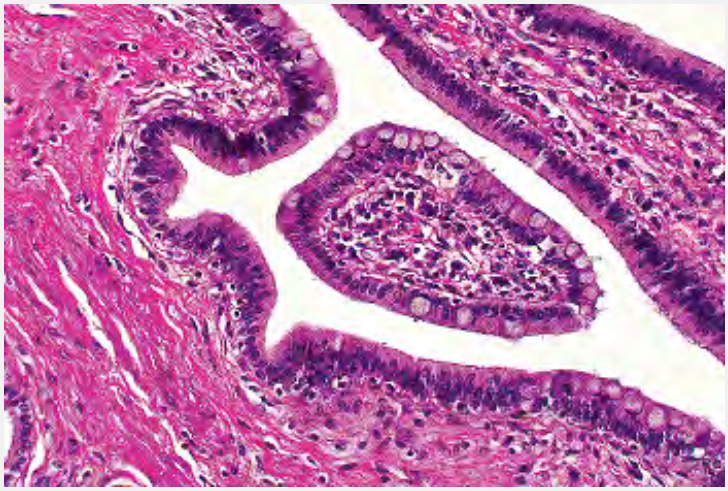

Figure 29.25 The duct of Santorini at the minor papilla is lined by tall columnar cells with interspersed goblet cells.

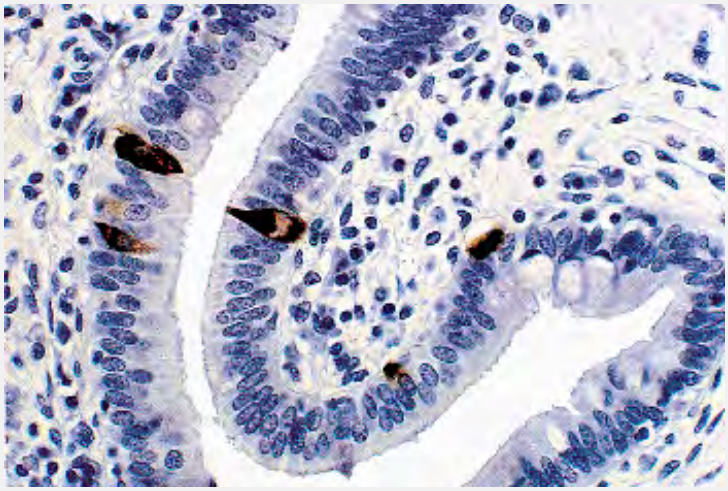

Figure 29.26 A few cells that line the duct of Santorini at the minor papilla are flask-shaped and immunoreactive for chromogranin A (immunoperoxidase technique).

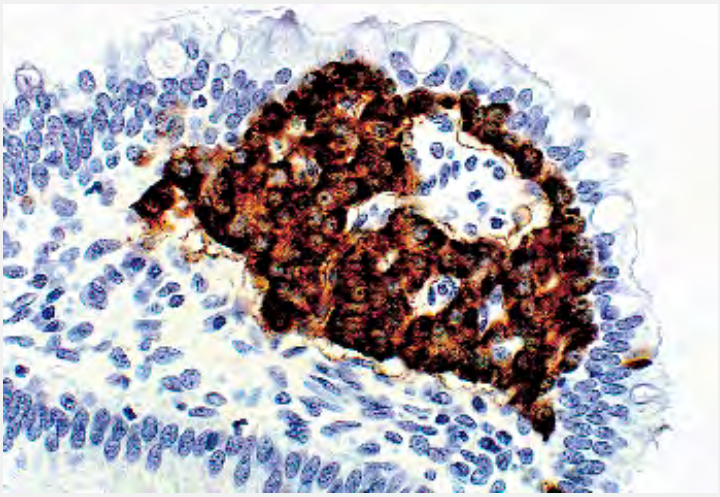

Figure 29.27 A group of cells below the lining epithelium of the duct of Santorini at the minor papilla is immunoreactive for chromogranin A (immunoperoxidase technique).

Introduction

The pancreas is an unpaired organ located in the left superior retroperitoneum. It is principally an epithelial organ that includes both exocrine elements (acini and ducts) and endocrine elements (islets of Langerhans). The stroma is sparse in the normal gland, although areas of fibrosis commonly occur as individuals age. There are relatively few opportunities for pathologists to observe the normal histology of the pancreas because (a) the gland quickly autolyzes; (b) normal pancreatic tissue is rarely resected; and (c) when the pancreas is resected for a neoplasm, the adjacent nonneoplastic parenchyma usually has substantial abnormalities. For this reason, minor histologic alterations or even normal structures may not be accurately recognized.

Anatomic Considerations

Location and Relationship to Other

Structures

Located in the retroperitoneum posterior to the omental bursa at the level of the second and third lumbar vertebrae, the pancreas extends from the duodenal loop at the right of the midline to the left across the posterior abdominal wall toward the hilum of the spleen (Figure 30.1) (1). The head of the gland is cupped within the C-shaped second and third portions of the duodenum. The distal portion of the common bile duct passes through the posterosuperior head of the pancreas to enter the duodenum at the ampulla of Vater. The left lobe of the liver lies anterior to the head. The neck of the gland is the slender area of the pancreas anterior to the mesenteric vessels and inferior to the pylorus. The body of the pancreas extends from the neck lateral to the left border of the aorta. The posterior wall of the gastric antrum usually overlies the body, and the proximal jejunum immediately distal to the ligament of Treitz passes inferior to the body. The posterior aspect of the body approaches the left adrenal gland and kidney (2). The tail of the pancreas extends from the left border of the aorta laterally and gradually tapers to a blunt end within several centimeters of the hilum of the spleen. In most individuals, the tail is located either centrally (50%) or inferiorly (42%) within the splenic hilum; rarely (8%) it is in the superior hilum (3,4). The anterior aspect of the pancreas, as well as the superior surfaces of

the neck, body, and tail, are covered by the peritoneal surface of the posterior aspect of the lesser sac (5).

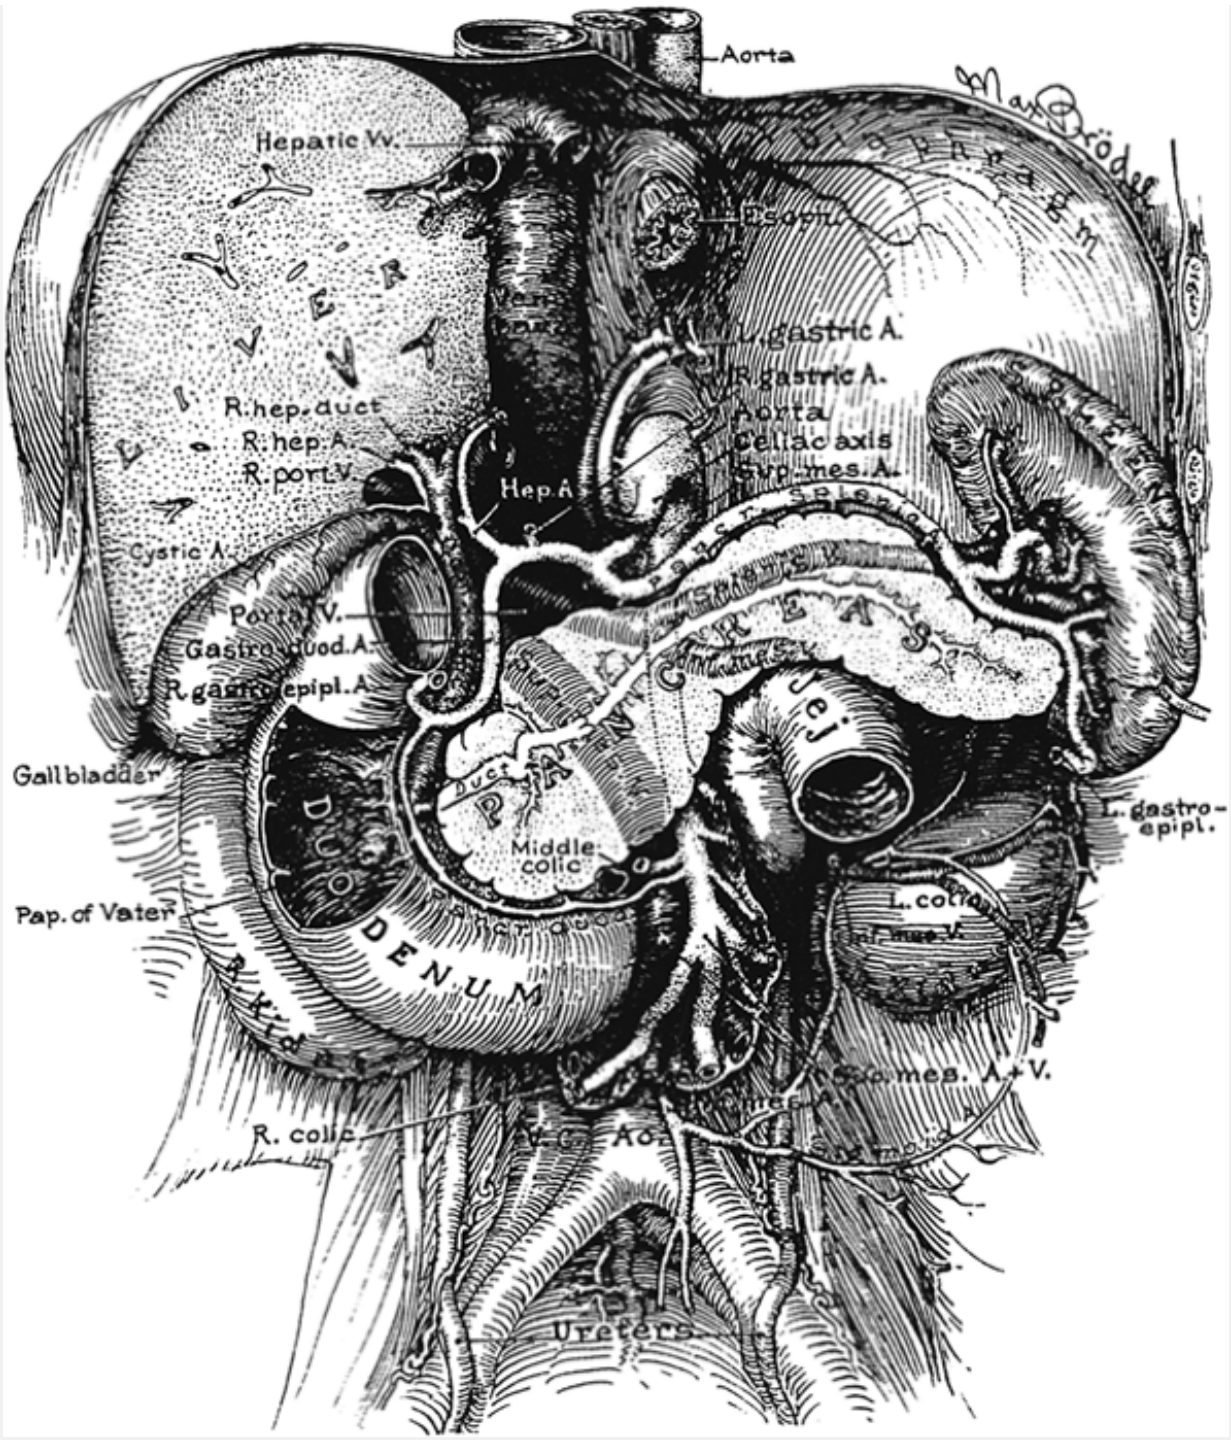

Figure 30.1 Anatomic relationships of the pancreas. The anterior aspect of the upper abdominal viscera is shown after removal of the stomach and omentum. Note the close relationship of the pancreas to the duodenum, jejunum, spleen, and major vessels.

M. BrÃ¶del. Reprinted with permission from: Fawcett DW. *Bloom and Fawcett: A Textbook of Histology.* 12th ed. New York: Chapman & Hall; 1994.

Because of the proximity of the pancreas to several organs and other anatomic structures, tumors of these sites may be difficult to distinguish radiographically. Pancreatic masses may be confused with neoplasms of the duodenum, the ampulla of Vater, the distal bile duct, the left adrenal gland, the superior poles of either kidney, the spleen, the left lobe of the liver, the greater curve of the stomach, the root of the mesentery, and the superior retroperitoneum.

A number of major blood vessels are closely related to the pancreas (5,6). The body rests on the aorta. The celiac trunk arises from the aorta superior to the neck of the pancreas and gives off the hepatic artery as well as the tortuous splenic artery, which runs superior to the pancreatic tail. The superior mesenteric artery arises posterior to the junction of the neck and body, and the adjacent superior mesenteric vein passes through a groove between the head and the neck, with a portion of the head (the uncinate process) extending around the superior mesenteric vessels to lie anterior to the aorta. The head of the gland also rests on the inferior vena cava, the right renal vessels, and the left renal vein. These major vessels all lie posterior to the pancreas, allowing for safe surgical access to the gland from the anterior aspect (7). The splenic vein accompanies the splenic artery along the superior aspect of the tail, joining the superior mesenteric vein to form the portal vein near the posterosuperior border of the head.

The arteries supplying the pancreas are primarily branches of the celiac trunk and the superior mesenteric artery (2,4). The arterial supply has many anastomoses between the different vessels, and numerous anatomic variations exist. The pancreatic head is supplied by the anterior and posterior pancreatoduodenal arteries, which form

arcades in the pancreatoduodenal sulcus. The anterior or prepancreatic arcade is formed from the anterior superior pancreatoduodenal artery (a branch of the gastroduodenal artery) and the anterior inferior pancreatoduodenal artery (a branch of the superior mesenteric artery). The posterior arcade is formed from the posterior superior pancreatoduodenal artery (from the gastroduodenal artery) and the posterior inferior pancreatoduodenal artery (from the superior mesenteric artery). Venous drainage is by the pancreaticoduodenal veins, tributaries of the splenic and superior mesenteric vein (7).

The body and tail of the gland are supplied by the dorsal, inferior, and caudal pancreatic arteries and are drained by the inferior and left pancreatic veins. The dorsal pancreatic artery, also know as the superior pancreatic artery, has various origins, including the first 2 cm of the splenic artery, the hepatic artery, the celiac trunk, or the superior mesenteric artery. The right branch of the dorsal pancreatic artery extends across the pancreatic head and supplies the neck of the pancreas, joining the anterior pancreatic arcade. The left branch, known as the inferior pancreatic artery, runs along the inferior body of the pancreas.

Within the pancreas, a large branch of the splenic artery known as the great pancreatic artery, or pancreatica magna, provides left and right branches that course parallel to the main pancreatic duct. The right branch joins the inferior or dorsal pancreatic arteries, and the left branch joins the caudal pancreatic artery. Branches of these pancreatic arteries supply interlobular arteries, and one intralobular artery supplies each lobule.

Major lymphatic vessels follow the course of the blood vessels. Approximately 55% of interlobular lymphatics are closely related to the accompanying artery and vein, 25% are separated from other structures by connective tissue, and 20% are closely related to acinar cells. Only 2% border the ductal system (8). The interlobular lymphatics drain toward the surface of the pancreas and enter a

surface network, sometimes referred to as collecting vessels, and converge toward the lymph nodes.

There are two major systems of lymph nodes draining the pancreas: one rings the pancreas and the other surrounds the aorta from the level of the celiac trunk to the origin of the superior mesenteric artery. Lymph nodes may be closely apposed to the periphery of the gland or even embedded within its substance, especially along the inferior and superior borders and in the anterior and posterior pancreatoduodenal

regions. Many lymph nodes are also found around the celiac axis, adjacent to the common bile duct, and at the splenic hilus (9). Several classification systems exist for these lymph nodes (9,10,11,12), although from the standpoint of involvement by carcinoma, the lymph node classifications appear not to have clinical significance.

Innervation of the pancreas is from the vagus nerve (parasympathetic) and the splanchnic nerves (sympathetic) via the celiac and superior mesenteric plexi (2,5). The course of the nerves accompanies the vasculature (4).

Gross Anatomy

In adults, the pancreas usually measures 15 to 20 cm in length and weighs 85 to 120 g. It is slightly larger in men than in women (6,13). The pancreas weighs 2 to 3 g in the newborn and reaches 7 g at 1 year of age (14). The weight of the gland gradually decreases after 40 years of age to a mean of 70 g in the ninth decade of life (13).

The pancreas is composed of four rather indistinct anatomic regions: the head, neck, body, and tail (Figure 30.2). The bulk of the organ is composed of the head, including the uncinate process, which develops separately and may be anatomically separate in some individuals (see below). The uncinate process (from the Latin *uncus*

or â€œhookâ€•) extends inferiorly and posteriorly from the head of the gland and lies behind the pancreatic neck and the superior mesenteric vessels. These vessels frequently indent the uncinate process, producing the hook shape. This vascular sulcus is helpful for orienting the pancreas in pancreatoduodenectomy specimens. The neck of the pancreas is the short constricted area of the pancreas that rests anterior to the mesenteric vessels. The neck and body are somewhat triangular in cross section, whereas the distal-most tail is flat (2).

The normal pancreas is pink-tan to yellow and uniformly lobulated. The anterior surface is smooth and covered by a layer of peritoneum; the remaining surfaces are invested by a thin layer of loose fibroconnective tissue. No discrete capsule is present; and, depending on the amount of parenchymal fat and the extent of any fibrosis, the interface with the surrounding retroperitoneal adipose tissue may be indistinct.

Cut sections of the pancreas reveal arborizing thin-walled white ducts extending into the well-demarcated lobules. The main pancreatic duct of Wirsung averages 3.0 mm (ranging from 1.8 to 9.0 mm) in diameter (15), gradually enlarging to 4.5 mm near the ampulla of Vater, through which it drains into the duodenum. Main ducts greater than 10 mm in diameter are considered pathologically dilated. Up to 50 secondary or branch ducts drain into the main duct (16,17), entering alternately from either side in a herringbone pattern (Figure 30.3) (6). The course of the major ducts varies depending on the pattern of fusion and atrophy of ducts that occurs during development. In general, the main pancreatic duct of Wirsung begins in the tail, collecting tributaries as it passes through the body and neck toward the head. The duct makes an acute turn inferiorly in the head of the gland, where it is joined by the accessory duct of Santorini from the superior head as well as the major duct from the uncinate process, ultimately exiting through the ampulla at the major papilla. The accessory duct generally does not communicate separately with the duodenum, although retention of embryonic

patency through the minor duodenal papilla is not uncommon.

Figure 30.2 Gross appearance of the normal pancreas. The bulbous head (*left*) is connected to the neck, body, and tail, which merge imperceptibly. The parenchyma consists of distinctly lobulated pink-tan fleshy tissue. The pancreatic duct (opened longitudinally) is thin and smooth throughout its course.

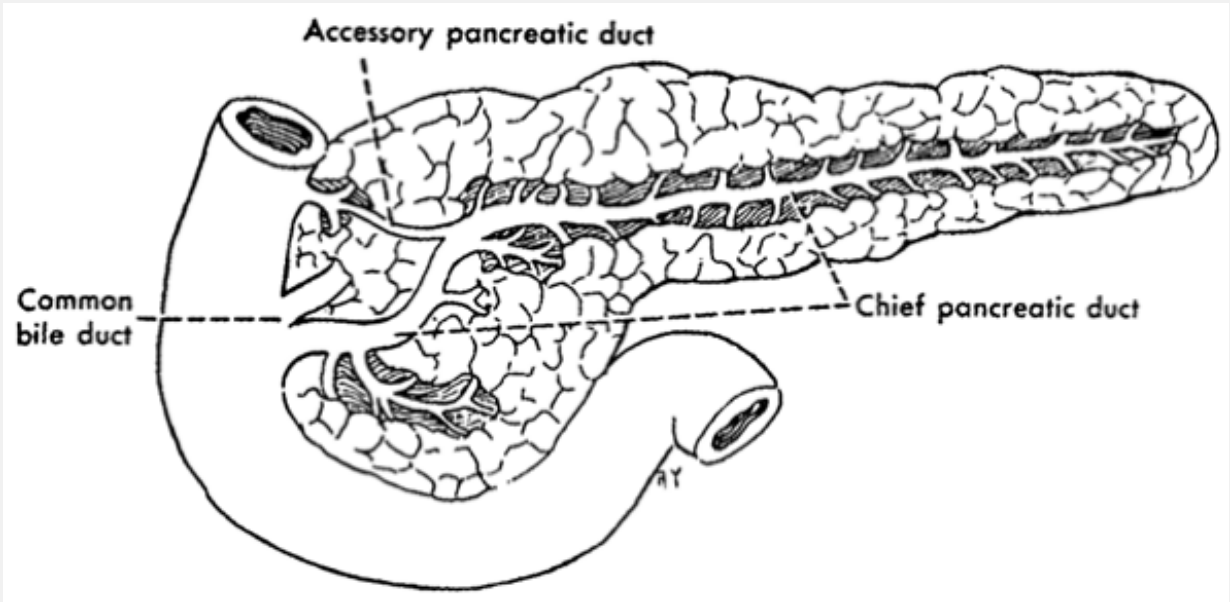

Figure 30.3 Schematic diagram of the pancreas showing the pattern of the major ducts and their tributaries. In this example the accessory duct is patent at the duodenum through the minor papilla. Reprinted with permission from:
Cubilla AL, Fitzgerald PJ. Tumors of the exocrine pancreas. In: Hartmann WH, Sobin LH, eds. *Atlas of Tumor Pathology.* 2nd series, fascicle 19. Washington, DC: Armed Forces Institute of Pathology; 1984.

The relationship of the main duct to the distal common bile duct is also highly variable. The prototypical ampulla is a flask-shaped common channel within the wall of the duodenum formed by the fusion of the two ducts. A significant common channel is uncommon, however. In many cases, length of the common channel is less than 3 mm. In others, the two ducts remain separate throughout their course, entering side by side at the major papilla or completely separately (Figure 30.4) (4,13,18). In these individuals, a common channel does not exist or is extremely short. In one study, only 43% of individuals had a common channel greater than 3 mm in length (19). Villiform mucosal projections are present within the distal ducts; these valves of Santorini may prevent the reflux of duodenal secretions (20,21). The intraduodenal portions of the pancreatic and bile ducts are surrounded by thin fascicles of smooth muscle (the sphincter of Oddi), which are continuous with both the muscularis mucosae and the muscularis propria of the surrounding duodenum.

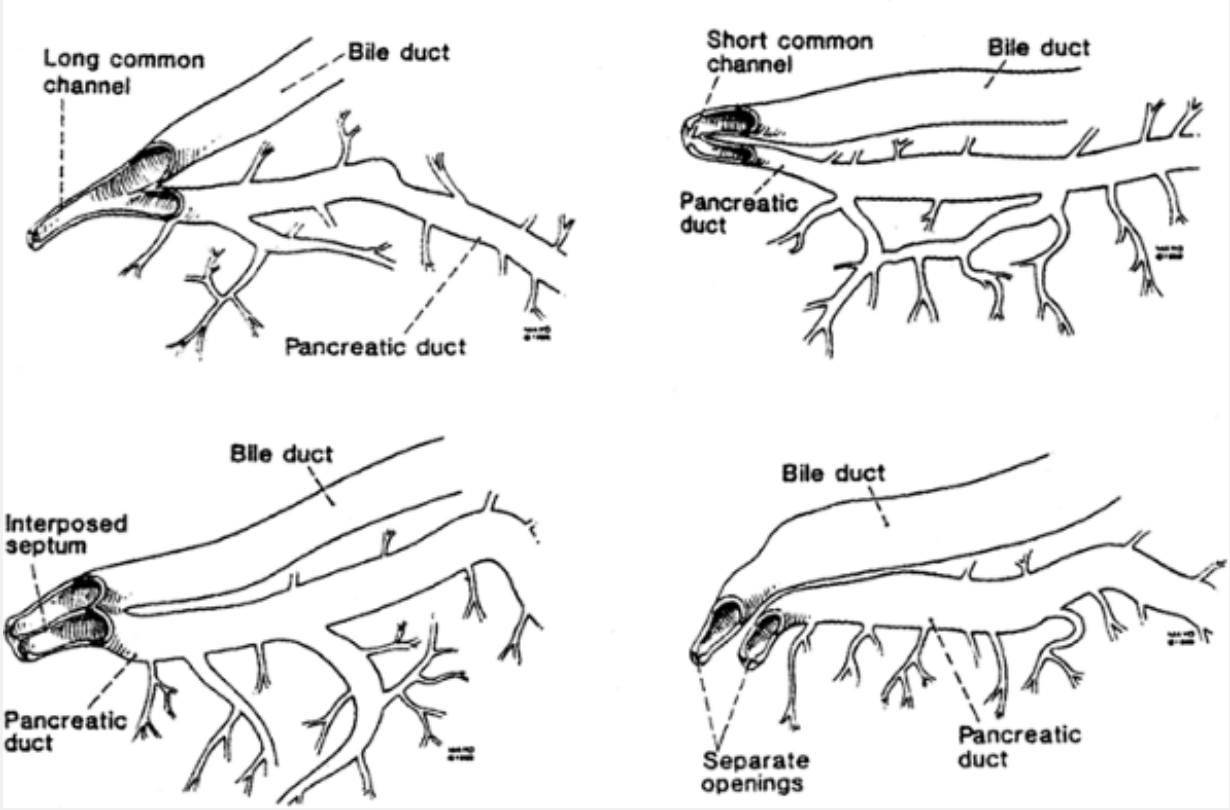

Figure 30.4 Anatomic variations in the paths of the pancreatic and bile ducts at the ampulla. A long common channel (the prototypical ampulla) is only present in some individuals. In others, the ducts fuse within only a few millimeters of the duodenum, resulting in a short common channel, or the two ducts enter separately. Relationships between pancreaticobiliary ductal anatomy and pancreatic ductal and parenchymal histology. *Cancer* 1982;49:361â€“368.

Development

Organogenesis

During the fourth to fifth weeks of gestation, the pancreas forms from the endoderm of the distal embryonic foregut as dorsal and ventral buds (22,23). The dorsal bud forms opposite the hepatic diverticulum, whereas the ventral bud, which may be bilobed, forms adjacent to the hepatic diverticulum (17). Thus, the duct from the ventral pancreas is closely apposed to the common bile duct. With the rotation of the duodenum during the sixth week, the ventral pancreas with the common bile duct migrates circumferentially to the right around the posterior aspect of the duodenum to lie posterior and inferior to the dorsal pancreas (Figure 30.5). The two portions generally fuse during the seventh week. The dorsal portion makes up the superior head as well as the entire neck, body, and tail of the adult gland, and the ventral portion becomes the remainder of the head, including the uncinate process (23). The ductal systems of the two lobes also normally fuse, with connection of the dorsal duct to the duodenum at the minor papilla being lost and the ventral duct providing the drainage for the exocrine secretions. Thus, the distal two-thirds of the main pancreatic duct (of Wirsung) develop from the embryonic dorsal duct, whereas the proximal one-third forms from the ventral duct. The complicated union of these different ducts accounts for the tortuous nature of the main pancreatic duct in adults. The remaining proximal portion of the dorsal embryonic duct becomes the accessory duct of Santorini. The ampulla of Vater develops during the eighth week.

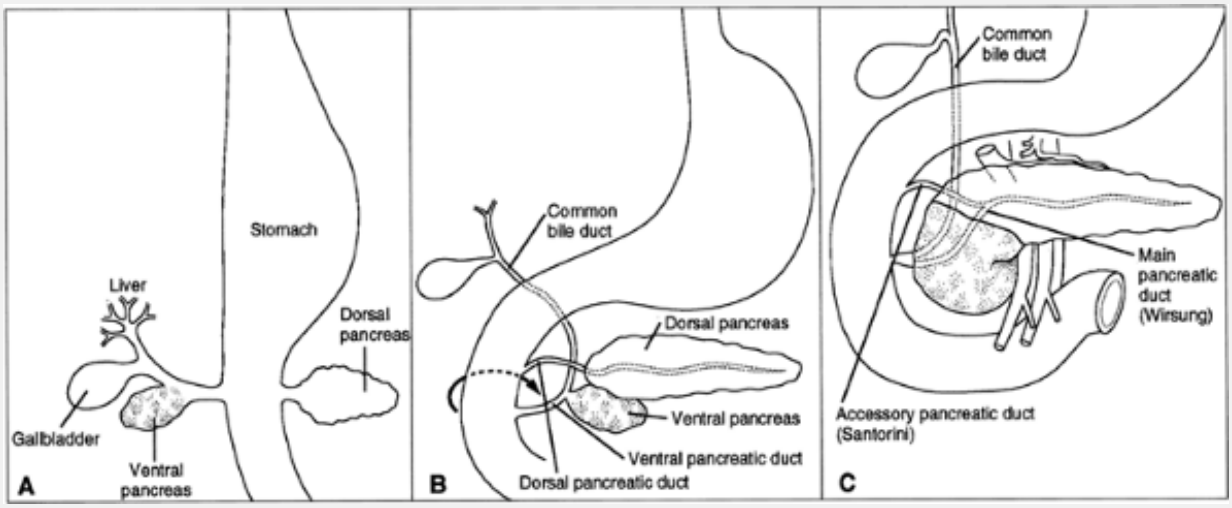

Figure 30.5 Development of the pancreas. The dorsal and ventral buds form on opposite sides of the duodenum (A). During the sixth week, the ventral pancreas migrates posteriorly around the duodenum (B) to lie inferior to the dorsal pancreas, where it comprises much of the head of the gland (C). Cytogenesis

The complex events required for normal cellular development of the pancreas have three components (24). First, as described above, the foregut endoderm becomes patterned to form the dorsal and ventral pancreatic buds. Second, the cells undergo lineage commitment to either endocrine or exocrine cell fates. Third, pancreatic morphogenesis occurs by way of extensive growth and branching. Recent studies suggest that distinct signaling pathways control these

events, but it is important to note that tissue specification, lineage commitment, and growth are highly interdependent and have considerable spatial and temporal overlap.

Several transcription factors are required for pancreas specification. Prior to and during budding, the pancreatic primordium expresses the homeodomain protein Pdx1 (also known as IPF1) (24), and Pdx1-positive progenitors give rise to all three epithelial cell lines (25). The developing ductal epithelium retains uniform Pdx1 expression, but later Pdx1 expression is lost in the ductal cells, being primarily restricted to the islet cells, with low levels detectable in some acinar cells. Under certain conditions, Pdx1 expression again becomes detectable in individual pancreatic ductal epithelial cells, raising the possibility of multipotential stem cells within the mature ductal epithelium (26).

Among others, additional transcriptional factors involved in pancreatic morphogenesis include Sox17, HLXB9, and PTF1; and many endocrine lineage-specific transcription factors are known, such as Ngn3, NeuroD/Beta2, Nkx2.2, and Nkx6.1 (27,28,29,30). However, little information exists regarding similar factors required for exocrine differentiation. The p48 component of the heterotrimeric PTF1 transcription factor complex is required for normal exocrine differentiation (31).

Pancreatic development is also regulated by cell fate determining signals from developmental patterning pathways, such as the *Notch* and *Hedgehog* (*Hh*) signaling pathways. Notch signals are required for epithelial branching and normal exocrine lineage commitment (32). Of the three hedgehog genes essential for mammalian embryogenesis (*sonic hedgehog* [*Shh*], *Indian hedgehog* [*Ihh*], and *desert hedgehog* [*Dhh*]), *Shh* expression in midgestational embryos is critical for proper foregut and gastrointestinal development. In contrast, *Shh* is excluded from the developing pancreas, and repression of *Shh* permits appropriate transcriptional activation of pancreatic genes (33).

The developing ducts form solid cellular cords that proliferate into the surrounding mesenchyme. As the ducts branch progressively, luminal spaces are formed. Both acinar and endocrine cells develop from these primitive ducts (34). The cells at the termini of the branches differentiate into acinar cells during the third month of gestation (34). The pancreatic lobules are formed by the accumulation of acinar units around ductular branches that are separated by layers of mesenchyme. By the fourth month the acinar cells contain zymogen granules (14). The earliest granules identified in acinar cells are elongated and angular, with a fibrillary internal matrix. These granules, along with small spherical granules, may be detected at 15 to 20 weeks gestation (23,35,36). By 20 weeks, the granules resemble the zymogen granules of the adult pancreas, and the elongate granules disappear. The nature of the elongate granules remains unclear, and enzymes have yet to be detected in them. However, it is interesting that similar â€œirregular fibrillary granulesâ€• have been repeatedly detected in pancreatic neoplasms with acinar differentiation (36,37,38,39,40,41).

Islet cells also develop from the ducts at 8 to 10 weeks gestation. Most of the islet cells appear to originate from the intralobular and interlobular ducts (16). In the third month, developing endocrine cell clusters bud off from the ducts and surround capillaries to form discrete islets (42,43). In even the earliest developing islets, differentiated Î± and Î² cells can be recognized (43,44,45). At 16 weeks the Î± and Î² cells segregate to opposite ends of the islets; these bipolar islets are gradually replaced between 18 and 20 weeks by mantle islets having a central core of Î² cells surrounded by a rim of Î± cells (34,43,45). Although the microscopic architecture of the mature adult islets is more complex, the peripheral location of the Î± cells found in the mantle islets is roughly maintained.

During the third to fourth months, the pancreatic tissue becomes increasingly organized around the branching ductal structures to form lobules (Figure 30.6Aâ€“B). The characteristics of the ductal lining cells specific to their level within the ductal system become

established during this period. The mesenchymal elements of the early pancreas are prominent. The early periductal stroma is highly cellular (Figure 30.6C), resembling the ovarian-like stroma that characterizes mucinous cystic neoplasms (46,47). As the pancreas develops, the mesenchyme becomes increasingly less abundant and less cellular, ultimately constituting a relatively minimal component of the adult gland.

Developmental Anomalies and Heterotopia

Complete or partial pancreatic agenesis is rare. Complete agenesis is associated with gallbladder agenesis, diaphragmatic hernia, and growth retardation. A homozygous deletion in the *Pdx1* gene was recently identified in a girl born with complete pancreatic agenesis (48), interesting because of the role *Pdx1* plays in pancreatic development. Most patients with partial pancreatic agenesis survive; but, depending upon the amount of pancreatic tissue that develops, they may have diabetes mellitus. More common than pancreatic agenesis is pancreatic hypoplasia, also referred to as congenital short pancreas. This condition may be part of a congenital syndrome or present as an isolated anomaly. The pancreas appears short and stubby but otherwise retains the

normal appearing lobular architecture. Pancreatic hypoplasia typically is not associated with hypofunction.

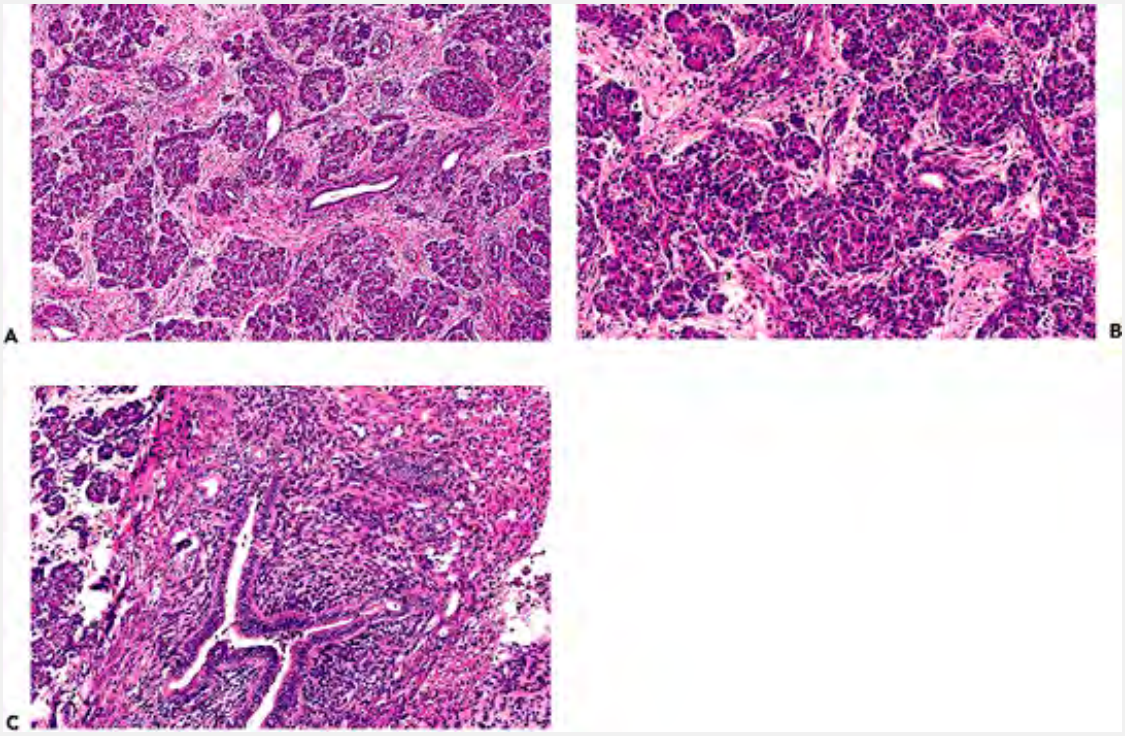

Figure 30.6 A. The fetal pancreas at 18 to 20 weeks of gestation exhibits a well-developed lobular architecture. The loose connective tissue between the lobules is relatively abundant. B. Both acinar and endocrine elements are well developed and are functioning at this stage. C. The mesenchyme surrounding the ducts is highly cellular, resembling the so-called ovarian-like stroma of mucinous cystic neoplasms.

Annular or ring pancreas is an extremely rare developmental anomaly in which there is partial or complete encircling of the second part of the duodenum by pancreatic tissue (Figure 30.7) (4,49,50,51). Pancreas divisum usually accompanies annular pancreas (52), and the condition affects only 0.015% of the population (53). Possibly it is the failure of one of the lobes of the ventral embryonic bud to regress, causing it to encircle the duodenum during the normal rotation of the duodenum. Annular

pancreas commonly causes duodenal obstruction, which varies in severity and age of onset, depending on the extent of luminal constriction. Some cases are also associated with duodenal atresia (51). The band of pancreatic tissue partially or completely encircling the duodenum is flattened and may be embedded within the muscularis propria. Histologically it contains all of the normal parenchymal elements. Because the portion of pancreas encircling the duodenum is derived from the ventral pancreas, it is rich in pancreatic polypeptide-containing islets (54).

There are many variations in the paths of the pancreatic ducts and their relationship to the common bile duct (17,51). The communication between the dorsal pancreatic duct and the duodenum fails to obliterate in up to 40% of adults (17,55), resulting in a patent accessory duct (of Santorini) at the minor papilla, proximal to the opening of the main duct and bile duct at the major papilla. In such instances, the dorsal duct may provide the main route of drainage for the gland and may be much larger in circumference than the ventral duct. This condition appears to be more prevalent in children, suggesting that obliteration of

the accessory duct opening may continue to occur in adulthood (56). Also, the two ducts may fail to fuse entirely, resulting in two separate ductal systems, a condition known as pancreas divisum. This anomaly occurs in 5 to 10% of individuals (17,57). The pancreatic parenchyma of the two lobes is usually fused (23), and the abnormality may not be detected unless a careful study of the ductal system is performed. There are three types of pancreas divisum: type 1, or classical pancreas divisum, involves total failure of duct fusion, causing most of the pancreatic secretions to drain through the duct of Santorini at the diminutive minor papilla, with the duct of Wirsung draining the small ventral pancreas through the major papilla; type 2 involves dominant dorsal drainage in which the ventral duct regresses completely, leaving the single dorsal duct and minor papilla as the only means of egress for exocrine secretions;

and type 3 involves incomplete pancreas divisum, where a small communicating branch of the ventral duct remains (58). Patients with pancreas divisum seem to have a higher incidence of pancreatitis, especially when the opening of the dorsal duct at the minor papilla is small (51,57,59).

Figure 30.7 Annular pancreas. The pancreatic tissue completely encircles the duodenum, which is opened longitudinally.

Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. In: Silverberg SG, Sobin LH, eds. *Atlas of Tumor Pathology.* 4th series. Washington, DC: Armed Forces Institute of Pathology; 2006.

Anomalous junction of the main pancreatic duct with the distal common bile duct may occur within the head of the pancreas more than 2 cm proximal to the duodenum (17,51). This abnormality may be associated with choledochal cysts and carcinomas of the extrahepatic bile ducts or gallbladder (17,60,61). In a rare abnormality of the pancreatic duct, bifid pancreas, the main pancreatic duct bifurcates within the body of the pancreas (62).

Pancreatic heterotopia is defined as pancreatic tissue located outside of the normal anatomic position of the gland (51). Heterotopic pancreatic tissue is found in portions of the upper gastrointestinal tract and its appendages in up to 15% of individuals at autopsy (63). The surgical incidence, however, is only 0.2% (64). Of the cases detected during life, 25 to 50% are symptomatic (63,65). Although it is presumed to be congenital in origin, most symptomatic cases are detected in adulthood (65). The duodenum and stomach are the most common locations of pancreatic heterotopia (4,66), with most duodenal cases occurring in the second portion several centimeters proximal to the ampulla of Vater. Often the tissue is found in the submucosa beneath the minor duodenal papilla and represents remnants of the embryonic dorsal ductal system. Pancreatic heterotopia also may occur elsewhere in the duodenum and may involve the ampulla of Vater (67,68). Other sites of pancreatic heterotopia include the jejunum, Meckel's diverticulum, the large bowel, and the liver, where it is generally located around the bile ducts (69). In the tubular gastrointestinal tract, heterotopic pancreas appears as lobulated submucosal nodules of yellow to white firm tissue ranging from several millimeters to several centimeters in size. The overlying mucosa may be umbilicated in larger examples (Figure 30.8A). Rarely heterotopic pancreatic tissue is present on the serosal surface. Microscopically, the type and amount of the different pancreatic cell types varies. Most cases have ducts, and they may be the only epithelial component. Such cases have submucosal aggregates of small ducts and lobules of ductules, typically surrounded by interlacing smooth muscle fascicles, resulting in the appearance of so-called adenomyoma. Many cases do show some acinar and endocrine elements, and some resemble normal pancreatic parenchyma (Figure 30.8B). Some duodenal foci of heterotopic pancreas exhibit acini with the features of Brunner's glands, emphasizing the embryologic relationship these glands have with the pancreas (16). One of the important reasons to recognize heterotopic pancreas is to avoid misinterpretation of these ductules

as carcinoma; however, cases of adenocarcinoma arising in heterotopic pancreas have been described (70,71,72), as have pancreatic pseudocysts.

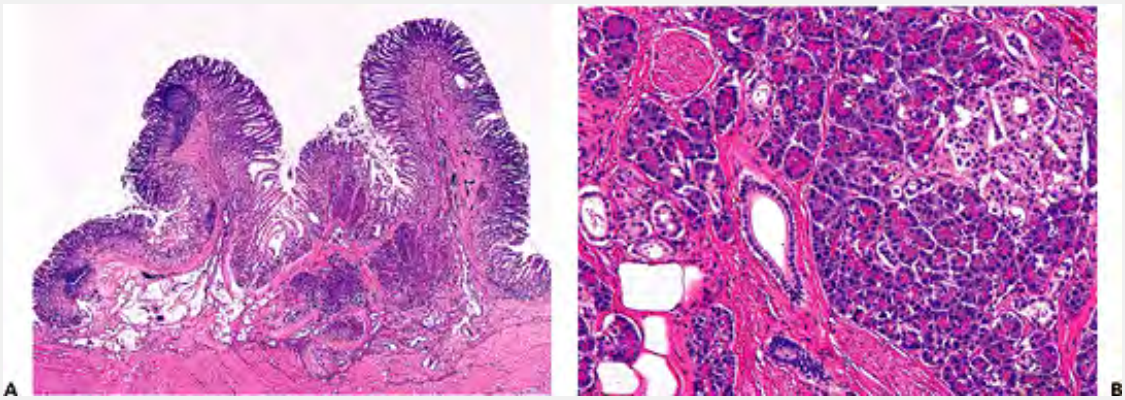

Figure 30.8 Heterotopic pancreatic tissue in the stomach. A. At low power, a submucosal nodule of pancreatic tissue results in an umbilicated appearance. B. In this example, lobules of normal-appearing acinar and ductular structures are separated by bands of fibromuscular tissue. Acini, ducts, and islets are arranged in a disorganized pattern, with interspersed bundles of smooth muscle.

Heterotopic tissues also may be found within the pancreas. Accessory splenic tissue may be found in the tail of the pancreas or, more rarely, in the head (73). In most cases, the splenic tissue is small (less than 2 cm), dark red, and spherical. Intrapancreatic adrenal cortical tissue has also been described (74).

Microscopic Features

Microscopically, the pancreas is arranged in 1- to 10-mm lobules (Figure 30.9). The parenchyma within the lobules consists almost

entirely of the epithelial elements of the pancreas, including the acini, the ducts, and the islets of Langerhans. There is minimal intralobular connective tissue, but fibroconnective tissue containing vessels and nerves separates the lobules.

Acini

Acinar cells make up approximately 85% of the mass of the pancreas and constitute the main exocrine secretory component of the gland. The prototypical architecture of the acinus in routine histologic sections appears to be a single layer of polygonal cells surrounding a minute central lumen, suggesting a spherical configuration (Figure 30.10); however, the three-dimensional architecture of the pancreatic acini is much more complex (75). In fact, tubular acini are commonly detected in histologic sections (Figure 30.11). Also, not all acini are located at the terminal end of ductules. Some acini bud from the sides of the ductules or are situated between two ductules. Anastomosing loops of acini also may be found (75). Thus, the secretions of a given acinus may pass through a number of different pathways to reach the ductal system.

Individual acinar cells are polarized, with basally situated round nuclei and apical granular eosinophilic cytoplasm. The eosinophilia of the apical cytoplasm reflects the accumulation of numerous zymogen granules (Figure 30.10), which contrast with the basophilic zymogen granules of salivary serous acini. The zymogen granule content is highly dynamic, depending on the secretory state of the pancreas, which is largely regulated by digestive hormones (1). The basal cytoplasm of the acinar cells is basophilic due to the high concentration of ribonucleoproteins in the abundant rough endoplasmic reticulum (RER). There may be a clear cytoplasmic zone on the luminal side of the nucleus that contains the Golgi apparatus. The nuclei are uniform and frequently contain distinct central nucleoli; clumps of chromatin are generally present beneath the nuclear membrane. The acinar cells sit directly upon the basement

membrane; in contrast to salivary acini, there are no myoepithelial cells surrounding the pancreatic acini.

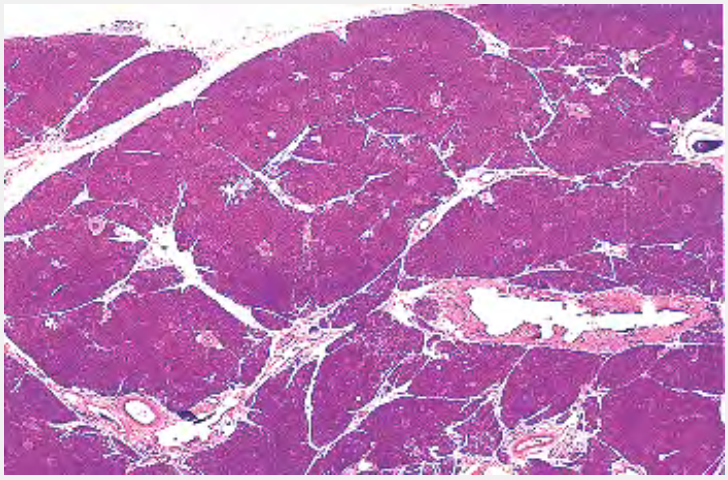

Figure 30.9 At low power, the normal pancreas has a well-developed lobular arrangement of highly cellular glandular tissue.

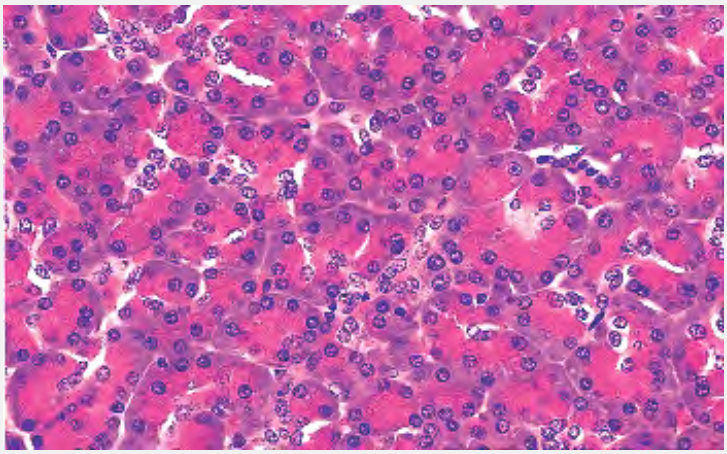

Figure 30.10 Acinar cells contain abundant granular eosinophilic cytoplasm in the apical aspect, with basophilic basal cytoplasm. The nuclei are also basally located. Most acini consist of

spherically arranged individual acinar cells.

Although the acinar cells from different regions of the pancreas are all morphologically and functionally similar, there are subtle differences in the size and zymogen granule

content in the acinar cells immediately adjacent to islets compared with those distant from islets, perhaps as a reflection of regional variations in islet hormone levels (76,77).

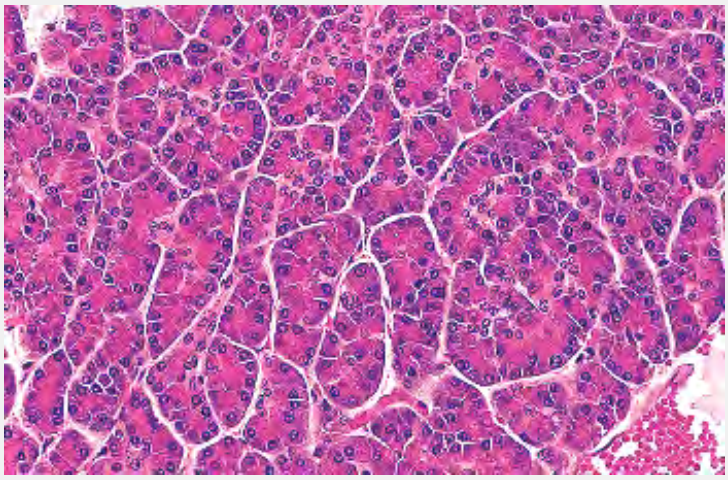

Figure 30.11 Other acini have tubular configurations and exhibit interanastomosing loops when studied by serial sectioning.

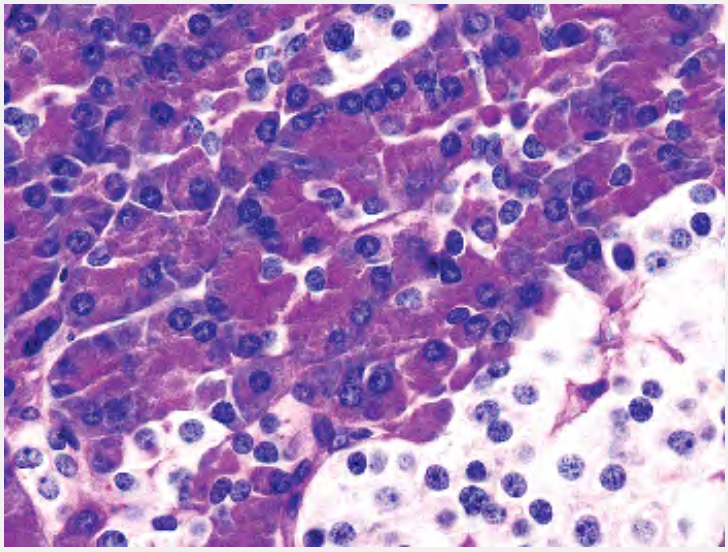

Figure 30.12 Zymogen granules are positive with periodic acid-Schiff's stain with diastase pretreatment. Islet cells (*lower right*) are negative.

Zymogen granules stain positively with periodic acid-Schiff (PAS) stain and are resistant to diastase digestion (Figure 30.12). Acinar cells also can be demonstrated using stains for butyrate esterase, which is positive in the presence of enzymatically active lipase (38). Immunohistochemical labeling for pancreatic enzymes such as trypsin, chymotrypsin, lipase, amylase, and elastase is positive in acinar cells (Figure 30.13) and, with the exception of amylase, these are also sensitive markers for acinar differentiation in pancreatic neoplasms (38,39,40,78). Each individual zymogen granule contains all of the various digestive enzymes, usually in a proenzyme form (79,80). Keratins detected by the CAM 5.2 antibody (cytokeratins 8 and 18) are present in acinar cells; however, there is no labeling with the AE1 antibody nor is there with antibodies against cytokeratins 7, 19, and 20 (Figure 30.14). Mucins are not produced, and immunohistochemical labeling for glycoproteins such as DUPAN-2, CEA, and CA19.9 is negative. Finally, endocrine specific antibodies

such as chromogranin and synaptophysin are negative as well.

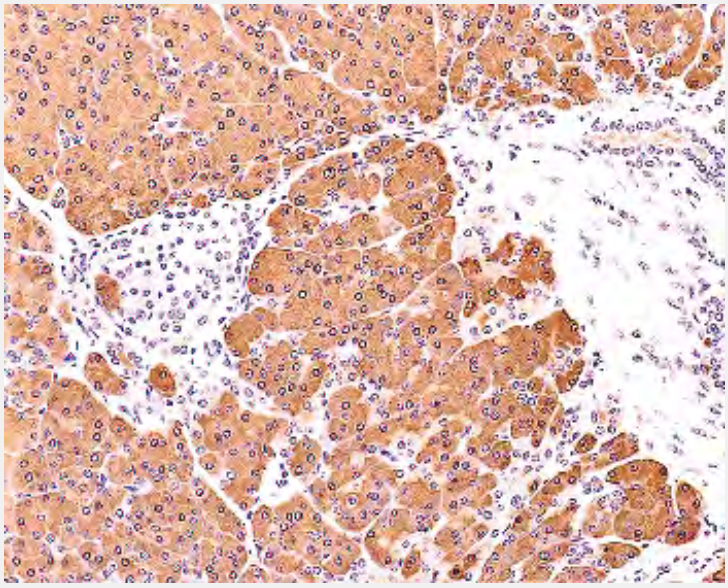

Figure 30.13 Immunohistochemical staining for trypsin results in intense labeling of acinar cells but not ductal and islet cells. Faint luminal labeling of ductal cells may be seen due to deposition of luminal enzymatic secretions on the apical cell surfaces (*upper right*).

Ultrastructural examination shows features characteristic of active exocrine secretion. The RER is arranged in parallel stacks and fills the basal cytoplasm (Figure 30.15). Scattered mitochondria and free polyribosomes are present between RER cisternae (81). The Golgi apparatus is situated in the

central region of the cytoplasm near the nucleus. Immature electron-dense zymogen granules emanate from the *trans* side of the Golgi apparatus. Larger round, homogeneous mature zymogen granules are present within the apical cytoplasm. They measure 250 to 1000 nm and have limiting membranes closely apposed to the dense

secretory content. Upon stimulation, the membranes of the secretory granules fuse with the apical plasma membrane, expelling the contents into the lumen; the excess cell membranes are then recycled to the Golgi apparatus (82,83). Accumulated secretions are often present within the lumina, sometimes with crystal formation. The luminal membranes have sparse, short microvilli containing inner microfilaments that are continuous with the terminal web of filaments beneath the apical membrane (81). Adjacent acinar cells are joined by apical junctional complexes composed of zonula occludens- and zonula adherens-type junctions, whereas desmosomes (macula adherens junctions) join cells along the basal aspects of their lateral membranes (14,81). Each acinus is surrounded by a continuous basement membrane.

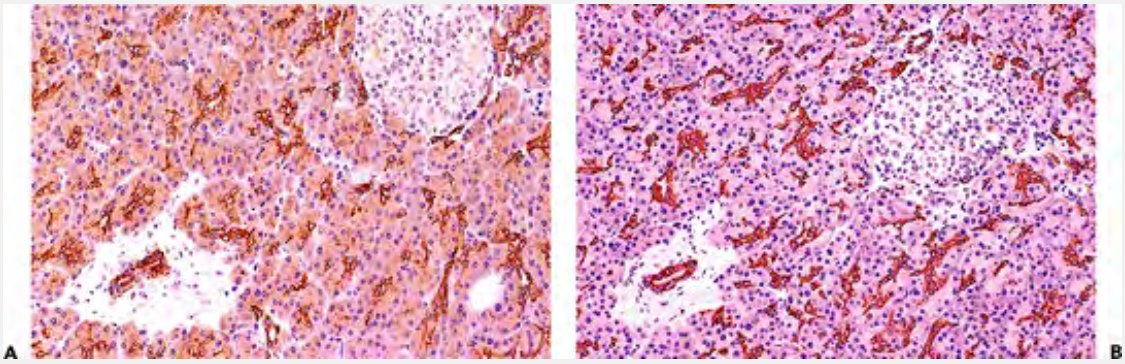

Figure 30.14 Immunohistochemical labeling for keratins. A. The CAM 5.2 antibody shows diffuse labeling of acinar cells and ductal cells, the latter being more intensely positive. B. The AE1/AE3 antibodies label only ductal cells. Islet cells show only focal faint labeling with any of these antibodies.

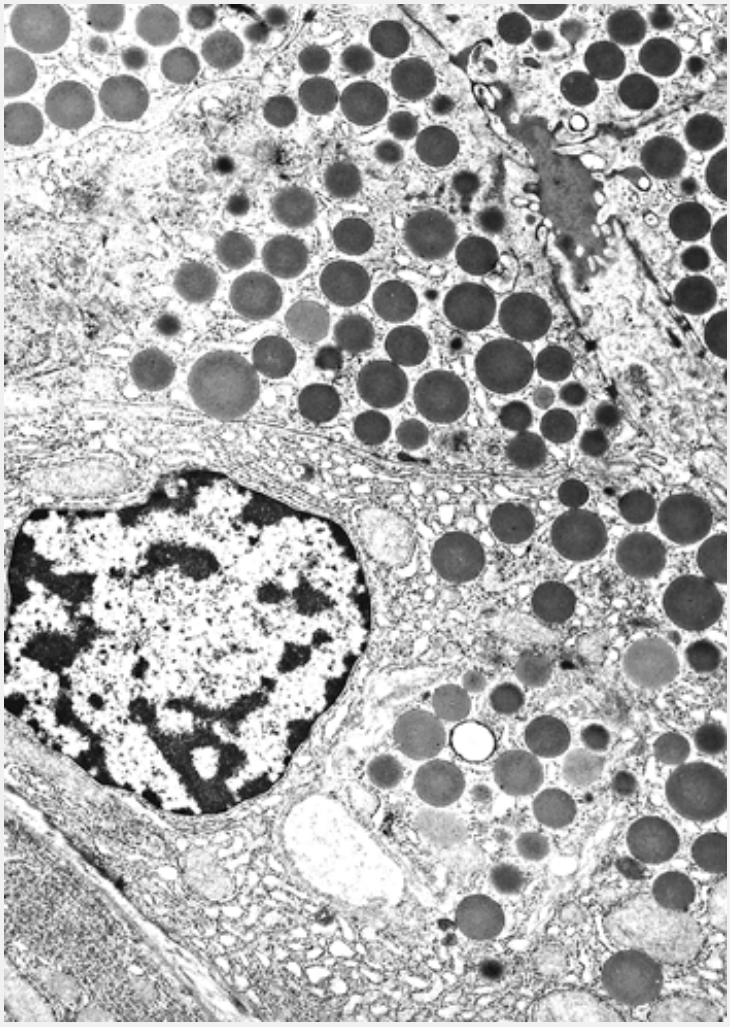

Figure 30.15 The ultrastructural appearance of acinar cells. These polarized cells have abundant parallel stacks of rough endoplasmic reticulum with interspersed mitochondria in the basal cytoplasm. Homogeneous electron-dense zymogen granules are concentrated in the apical cytoplasm underlying the lumina. The luminal spaces are lined by short microvilli. Adjacent acinar cells are joined to one another and to the centroacinar cells (*) by apical junctional complexes. The centroacinar cells have lucent cytoplasm devoid of secretory granules.

Ducts

The ductal system of the pancreas serves to transport the acinar cell secretions to the duodenum. The ductal epithelial cells secrete water, chloride, and bicarbonate to buffer the acidity of the pancreatic juices and stabilize the proenzymes until activation within the duodenum. The ductal system is subdivided into five portions: centroacinar cells, intercalated ducts, intralobular ducts, interlobular ducts (large and small), and main ducts (84). The ductal system begins with the centroacinar cells, which are small, relatively inconspicuous, flat to cuboidal cells with pale or lightly eosinophilic cytoplasm and central oval nuclei (Figure 30.16). Centroacinar cells are located in the middle of the acini, where they partially border

the acinar lumina along with the acinar cells, to which they are joined by tight junctions. Ultrastructurally, the centroacinar cells have cytoplasm largely devoid of organelles, with only scattered mitochondria; no zymogen, neurosecretory, or mucigen granules are present. Relative to the acinar cells, the cytoplasm is less dense and rough endoplasmic reticulum is minimal. The cell surfaces contain scattered short microvilli similar to those on the adjacent acinar cells. Adjacent cells are joined by abundant junctional complexes, and there are often complex interdigitations between them. Some centroacinar cells have more abundant granular oncocytic cytoplasm (Figure 30.17) that reflects numerous mitochondria (84,85); the significance of this variation is unknown.

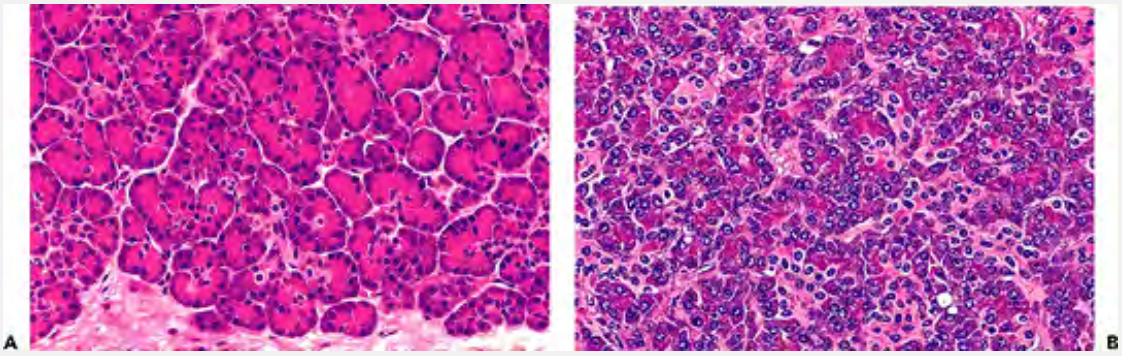

Figure 30.16 A. Most centroacinar cells are inconspicuous small cells with minimal cytoplasm and oval nuclei situated in the center of the acini. B. In other regions the centroacinar cells may be more prominent, with more abundant lightly eosinophilic cytoplasm. Centroacinar cells constitute the beginning of the ductal system and convey the secretions of acinar cells to the intercalated ducts.

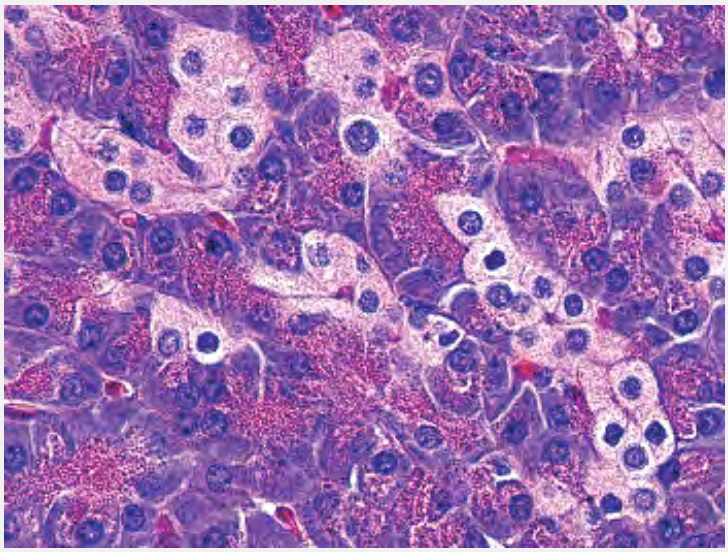

Figure 30.17 Some centroacinar cells are enlarged and have oncocytic cytoplasm, a variation of uncertain significance.

The lumen surrounded by acinar and centroacinar cells drains into the intercalated ducts, which are the smallest ducts outside the acini (Figure 30.18). The cells lining the intercalated ducts resemble the centroacinar cells. They are cuboidal and have central oval nuclei with indistinct nucleoli. Mucins are not detected with Alcian blue or mucicarmine stains in centroacinar or intercalated duct cells. The intercalated ducts fuse to form the intralobular ducts, and the transition is imperceptible. The cells lining the intralobular ducts are essentially identical to those of the intercalated ducts, although the nuclei are round rather than oval (Figure 30.18). Neither intercalated nor intralobular ducts have a significant collagenous matrix surrounding them. The ductal cells rest directly on the basement membrane and lack both myoepithelial and basal cells; thus, in contrast to several other organs, the presence or absence of these cells cannot be used to help distinguish benign ducts from invasive pancreatic ductal adenocarcinoma.

Once the ducts leave the lobules, they become enveloped by a variably thick rim of collagen and are termed interlobular ducts (Figure 30.19). The interlobular ductal cells have slightly more cytoplasm than those of the intralobular ducts

and assume a low columnar shape in the larger ducts. As in the smaller ducts, cytoplasmic mucin is not detectable by routine histology in intralobular or interlobular ductal cells; mucinous cytoplasm visible by routine histology is considered a pathological change (see below). However, some cytoplasmic mucin may be found using special stains. As the interlobular ducts approach the main pancreatic ducts (of Wirsung or Santorini), they develop an increasingly thick collagenous wall within which lobular aggregates of

small ductules may be seen, resembling the ductules of Beale that surround the major bile ducts (Figure 30.20).

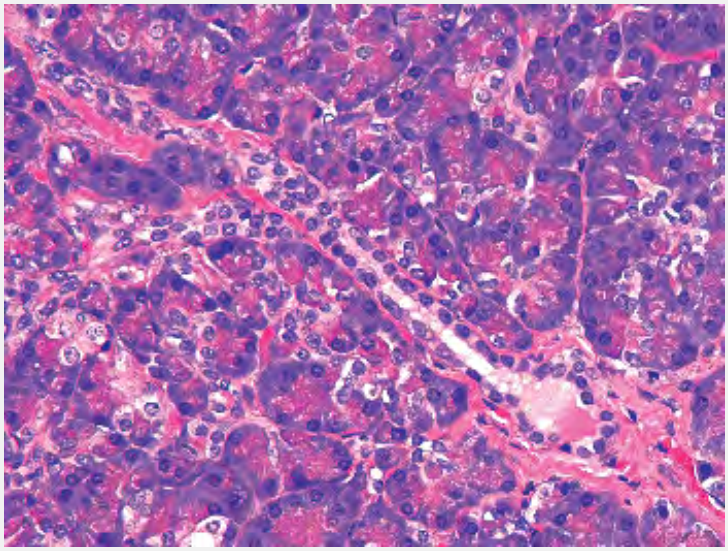

Figure 30.18 The ductal system within the lobules consists of innumerable intercalated ducts that fuse to form intralobular ducts. The cytologic appearance of the intercalated and intralobular ductal cells resembles that of the centroacinar cells, and the transition from one to the next is imperceptible. Only minimal collagenized stroma surrounds the intralobular ducts (*lower right*).

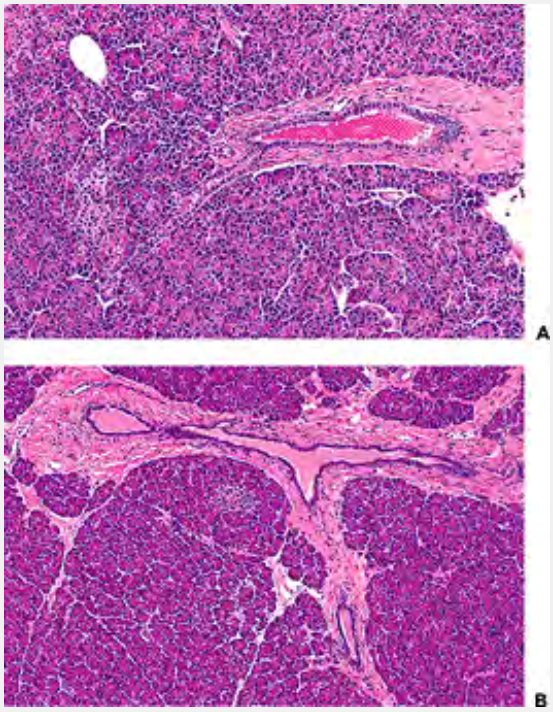

Figure 30.19 A. Intralobular ducts come together to form interlobular ducts. B. The interlobular ducts are surrounded by a variably thick rim of dense fibrous tissue and carry the pancreatic secretions to the major ducts, receiving tributaries of small interlobular ducts as they pass through the connective tissue septa of the gland.

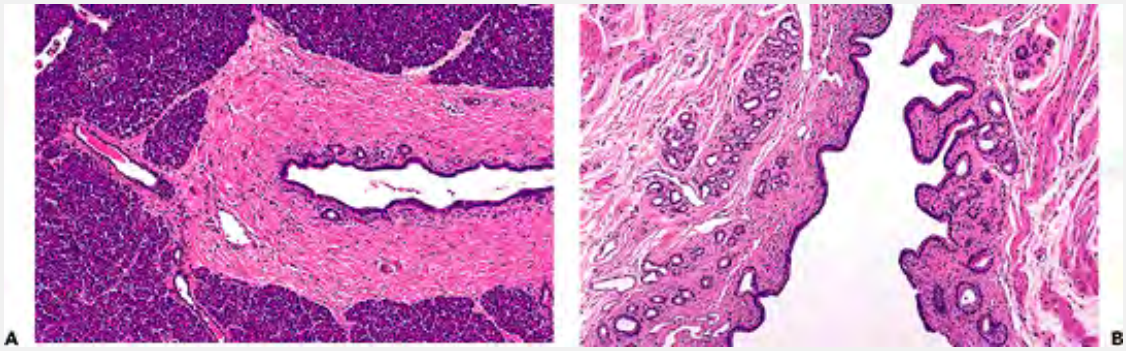

Figure 30.20 A. The largest interlobular ducts are surrounded by a thick rim of collagen. B. Small lobular aggregates of ductules are present within the wall of the larger ducts.

The main pancreatic ducts receive numerous tributaries of interlobular ducts (Figure 30.21). The lining epithelium remains flat, without papillary projections, except in the very distal duct within the ampulla, where simple papillae are found (Figure 30.22). The cells are low columnar with basal round nuclei. In these large ducts, there may be apical cytoplasmic clearing, reflecting mucin, but tall columnar cells with obvious abundant mucin are not normally found, and special stains or electron microscopy are often needed to identify the mucin (84). The mucins of the intralobular and smaller interlobular ductal cells are predominantly sulphomucins and stain positively with Alcian blue at pH 1.0 (Figure 30.23) (55,86). In the cells of the larger ducts, there are fewer sulfomucins and more neutral mucins and sialomucins (86). There is relatively frequent cell exfoliation in the main duct, perhaps reflecting a high turnover rate due to injury; degenerating cells may be observed within the epithelium by electron microscopy (81). The thick connective tissue wall contains numerous periductal ductules, as well as fascicles of smooth muscle (1).

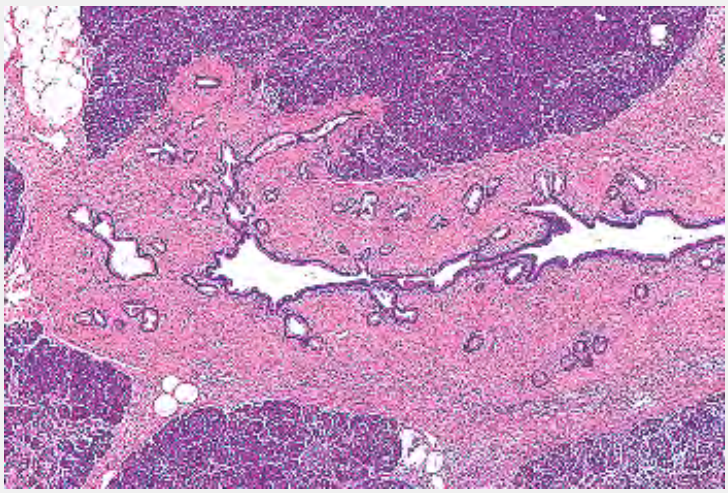

Figure 30.21 Numerous interlobular ducts join the main pancreatic duct along its course.

Other than the appearance of increasing numbers of mucigen granules and increased exocrine secretory apparatus (RER, mitochondria, and Golgi) in the larger ducts, the ultrastructural appearance of the ductal cells resembles that of the centroacinar cells (Figures 30.24,30.25). In ductal cells from the level of the small interlobular ducts, single long kinocilia project from the cell surfaces (81,84); cross

sections of these cilia may be observed within the lumina of the ducts (Figure 30.24). The cilia are connected to basal bodies in the paranuclear cytoplasm and may function in mixing and propulsion of the pancreatic secretions (81).

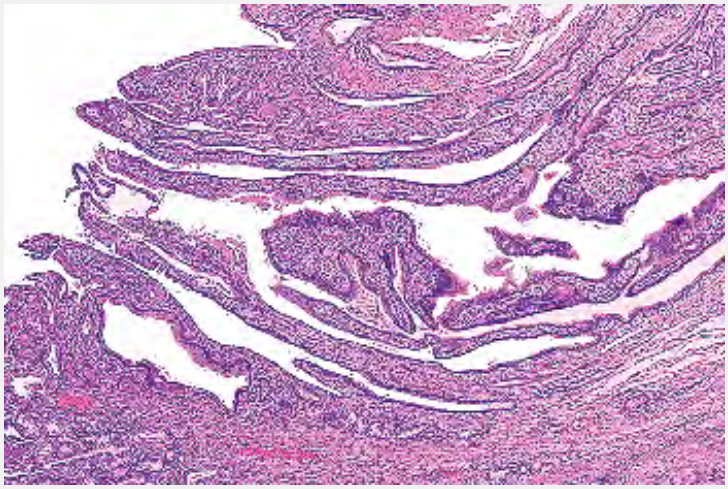

Figure 30.22 As the main pancreatic duct enters the ampulla of Vater, the ductal epithelium forms broad, simple papillae known as the valves of Santorini.

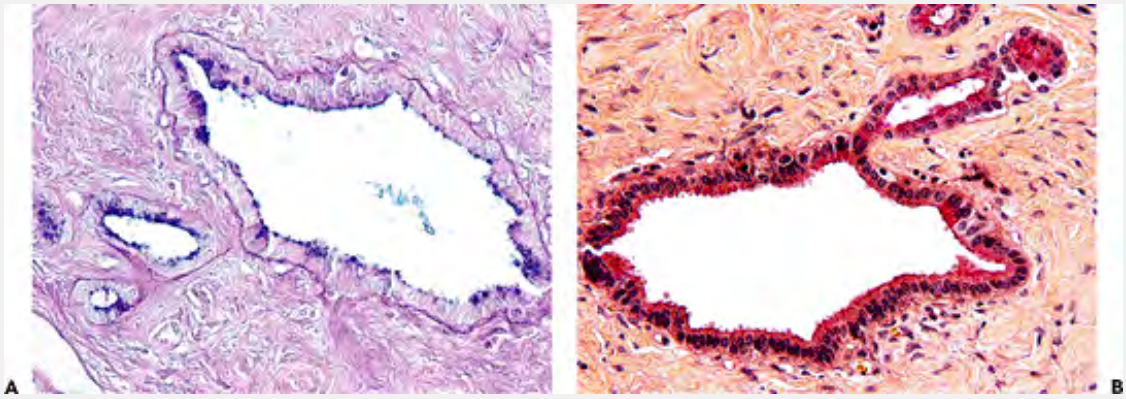

Figure 30.23 A. The cells of the intralobular and smaller interlobular ducts contain mucin in the apical cytoplasm that stains positively with Alcian blue/PAS. B. Staining with mucicarmine shows a similar distribution of mucin.

Ductal cells contain cytokeratins 7, 8, 18, and 19; hence, they are immunohistochemically reactive with the AE1, AE3, and CAM 5.2 antibodies, in addition to antibodies against the specific individual cytokeratins (Figure 30.14). They do not express cytokeratin 20. Enzyme and endocrine markers are also negative. Carbonic anhydrase is detectable in ductal cells, reflecting their role in fluid and ion transport (87); most is detected in intercalated and intralobular ducts (88), although ducts of larger caliber may weakly express this enzyme (Figure 30.26).

Other markers of ductal cells include antibodies against CA19-9, DUPAN-2, cystic fibrosis transmembrane conductance regulator (CFTR), and N-terminal gastrin-releasing peptide (N-GRP) (89,90,91,92,93). Normal ducts do not label with antibodies to carcinoembryonic antigen when monoclonal antisera are used (94) and also fail to label for B72.3 and CA125. Members of the MUC family of glycoproteins are variably expressed; MUC1 is present in smaller intralobular and intercalated ducts, MUC6 is expressed in centroacinar cells and intercalated ducts; MUC2 and MUC5AC are not normally expressed (95,96).

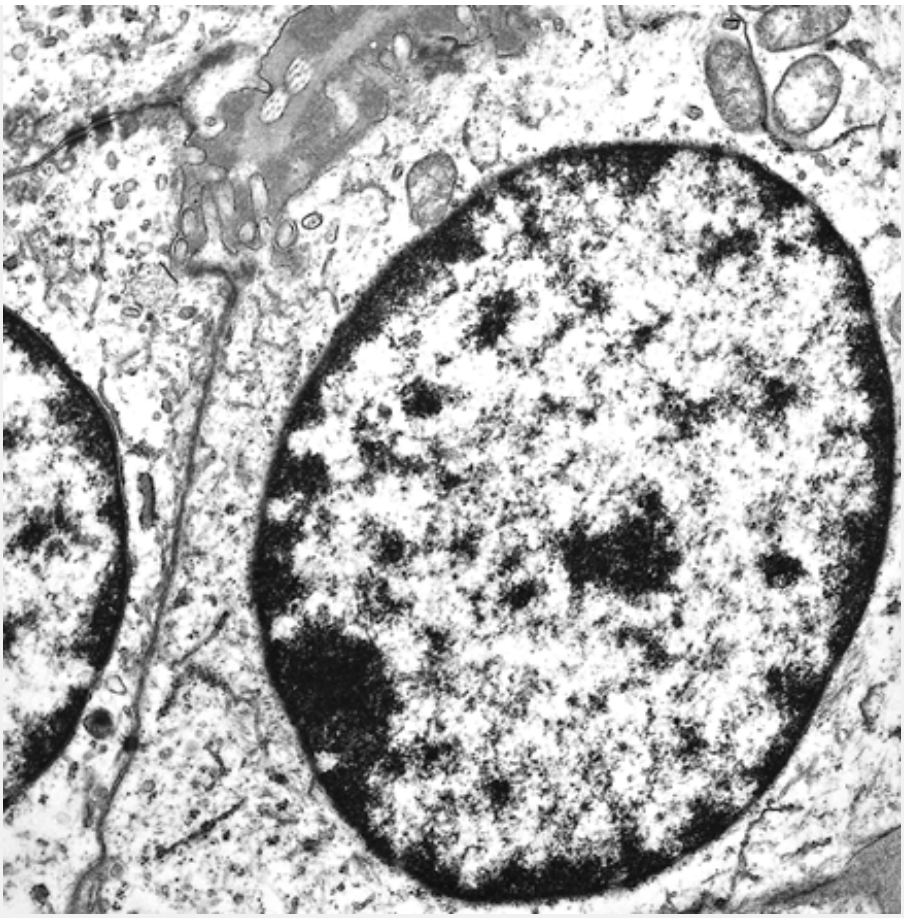

Figure 30.24 Ultrastructural appearance of intralobular ductal cells. The cytoplasm resembles that of centroacinar cells, with an electron-lucent appearance and scattered mitochondria and rough endoplasmic reticulum. In the smaller ducts, mucigen granules are largely absent. The luminal surface exhibits short microvilli. In addition, scattered cilia are present, the cross section of which may be seen within the lumen (*top*).

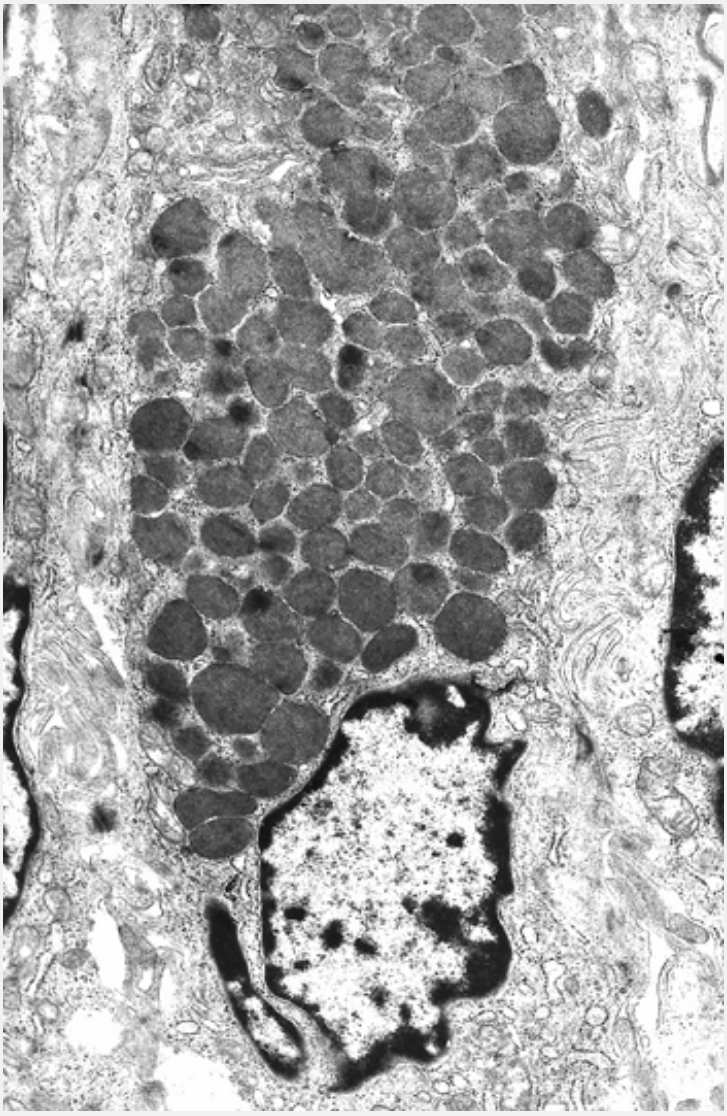

Figure 30.25 In the larger ducts, more abundant mucigen granules accumulate within the apical cytoplasm. These granules vary in size and have irregular contours and heterogeneous, variably electron-dense secretory contents. There are complex interdigitations of the lateral membranes between adjacent cells.

Islets of Langerhans

The endocrine component of the pancreas constitutes only 1 to 2% of the volume of the gland in adults (1,77) but about 10% in the newborn (55,97). The vast majority of endocrine cells are found in the over one million islets of Langerhans, first described by Paul Langerhans in 1869. Although islets are distributed throughout the pancreas, they are somewhat more numerous in the tail (98). Apparently random variations in islet concentration may occur from one lobule to the next, resulting in the appearance of plentiful islets in one area and sparse islets in an adjacent region (Figure 30.27).

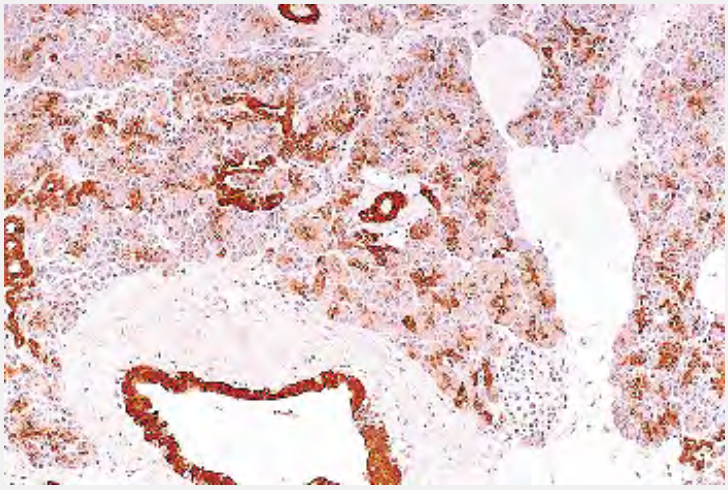

Figure 30.26 Immunohistochemical staining for carbonic anhydrase. In this preparation, there is staining of ductal cells of all sizes, including centroacinar, intercalated duct, and intralobular and interlobular ductal cells.

The apparent volume of islets observed in histologic sections also varies with the age of the individual and the presence and extent of exocrine atrophy, as commonly occurs in chronic pancreatitis. In the fetus and neonate, the relative volume of endocrine cells far outmeasures that of the adult, especially in the portions derived from the dorsal lobe (Figure 30.28) (99).

Two types of islets are found. Most (90%) are the compact islets: sharply circumscribed nests usually measuring 75 to 225 Âµm, although islets as small as 50 Âµm or as large as 280 Âµm also may be found (100). Compact islets are found predominantly in the body and tail of the gland, with fewer in the head. The second type of islet, the diffuse islet, is essentially restricted to the posteroinferior head of the gland derived from the embryonic ventral lobe (101,102). These islets are much less numerous than the compact islets and may measure up to 450 Âµm.

Despite the circumscribed appearance of the compact islets, they are actually composed of interdigitating trabeculae that appear as small lobules in cross section (100). The cells of the compact islets have uniform round nuclei with coarsely clumped chromatin and inconspicuous nucleoli (Figure 30.29). The cytoplasm is pale and amphophilic. Occasional islet cells have nuclei two to four times the size of their neighbors, although no irregularities of shape or chromatin pattern are present. These nuclei have a 4n or 8n DNA content and have been shown to occur exclusively in Î² cells (103); they do not have any pathologic significance. Mitotic figures are only rarely encountered in normal islets (104). The islets contain numerous small vessels, although these capillary-sized vessels are almost inapparent by light microscopy. Essentially all of the islet cells contact the vasculature. In

contrast to those supplying the acinar tissue, the capillaries of the islets have a fenestrated endothelium (1). A thin layer of connective tissue separates the compact islets from the surrounding acinar tissue, but they are not truly encapsulated.

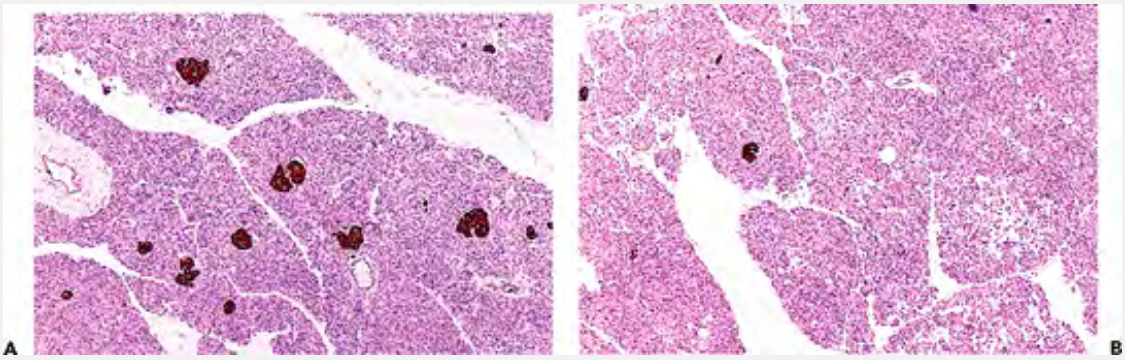

Figure 30.27 As highlighted by immunohistochemical labeling for chromogranin, the concentration of islets varies considerably from one lobule (A) to the next (B).

Diffuse islets have a trabecular appearance, with winding cords of cells intermingled among acini (Figure 30.30A). Because they are less commonly encountered and have a pseudoinfiltrative appearance, they may be mistakenly regarded as neoplastic, an occurrence even more likely in the setting of chronic pancreatitis. In addition to the architectural differences already mentioned, the diffuse islets contain columnar cells within the trabecula. The cytoplasm is basophilic, the nuclei are somewhat hyperchromatic, and there may be more prominent nucleoli than in the compact islets (Figure 30.30B).

Each endocrine cell produces only one specific peptide hormone. The four major peptides produced by islet cells are insulin, glucagon, somatostatin, and pancreatic polypeptide (105). Although some pancreatic endocrine neoplasms produce ectopic peptides such as gastrin or vasoactive intestinal polypeptide, these are not found in normal islet cells. Classical histochemical staining was used to distinguish the different cell types. Aldehyde-fuchsin stains insulin-secreting Î² cells, the Grimelius silver stain labels glucagon-secreting

Î± cells, and the Hellerstrom-Hellman silver stain identifies somatostatin-secreting Î´ cells. Immunohistochemical labeling with antibodies against insulin, glucagon, somatostatin, and pancreatic polypeptide provides a more specific method to distinguish the cell types. There is a fairly consistent distribution of the cell types within the compact islets. The Î² cells are more centrally located, whereas the Î± cells populate the periphery of the islets (Figures 30.31,30.32). Beta cells constitue 60 to 70% and Î± cells make up 15 to 20% of the compact islets,

whereas the Î´ cells are much less numerous (100,106). Alpha cells are generally found in close contact with Î´ cells (42), and PP cells are rare in the compact islets, being concentrated in the diffuse islets where they constitute the majority (70%) of the cells (Figure 30.33) (107,108). The remaining cells of the diffuse islets are largely Î² cells (20%), with minor amounts of Î± and Î´ cells (5% of each). The difference in proportion of cell types between the compact and diffuse islets reflects their different embryologic origins (101,102). The relative proportion of the different peptide-producing cells also varies with age; for instance, the ratio of Î² to Î´ cells in the compact islets is manyfold higher in adults than in infants, in whom Î´ cells constitute one-third of the islet cell population (97,109). All of the islet cells also express general endocrine markers such as neuron-specific enolase, CD56 (neural cell adhesion molecule), synaptophysin, and chromogranin (Figure 30.34). The last marker is expressed more intensely in Î± cells than in Î² cells, and the pattern of labeling also reflects the characteristic distribution of the cell types in the compact islets.

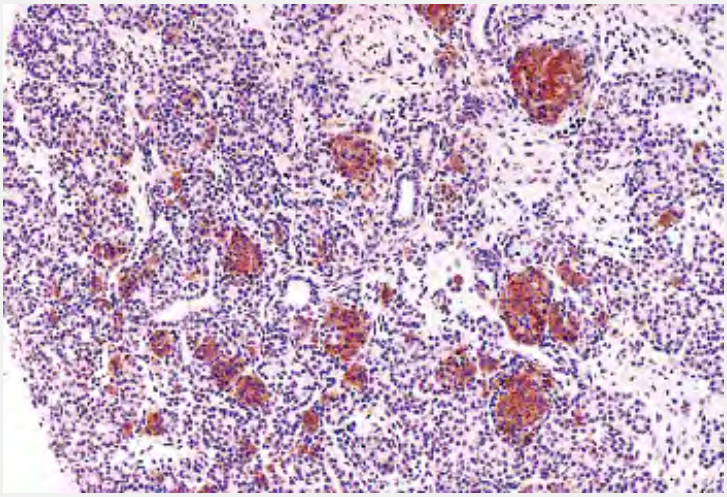

Figure 30.28 A fetal pancreas stained immunohistochemically for chromogranin. Note the abundance of endocrine cells relative to acinar cells at this stage of development.

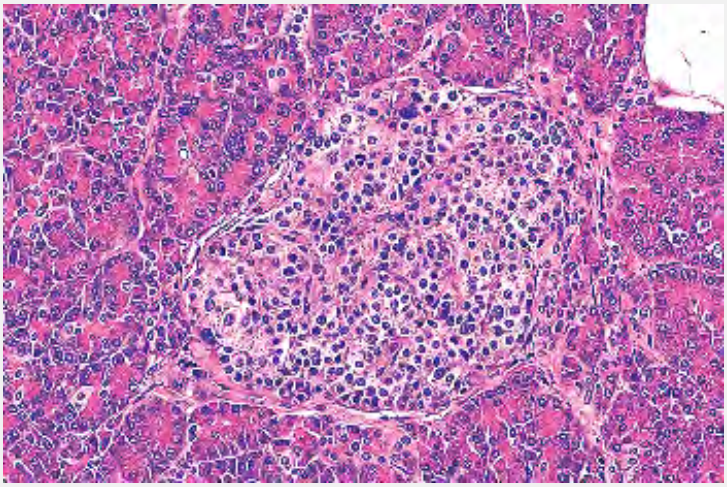

Figure 30.29 Compact islets consist of round to oval, generally circumscribed collections of endocrine cells. Small capillaries separate the islet into lobules. The nuclei have a stippled chromatin pattern, and there is moderate amphophilic cytoplasm.

Some islet cells contain enlarged nuclei several times the size of those in the neighboring cells.

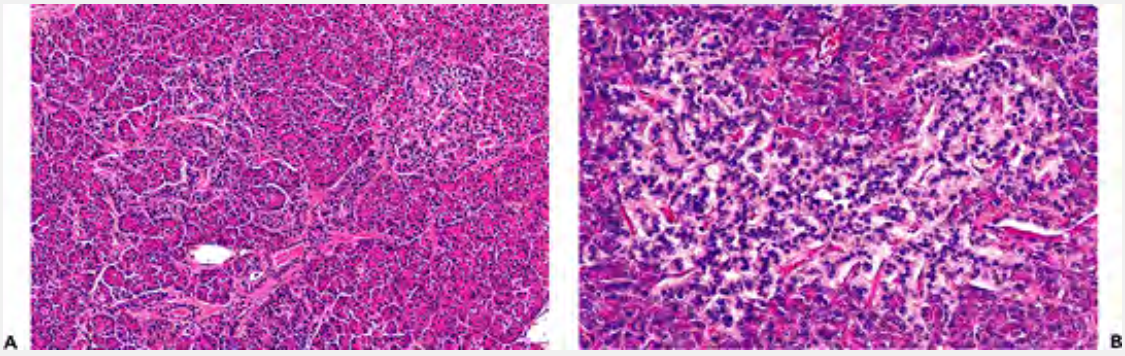

Figure 30.30 A. Diffuse islets are composed of trabeculae of endocrine cells interspersed between adjacent acini. B. The borders of the diffuse islets are ill defined. The cells have somewhat basophilic cytoplasm.

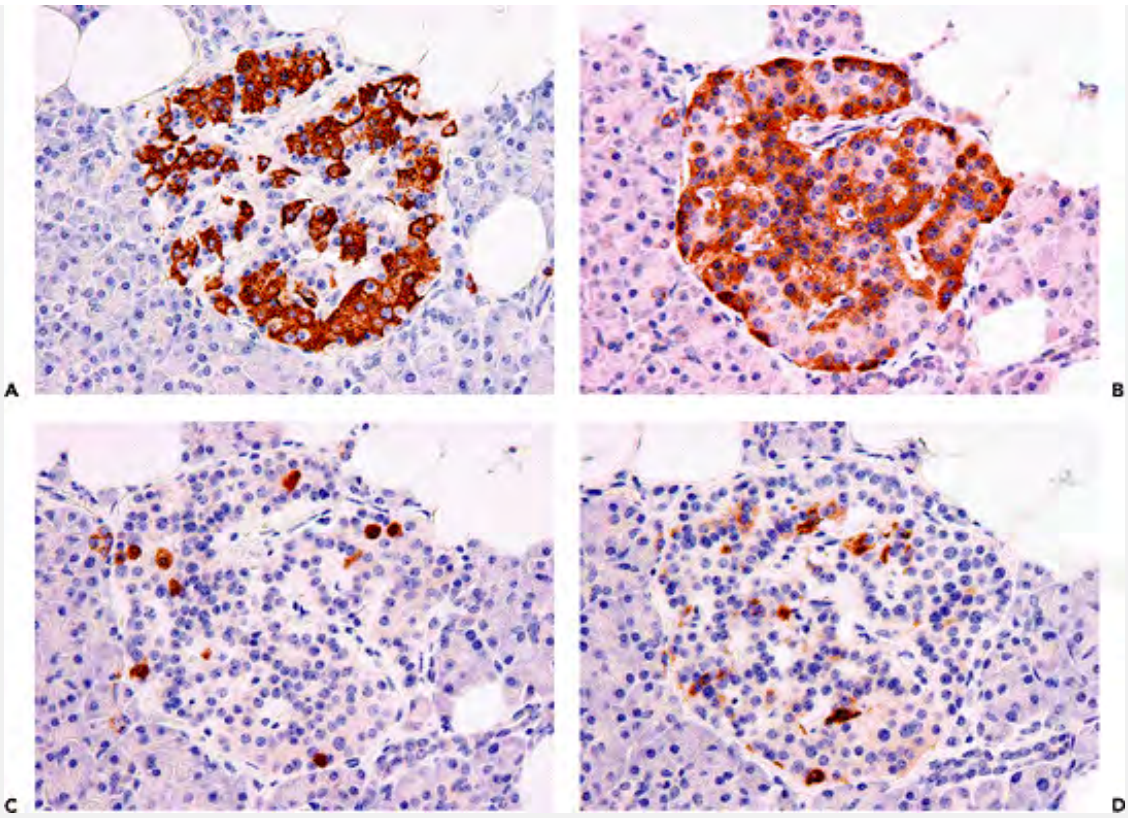

Figure 30.31 The distribution of the different peptide-producing cells within the islets of Langerhans. Beta cells (labeled for insulin) are the most numerous (A) and are situated in the central regions of the islet. Alpha cells (labeled for glucagon) are generally arranged around the periphery (B). Delta cells (labeled for somatostatin) (C) and PP cells (labeled for pancreatic polypeptide) (D) are much less numerous and do not display an obvious pattern of arrangement.

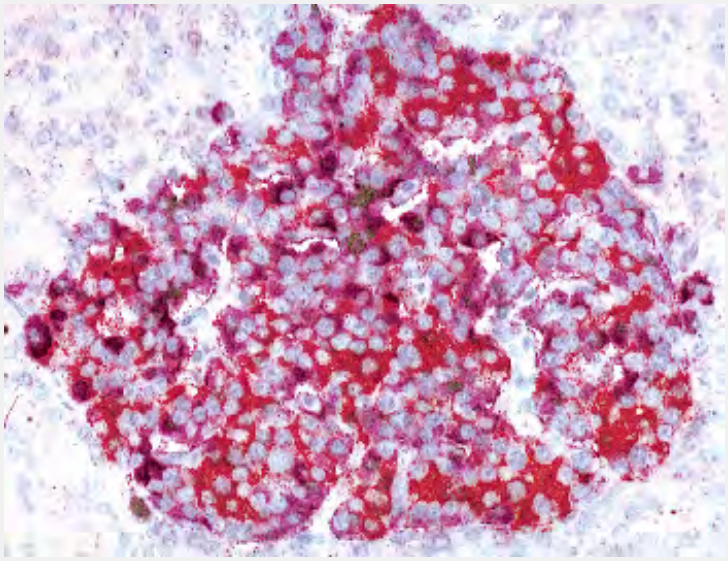

Figure 30.32 Triple immunohistochemical labeling of a compact islet for insulin (red-brown reaction product), glucagon (violet reaction product), and somatostatin (green reaction product) shows the characteristic distribution of the different cell types.

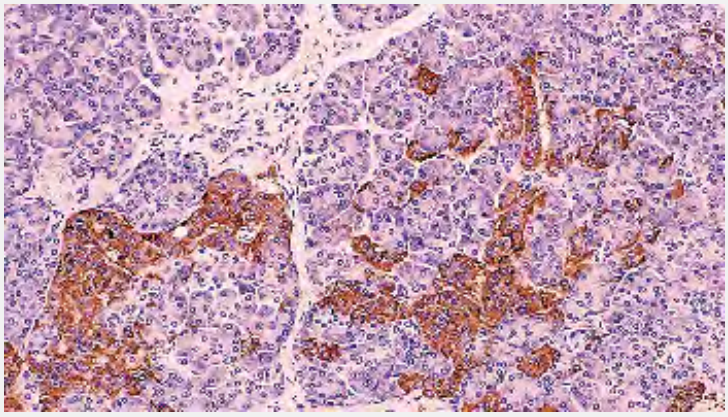

Figure 30.33 Immunohistochemistry for pancreatic polypeptide shows positive staining in most of the cells in the diffuse islets.

Keratins generally are not detected in islet cells by immunohistochemistry, although there may be some faint labeling with CAM 5.2. Enzymes also are not detectable. Progesterone and CD99 receptors are expressed in normal islets as well as in some pancreatic endocrine neoplasms (110,111,112). The homeodomain protein Pdx1, a transcription factor important in pancreatic development, is also expressed in adult islet cells.

Ultrastructural examination of the islets shows polygonal cells joined by tight and gap junctions, suggesting that there may be electronic or metabolic coupling between adjacent cells (42,100). Scattered desmosomes are also present. The cytoplasm contains all of the organelles necessary for protein synthesis, including RER, mitochondria, and

Golgi apparatus; however, the abundant parallel arrays of RER characteristic of acinar cells are absent (Figure 30.35). The granules are also more randomly distributed within the cytoplasm, with some concentration in the basal cytoplasm adjacent to the capillaries into which they are secreted. The granule sizes and morphologies are relatively specific for each cell type (105,113). Alpha cell granules measure 200 to 300 nm and contain an eccentrically located, dense core within a less dense outer region that is separated from the limiting membrane by a thin halo (Figure 30.36A). Beta cells contain 225- to 375-nm granules with either a finely granular or a crystalline core surrounded by a wide halo underlying the limiting membrane (Figure 30.36B). Cytoplasmic lipid inclusions (or ceroid bodies) are often found in Î²

cells (Figure 30.35) (42). Delta cell granules are slightly smaller (170 to 220 nm) than Î± cell granules and have a uniformly dense core (Figure 30.36C). Delta cells have cytoplasmic processes extending toward the Î± and Î² cells, presumably allowing local paracrine release of somatostatin in addition to systemic release into the

bloodstream (100). The PP cells of the ventrally derived portion of the pancreas have 180- to 220-nm granules of variable shape and density, whereas the PP cell granules of the remainder of the pancreas are smaller (120 to 150 nm) and more homogeneous (Figure 30.36D) (55). The cells are separated from the fenestrated endothelial cells of the capillaries only by the basement membranes of both cells and minimal interstitial material (42).

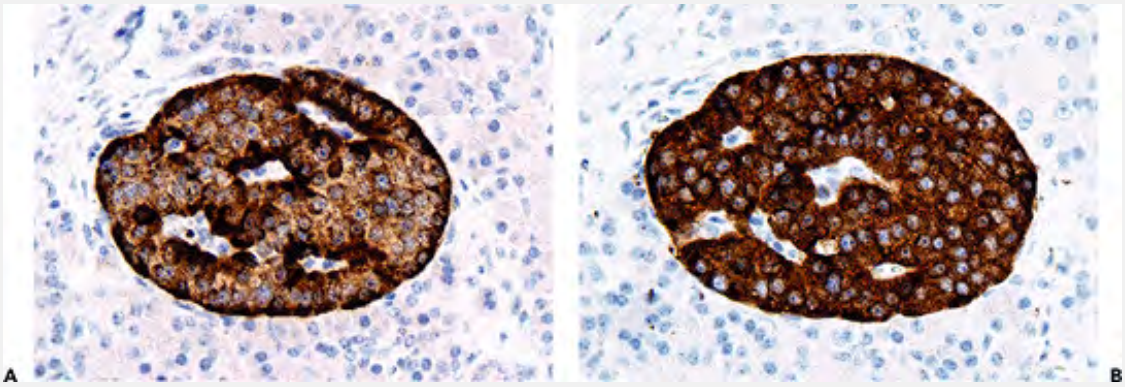

Figure 30.34 Alpha cells stain more intensely for chromogranin than do Î² cells (A), whereas all of the islet cells stain uniformly for synaptophysin (B).

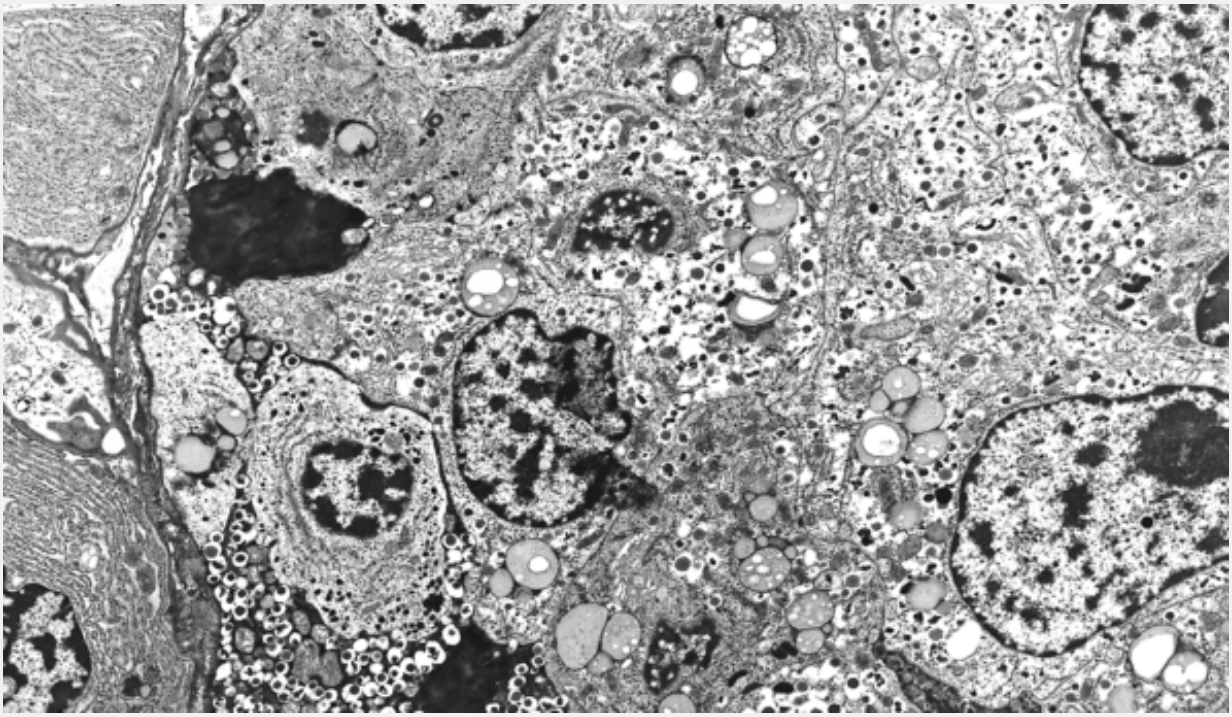

Figure 30.35 Ultrastructural appearance of islets of Langerhans. The islets are circumscribed and separated from the adjacent acinar cells (*left*). The peptide granules are randomly distributed within the cytoplasm. Lipid inclusions (ceroid bodies) are found within the Î² cells.

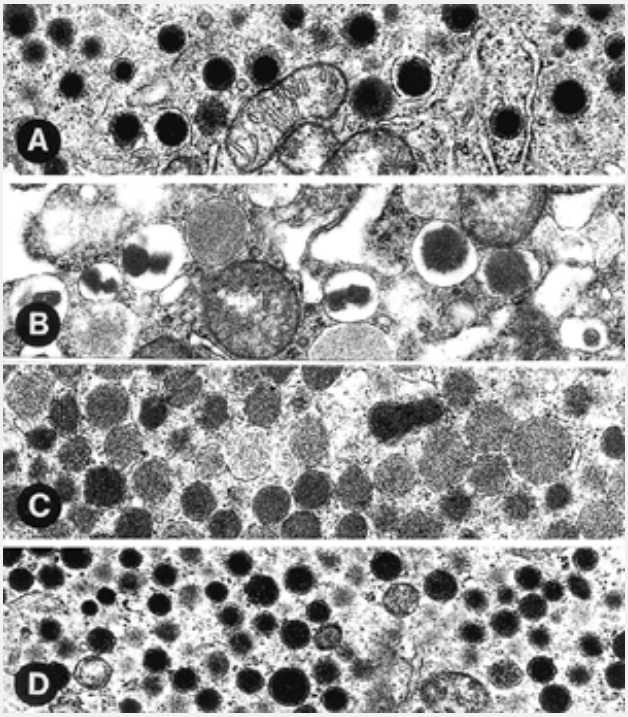

Figure 30.36 Ultrastructural appearance of islet cell granules. A. Alpha cell granules are round and contain an eccentric electron-dense core within a less dense peripheral region. There is a thin halo beneath the limiting membrane. B. Beta cell granules are polymorphous and contain crystalline cores with a wide halo beneath the limiting membrane. C. Delta cell granules are round with a moderately dense core surrounded by a very thin halo. D. The granules of PP cells are smaller and have homogenous hyperdense cores. Extrainsular Endocrine Cells

In addition to the endocrine cells of the islets of Langerhans, there

are small numbers of individual endocrine cells within the ducts and scattered among the acini (Figure 30.37). These extrainsular endocrine cells are especially abundant during infancy, but they constitute less than 10% of the total pancreatic endocrine cell population in the adult (55). The ductal endocrine cells are most commonly detected in the main and larger interlobular ducts and are rare in the smaller ducts (84,114). Some of them border the lumina and are joined to neighboring ductal cells by tight junctions (115), whereas others are situated between the ductal cells and the basement membrane. They may secrete peptides directly into the pancreatic ducts, accounting for the detection of endocrine peptides in pancreatic juice (115). Specific peptides may be found, especially insulin, somatostatin, and pancreatic polypeptide (114,116). Some of the extrainsular endocrine cells in the larger ducts also produce serotonin (116); these cells may be the origin of the extremely rare true carcinoid tumors of the pancreas (117,118). The number of ductal endocrine cells appears to increase in the presence of proliferation of the ductal epithelium (Figure 30.38) (114).

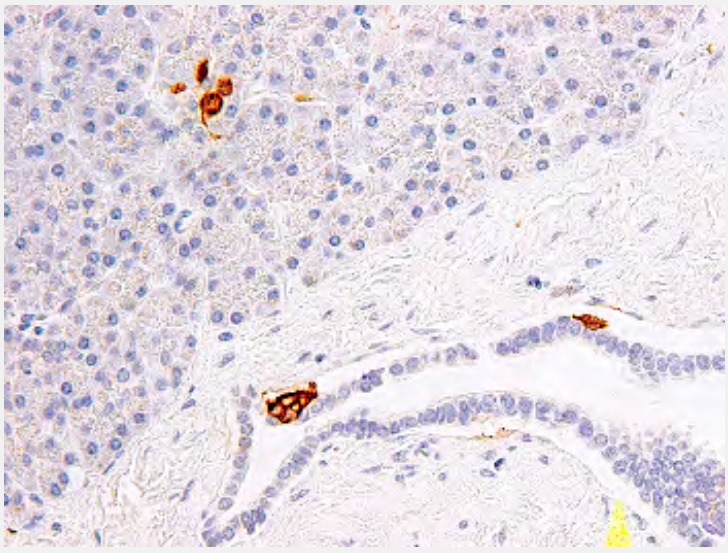

Figure 30.37 Extrainsular endocrine cells within the ducts and between the acini are only detectable with immunohistochemical

labeling for chromogranin.

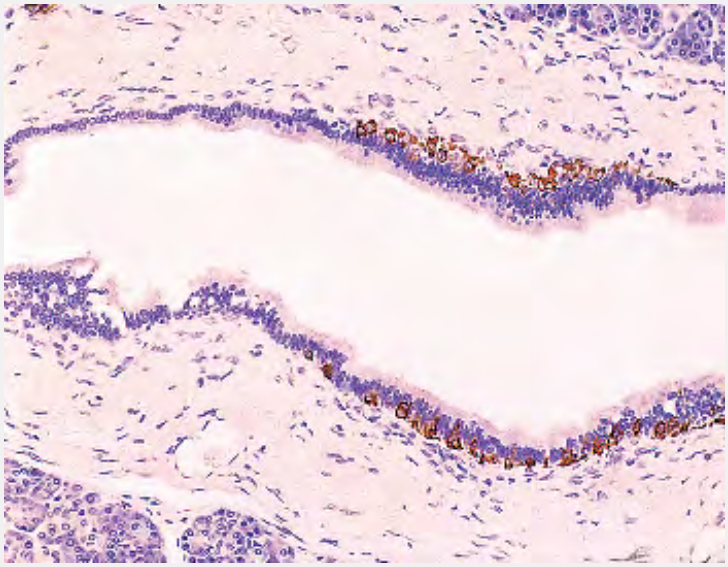

Figure 30.38 The number of ductal endocrine cells is increased in areas showing proliferation (the earliest stage of pancreatic intraepithelial neoplasia, PanIN-1) of the ductal epithelium (*right*).

Connective Tissues

In the normal adult pancreas, there is little connective tissue between the lobules and almost none within them. In the neonatal pancreas, mesenchymal tissue comprises nearly 30% of the volume of the gland; it gradually decreases during infancy (97). The acini are surrounded by basement membranes, but very little other collagen is present (Figure 30.39).

Small portal vessels exist that deliver hormonal secretions from the islets directly to the exocrine elements of the gland (76,77,119,120).

A complex capillary network surrounds the acini, and accompanying nerve fibers may be found. The acini and ducts are innervated by bundles of unmyelinated nerves that travel through the interlobular connective tissues. In most cases the nerve endings are separated from the acinar or ductal cells by the basement membrane, although in some cases direct contact with the basal cell membrane of acinar cells may be seen (84). Islets are innervated by both sympathetic and parasympathetic fibers; in addition, there are peptidergic fibers from the autonomic ganglia. Some of the periacinar nerves produce neuropeptide Y, whereas vasoactive intestinal polypeptideâ€“containing nerves are found within islets and adjacent to ducts (121). Other peptides found in pancreatic nerves include substance P, cholecystokinin, and calcitonin geneâ€“related peptide (121). Small autonomic

ganglia are located between clusters of acini (Figure 30.40). Paraganglia also may be found occasionally in the peripancreatic tissues. The muscular arteries run in the interlobular connective tissue, away from the centrally located pancreatic ducts. This separation of the ducts and muscular arteries is maintained in chronic pancreatitis, and presence of a gland close to a muscular artery suggests that the gland is malignant (122).

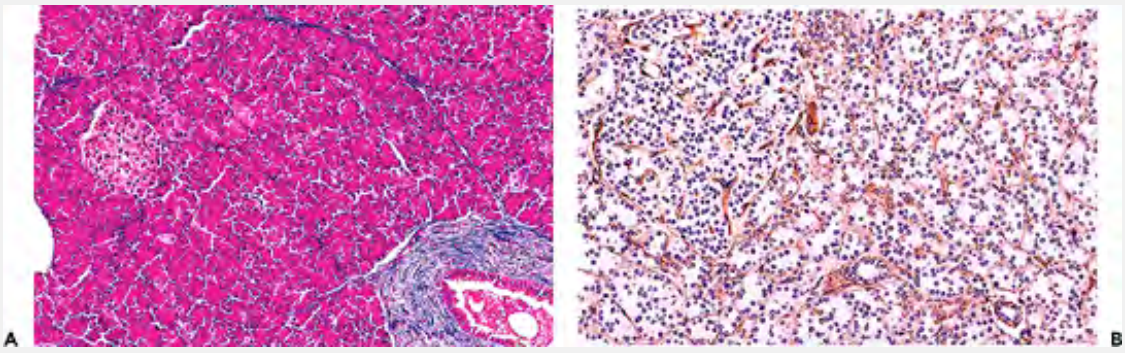

Figure 30.39 Connective tissues are minimal within the pancreas. A. Collagen is largely restricted to the tissues surrounding the interlobular ducts, with only thin bands extending into the lobules (trichrome). B. Immunohistochemical staining for type IV collagen shows that an extensive network of basement membranes surrounds each acinus and duct and accompanies the capillaries within the islets (*upper left*).

In almost every individual, there are some adipocytes within the pancreas. The proportion of the gland composed of fat varies from 3 to 20% (6). The amount of adipose tissue in the pancreas varies with the nutritional state and the age of the individual, older or overweight individuals having more intrapancreatic fat (123). The portions of the gland derived from the dorsal lobe may have more intraparenchymal fat than those from the ventral lobe (124,125).

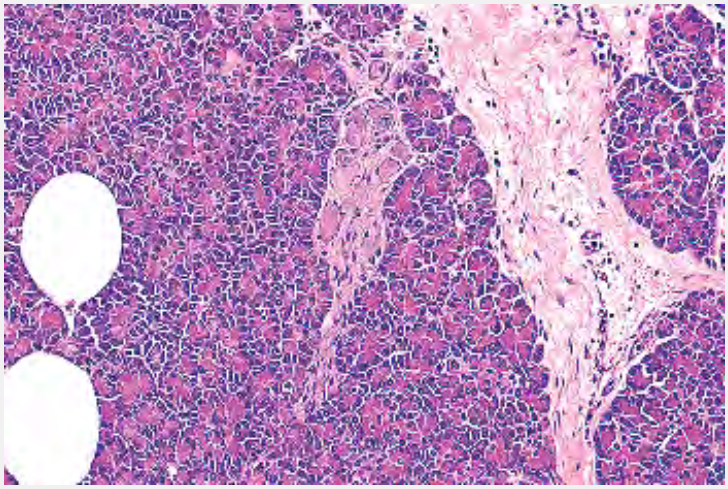

Figure 30.40 Small autonomic ganglia are located within lobules of acinar tissue.

Recently a population of vitamin Aâ€“storing fibroblast-like stromal

cell has been described (126). These pancreatic â€œstellate cellsâ€• are biologically and morphologically similar to hepatic stellate (or Ito) cells, and activation of these cells appears to play a major role in the production of extracellular matrix proteins during the development of fibrosis in chronic pancreatitis (126). Another recently described stromal cell type is the interstitial cell of Cajal. Pancreatic interstitial cells of Cajal have the same morphological and immunophenotypic properties as do those in the tubular gastrointestinal tract, including immunohistochemical labeling for CD117 (127).

Cytological Features

Normal pancreatic epithelial cells are commonly encountered in cytological preparations such as fine needle aspiration specimens. In aspirates of normal pancreas, acinar cells predominate over other elements. However, most fine needle aspirations are performed to diagnose solid or cystic neoplasms, and any nonneoplastic epithelium in these specimens usually originates from areas of chronic pancreatitis within or adjacent to the neoplasm, where acinar elements are atrophic and ducts remain. Thus, nondiagnostic aspirates of pancreatic adenocarcinoma often contain relatively few acini and moderate amounts of ductal epithelium. Atypia in this ductal epithelium can present a diagnostic pitfall.

Cytologically, acinar cells appear predominantly as cohesive, small grape-like clusters with scattered single cells and occasional stripped nuclei (Figure 30.41) (128,129). The round, regular nuclei are usually central to eccentric and have uniform chromatin and variably prominent or even conspicuous nucleoli. The polygonal cells have abundant granular cytoplasm that stains blue-green with the standard

Papanicolaou stain and purple with the Romanowsky's stain. The individual granules may be visible depending on the specific stain.

The Romanowsky's stain also reveals scattered small cytoplasmic vacuoles. The architectural arrangement of the cells is key to differentiating benign acinar cells from an acinar neoplasm, the latter generally forming large sheets and clusters as opposed to the small, uniform grapelike clusters of benign acini.

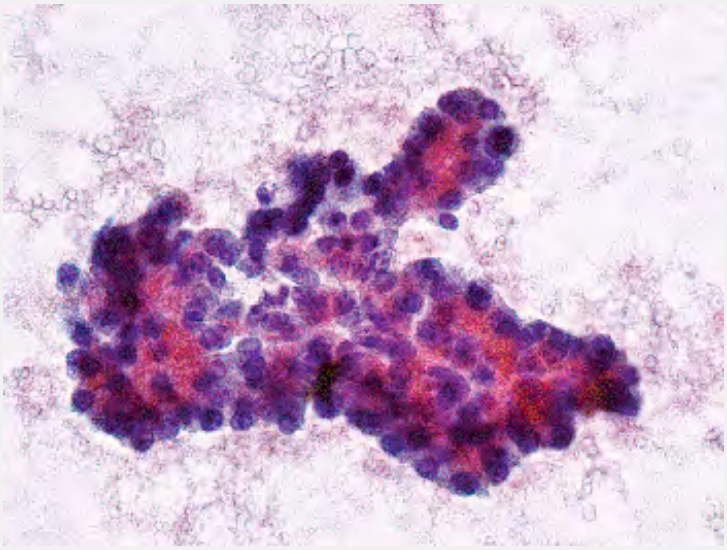

Figure 30.41 Cytology of normal acinar cells. There are grapelike clusters of cohesive cells with basal round nuclei having prominent nucleoli. The eosinophilic zymogen granules are apparent in the apical cytoplasm.

Normal ductal epithelium appears cytologically as large, flat cohesive sheets of epithelium containing round, uniform, evenly spaced nuclei that impart a honeycombed appearance (Figure 30.42) (128,129). The cytoplasm of these cells can best be seen when the epithelium is present in strips, yielding a â€œpicket fenceâ€• arrangement, or in sheets with a sharp luminal edge. Ductal cells have round to oval nuclei with even chromatin and generally small, inconspicuous nucleoli. The dense, nongranular and nonvacuolated cytoplasm stains aqua-blue with the Papanicolaou stain and more indigo-blue to purple

with the Romanowsky's stain. Features consistent with a nonneoplastic process on cytology include cohesion and nuclei with uniform size, shape, spacing, and chromatin pattern. Abundant mucinous cytoplasm may be seen in ductal cells with low-grade pancreatic intraepithelial neoplasia (see below), but mucinous ductal epithelium also raises the possibility of a mucinous cystic neoplasm, an intraductal papillary mucinous neoplasm, or even an infiltrating adenocarcinoma.

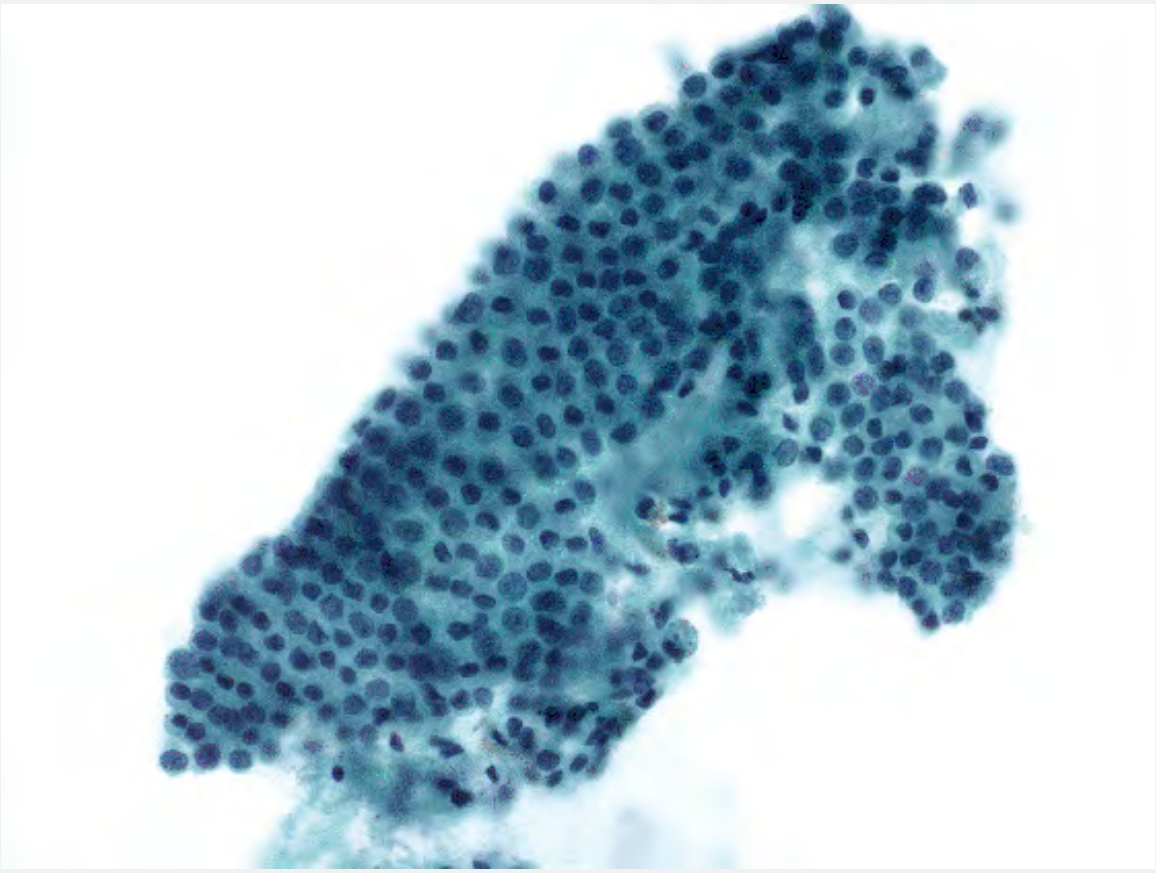

Figure 30.42 Cytology of normal ductal cells. There are sheets of evenly arranged cells with the characteristic honeycombed appearance. The nuclei are round and uniform.

Islet cells are rarely appreciable in aspirate smears. Islet cells are uniform and polygonal with round nuclei, coarsely clumped chromatin, inconspicuous nucleoli, and pale amphophilic cytoplasm.

Minor Alterations

A number of minor alterations may affect various components of the pancreas due to physiologic changes, response to injury, or aging. Some of these changes are so subtle that they may be overlooked, but others may be confused for a neoplastic process. Recognition of these potential diagnostic pitfalls is essential for the accurate interpretation of biopsies and is complicated by the fact that many of these alterations may accompany pancreatic neoplasms.

Acinar Cells

Acinar cell nodules are common incidental findings that consist of circumscribed clusters of acini showing cytoplasmic or nuclear differences from the surrounding acini (130,131). Alternative terms include atypical acinar cell nodule, focal acinar transformation, eosinophilic degeneration, and focal acinar cell dysplasia (13,55,132,133). The last term suggests the lesion may be preneoplastic, but there is no proof of neoplastic alterations in acinar cell nodules in humans, where they are found in nearly half of nontumorous pancreata (134). The lesions are more prevalent in adults, suggesting that they are acquired (132). Although sometimes larger, acinar cell nodules are often similar in size to compact islets, with which they may be confused.

Two types of acinar cell nodules exist (131). The more common is the eosinophilic type, which appears as an abnormally pale, eosinophilic cluster of acini (Figure 30.43A). At high power, the cells are larger than the adjacent normal acinar cells, and the deep basophilia of the basal cytoplasm is lacking. The cytoplasm also may be vacuolated. The nuclei appear normal or hyperchromatic. This

change is due to

dilatation of the RER (135) and may be a result of localized hypoxia or other degenerative phenomena. The other less common type of acinar cell nodule, the basophilic type, exhibits a loss of the eosinophilic zymogen granules from the apical cytoplasm, as well as an increased nucleus-to-cytoplasm ratio (Figure 30.43B). Nuclear enlargement, mild atypia, and prominent nucleoli also may be seen. The reason for such localized depletion of zymogen granules is unclear.

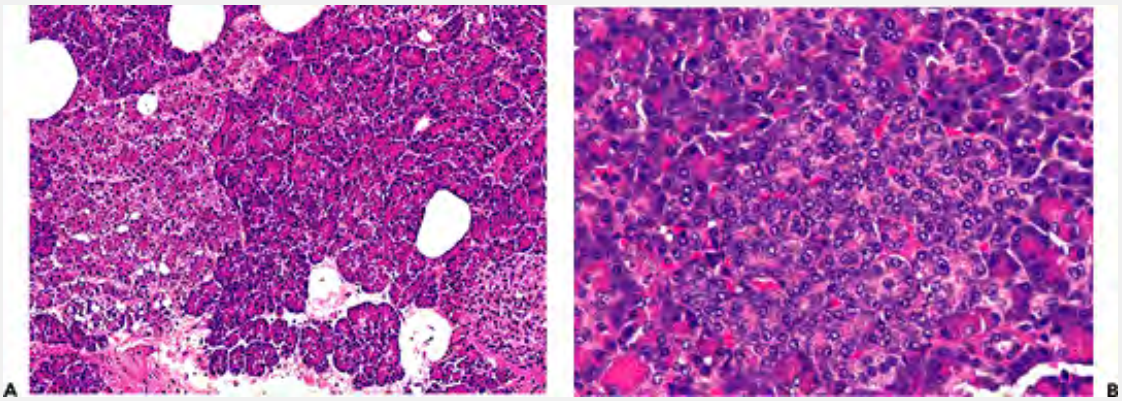

Figure 30.43 Atypical acinar cell nodules. A. The eosinophilic type is more common and consists of a collection of acini showing loss of basophilia in the basal cytoplasm and hyperchromasia of the nuclei. The eosinophilic granules within the apical cytoplasm are maintained. An islet of Langerhans, with which these lesions may be confused, is present at lower right. B. The basophilic type of atypical acinar cell nodule exhibits an increased nucleus to cytoplasm ratio with loss of eosinophilic granularity of the apical cytoplasm. Some degree of nuclear atypia is also present.

Acinar ectasia refers to the dilatation of acinar lumina that may occur during active secretion (1) or due to ductal obstruction (133). Acinar ectasia is also a relatively common finding at autopsy, where it is associated with premortem uremia, septicemia, and dehydration (13,136,137). Acinar ectasia often involves an entire lobular unit. The ectatic acini resemble small ductules, with flattened lining cells, but some of the cells are still recognizable as acinar cells that have lost most of their zymogen granules (Figure 30.44). Centroacinar cells also line the dilated lumina and may proliferate (137). The dilated lumina often contain retained eosinophilic secretions.

Metaplastic changes less commonly involve the acini than the ducts; they include replacement by mucinous cells or squamous cells (138). Proliferating centroacinar cells may appear to replace the acinar cells, especially in the presence of early atrophy (133). The possibility that acinar cells may transform into centroacinar or ductular cells (â€œacinar to ductal metaplasiaâ€•) has been suggested, especially in animal models of pancreatic neoplasia (139), but the occurrence of acinar to ductal metaplasia in humans is speculative (140).

Ductal Cells

Many metaplastic changes may affect the pancreatic ducts, including squamous, oncocytic, goblet cell (intestinal), and acinar metaplasia. However, the most common alteration in ductal cells, especially those of the medium-sized and large pancreatic ducts, is the replacement of the cuboidal, nonmucinous epithelium with tall columnar cells containing abundant luminal mucin that is easily appreciable on routinely stained slides (Figure 30.45A), resembling gastric foveolar or pyloric gland cells (141,142,143). For many years, this alteration was regarded as mucinous

metaplasia (or mucous cell hypertrophy, or pyloric gland metaplasia). The change is present in up to half of nontumorous pancreata

(13,16,133,142,144,145) and is usually more prevalent in the head of the gland (144). The ductal epithelium may remain flat, or there may be formation of micropapillae or true papillae with fibrovascular cores (Figure 30.45B). The lesion may involve a single ductal profile or may extend into clusters of ductules adjacent to larger ducts. The latter circumstance results in the appearance of collections of small back-to-back tubules of mucinous cells and has been termed adenomatous hyperplasia (141); it is particularly associated with areas of chronic pancreatitis (Figure 30.46). With the increasing knowledge of the molecular genetic events that occur in pancreatic ductal adenocarcinomas, it has become increasingly apparent over the past decade that these mucinous changes in the ductal epithelium share some of the genetic abnormalities of invasive carcinomas (such as activating mutations in codon 12 of the *KRAS* oncogene and telomere shortening (146,147,148,149,150,151)) and that they form the beginning of a spectrum of preinvasive neoplasia that also includes ductal lesions with increased degrees of cytoarchitectural atypia (141,142,145,152,153,154).

Thus, the lesions previously designated as mucinous metaplasia are now regarded to be the earliest stage of pancreatic intraepithelial neoplasia (or PanIN) and are termed PanIN-1 (155,156). Since not all mucinous ductal lesions have detectable oncogene mutations, it is possible that a histologically indistinguishable subset is not truly neoplastic; thus, an alternative designation is PanIN/L-1, the L referring to â€œlesionâ€•. The PanIN-1 lesions with flat epithelium are referred to as PanIN-1A; those with micropapillae or true papillae are referred to as PanIN-1B.

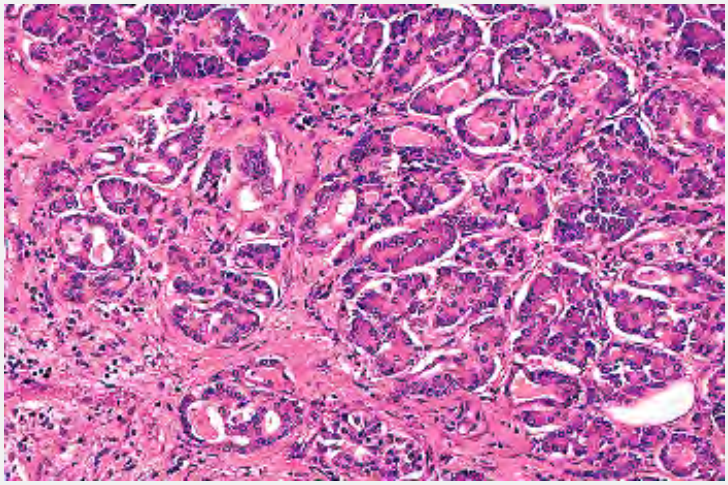

Figure 30.44 In acinar ectasia, the acinar lumina are dilated and filled with eosinophilic secretions. The lining cells have a flattened appearance, often resembling small ductules cells more than acinar cells.

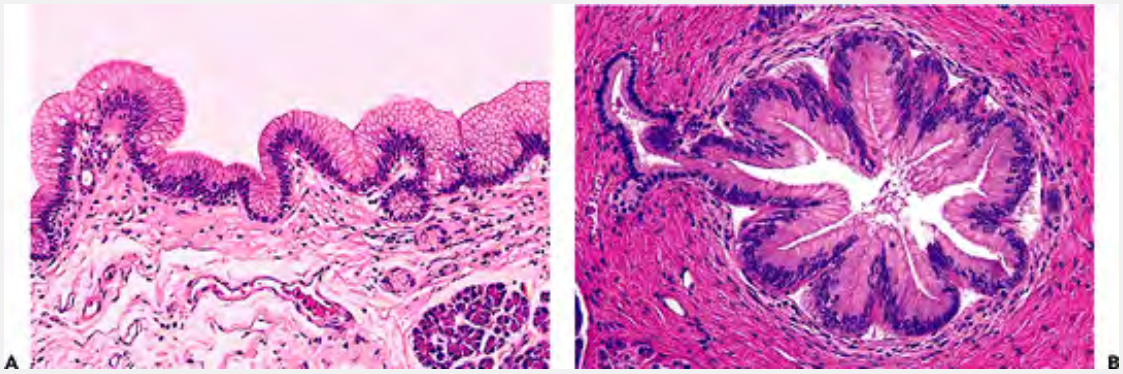

Figure 30.45 Pancreatic intraepithelial neoplasia (PanIN)-1. A. In PanIN-1A, the normal cuboidal to low columnar ductal epithelial cells are replaced by tall columnar cells containing abundant apical mucin. The nuclei remain basally located and show minimal pseudostratification. B. PanIN-1B has similar

cytological features but demonstrates papilla formation. Note the transition to normal ductal epithelium (*left*).

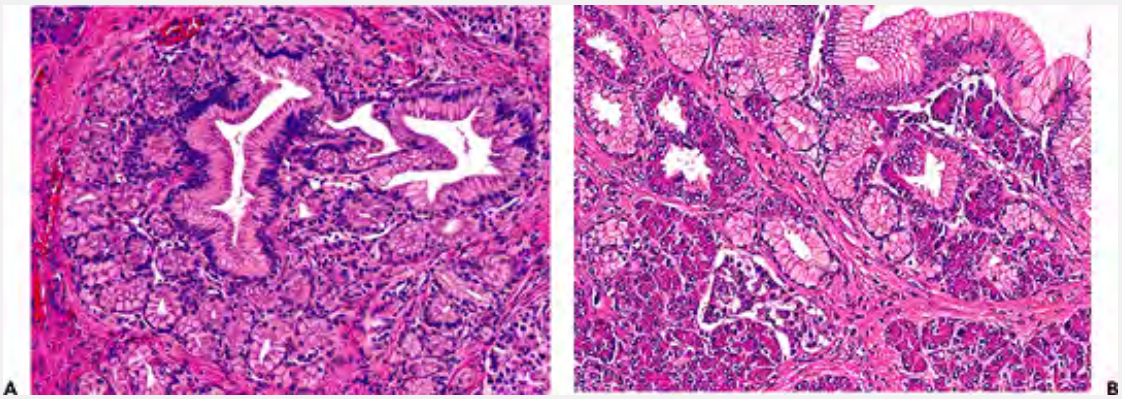

Figure 30.46 A. PanIN-1 may involve aggregates of small ductules around larger ducts, resulting in clusters of mucinous glands, a finding previously referred to as adenomatous hyperplasia (
Cubilla AL, Fitzgerald PJ. Morphological lesions associated with human primary invasive nonendocrine pancreas cancer. *Cancer Res* 1976;36 (pt 2):2690â€“2698.
). B. Because the smallest components of the ductal system are involved, cells with PanIN-1 may abut adjacent acinar cells.

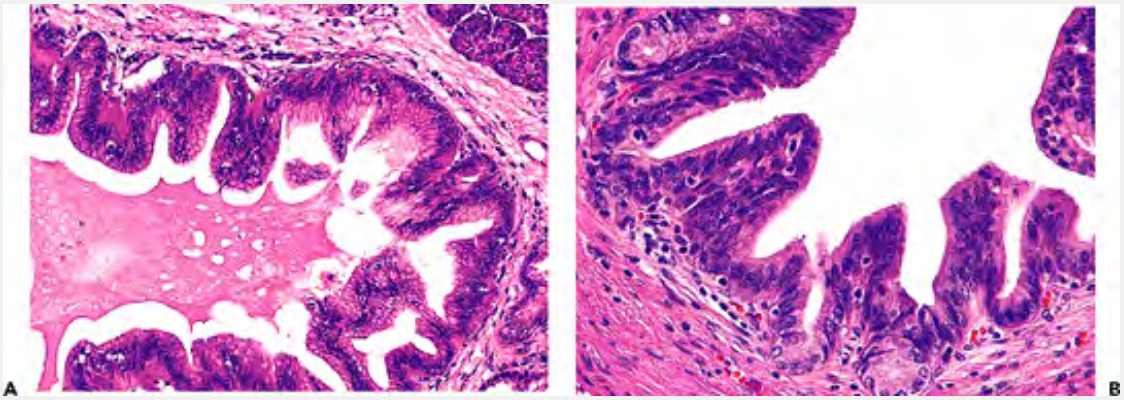

Figure 30.47 A. PanIN-2 is characterized by pseudostratified nuclei showing focal loss polarity. B. At higher power, the nuclei are enlarged, moderately atypical, and overlapping.

Ductal proliferative lesions with greater degrees of cytoarchitectural atypia are considered higher grades of PanIN. Most PanIN-2 lesions (previously designated as atypical hyperplasia or moderate dysplasia) are micropapillary, but some may be flat; PanIN-2 shows nuclear abnormalities, including early loss of polarity with full-thickness pseudostratification as well as nuclear crowding, enlargement, and hyperchromasia (Figure 30.47). Mitoses are found rarely and, when present, are basal and morphologically normal. The PanIN-3 lesions (previously designated carcinoma in situ or severe dysplasia) demonstrate more significant architectural and cytological atypia (Figure 30.48). These lesions are usually papillary or micropapillary, although rarely they may be flat. Cribriforming, budding off of clusters of cells into the lumen, and luminal necrosis may occur. Also, the nuclei show complete loss of polarity and are enlarged, hyperchromatic, and irregular. The nucleus-to-cytoplasm ratio is increased. Nucleoli can be prominent, and mitoses are usually identifiable, including atypical forms (155,156). Higher grade PanINs contain more of the mutations of invasive carcinomas, including

inactivating mutations in *p16/CDKN2A* (present at the PanIN2 stage), *SMAD4, TP53,* and *BRCA2* (all present in PanIN-3). Also, hypermethylation of the *ppENK*, *TSLC1,* and *p16* genes has been demonstrated in PanINs, the prevelance increasing from PanIN-1 through PanIN-3 (146,147,148,149,150,151). The proliferation rate, as measured by immunohistochemical staining for Ki-67, increases with increasing grades of PanIN (157).

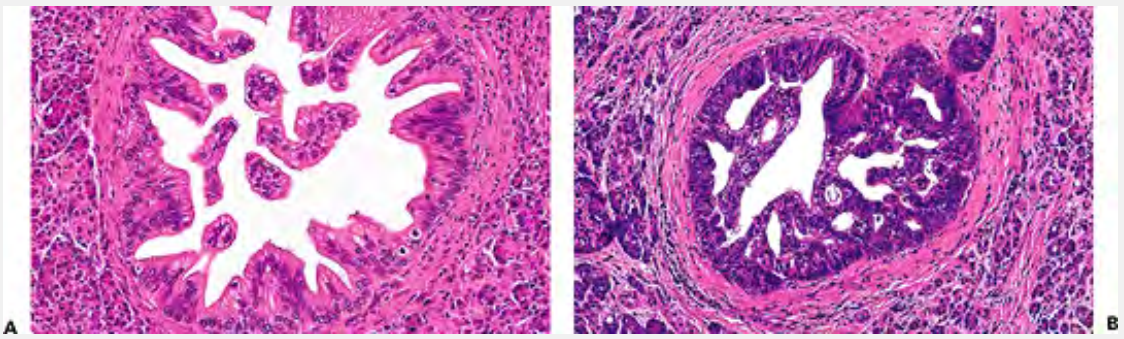

Figure 30.48 A. In PanIN-3, there is complete loss of polarity, with budding of disorganized cellular clusters into the ductal lumen. The nuclei are markedly irregular and vary in morphology between adjacent cells. Increased mitoses are present. B. In another focus, architectural abnormalities include cribriforming, and there is extreme nuclear atypia.

Multiple grades of PanIN tend to coexist within the same pancreas, with gradual transitions from one to the next. All grades of PanINs are associated with invasive ductal adenocarcinomas (92,141,142), and PanIN-3 is usually only found in pancreata also harboring an invasive ductal adenocarcinoma (141,142), although it can occur in a pancreas without invasive carcinoma. Along with the genetic data,

these observations support the concept that PanINs progress to carcinoma, but the frequency and time course of progression is unknown. The cells in foci of PanIN produce largely neutral mucins and sialomucins; sulfomucins are less abundant than in normal ductal cells (55). The histochemical and immunohistochemical profile of the mucins in these cells resembles that of the superficial gastric mucosa in some cases or of the pyloric glands in others (93,143). Because there is little morphologic difference between these two mucin-producing cells types, pyloric gland differentiation may not be distinguishable from gastric foveolar differentiation by routine microscopy. The morphological progression from PanIN-1 to PanIN-3 is also accompanied by increasingly abnormal expression of tumor-associated glycoproteins such as CEA, B72.3, and CA125 (92).

Up to one-third of pancreata exhibit squamous metaplasia (16,133,154). Although squamous metaplasia may occur in the larger interlobular and main ducts, it is most common in the intralobular and intercalated ducts, and metaplastic cells may extend into the center of the acini (Figure 30.49). It is exceptional for squamous metaplasia to exhibit keratinization or a granular cell layer, which occurs most commonly in the setting of advanced chronic pancreatitis (Figure 30.50). For this reason, the terms *multilayered metaplasia* and *transitional metaplasia* have been suggested for this lesion (133). Histologically, the stratified squamous epithelium appears immature, with only minimal flattening of the superficial layers. There may be retention of a luminal mucinous cell layer. In the smaller ducts and ductules, the metaplastic epithelium may fill the lumen, virtually obliterating it. In most instances, squamous metaplasia is associated with chronic pancreatitis; there is no known preneoplastic significance.

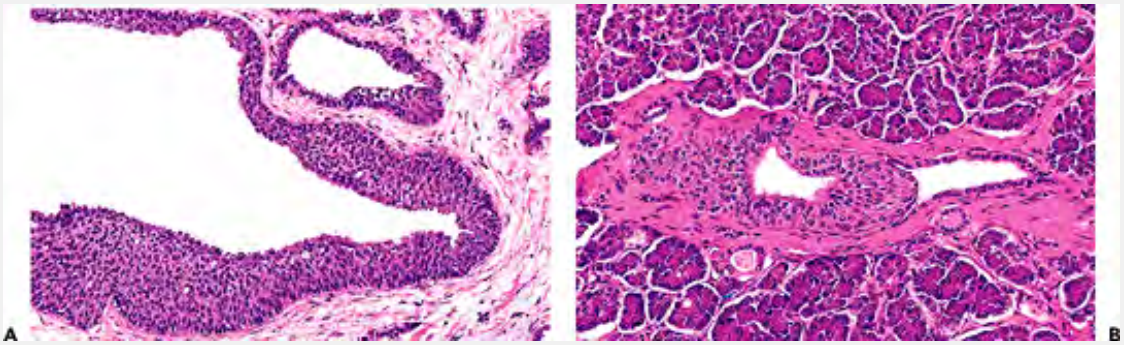

Figure 30.49 Squamous metaplasia of the ducts. A. There are multiple layers of immature-appearing squamous cells without keratinization. The process may involve larger ducts. B. In this example, there is partial involvement of a small interlobular duct.

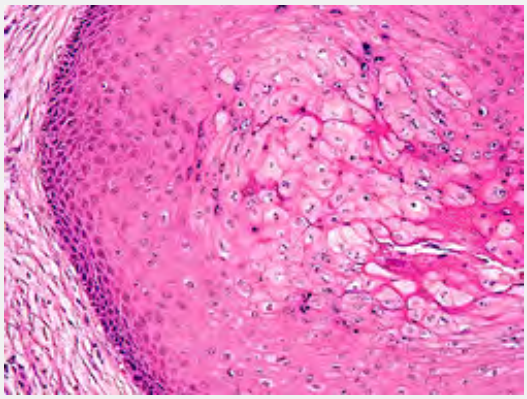

Figure 30.50 Squamous metaplasia of the ducts with keratinization, an uncommon finding.

Oncocytic changes are common in centroacinar cells, and oncocytic metaplasia may affect intercalated and intralobular ducts as well

(85,158,159). The oncocytic cells have abundant granular eosinophilic cytoplasm (reflecting the accumulation of mitochondria), and the nuclei may be

enlarged and contain prominent nucleoli (Figure 30.51). Involvement of clusters of small ductules may occur. Like mucinous and squamous metaplasia, oncocytic metaplasia may be associated with chronic inflammatory processes, or it may occur in the absence of other specific abnormalities (16,160). It has been suggested that oncocytic changes in the ducts may be a preneoplastic alteration (161), but molecular genetic abnormalities have yet to be identified in this lesion.

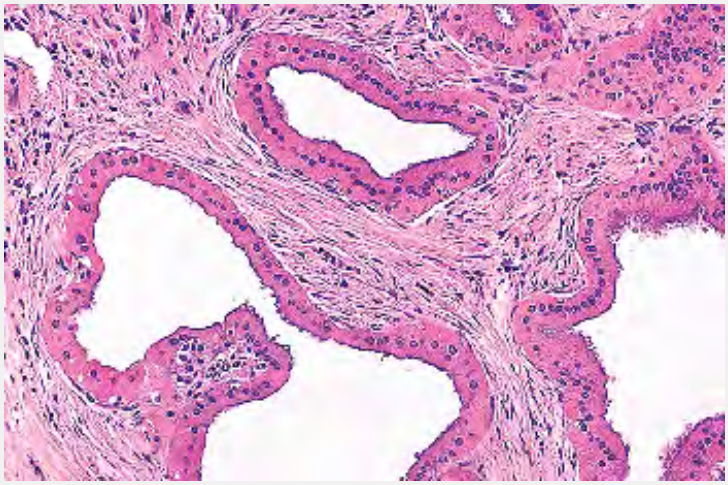

Figure 30.51 Oncocytic changes involving small ducts. In this example, there is associated fibrosing pancreatitis.

Goblet cells may be found within the ductal epithelium, especially in the main ducts near the ampulla of Vater (1,86). In addition, isolated goblet cells may appear in smaller ducts, presumably as a metaplastic change (Figure 30.52) (133,138). In contrast to PanIN-1, the mucin-containing goblet cells occur singly and are more flask-

shaped. Presumably they reflect an intestinal metaplastic phenotype rather than the gastric phenotype of PanIN. Replacement of the ductal epithelium with mucinous cells having all of the histologic and immunohistochemical features of intestinal epithelium has been described (161) but appears to be rare. True intestinal-type epithelium, with pseudostratified cells having elongate nuclei and expressing MUC2 and CDX2 by immunohistochemistry, is commonly found in intraductal papillary mucinous neoplasms (162,163), which may extend into smaller ducts, but this phenomenon is neoplastic and therefore not regarded as intestinal metaplasia of the ducts.

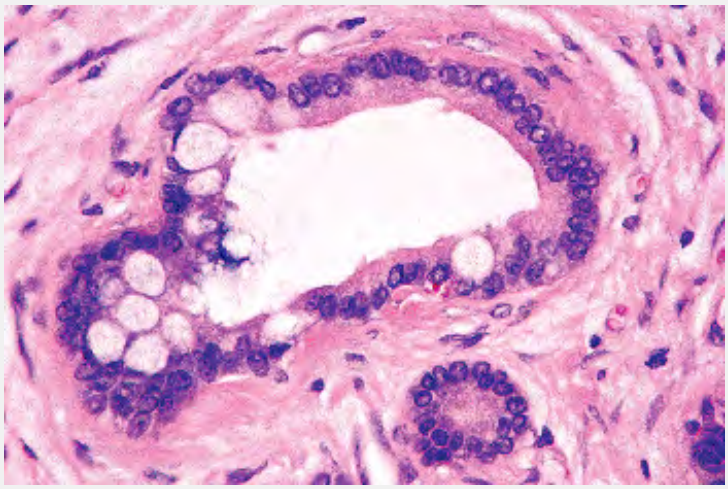

Figure 30.52 Goblet cell metaplasia involving a small duct. Flask-shaped goblet cells are distinct from the mucinous columnar cells of low grade PanIN.

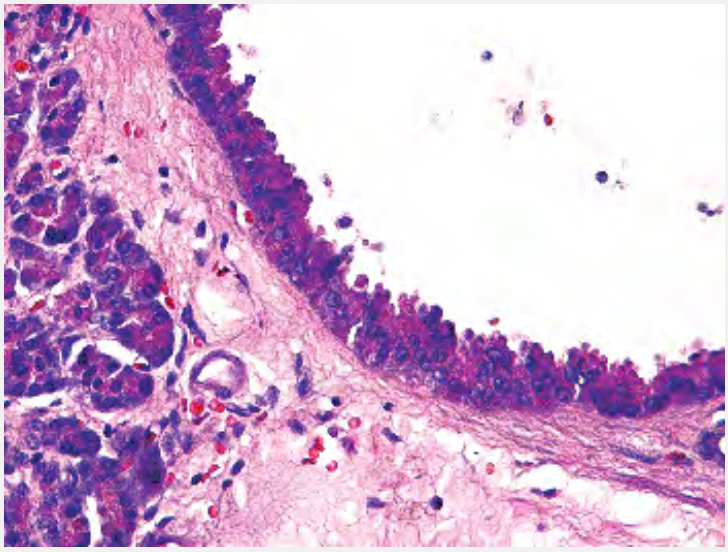

Figure 30.53 This small interlobular duct shows partial acinar metaplasia, with slightly enlarged acinar cells replacing the normal cuboidal ductal epithelium.

Sometimes small ducts may demonstrate partial or complete replacement by acinar cells. When this process is very localized, it has been referred to as acinar metaplasia. However, larger neoplasms composed of cystic spaces lined by benign acinar cells, designated as acinar cell cystadenomas, have also been described (164), and the distinction of microscopic examples of this neoplasm (which represent a significant proportion of the reported cases) from acinar metaplasia is somewhat arbitrary. In acinar metaplasia the acinar cells occur singly or in clusters within the ducts, and they exhibit the same appearance as their normally situated counterparts (Figure 30.53). Immunohistochemical labeling for trypsin or chymotrypsin facilitates identification of acinar metaplasia, although the granular apical cytoplasmic staining of true acinar cells must be distinguished from the labeling of deposited intraluminal enzyme secretions on the surface of ductal cells (Figure 30.13).

Another frequent alteration of the ducts is ectasia. Ectatic ducts are generally (but not invariably) found in association with chronic pancreatitis in older patients (13,16,165), often due to ductal obstruction. The ectatic ducts range up to several millimeters in size and occasionally are recognizable grossly. Dilatation of the main pancreatic duct to more than 4 mm is found in 16% of patients at autopsy (13). Because ectatic ducts are often tortuous and the dilatation may be localized, they may appear as single or multiple small cysts (retention cysts) in cross section (Figure 30.54A). Careful study of serial sections shows the

continuity with the ductal system. Retention cysts are usually grossly evident and may reach several centimeters in diameter. The lining epithelium may harbor PanIN, usually PanIN-1 but sometimes higher grade lesions as well (Figure 30.54B). Retention cysts with PanIN may be difficult to distinguish from intraductal papillary mucinous neoplasms (IPMNs) (166,167,168,169,170), and attempts have been made to reach a consensus on diagnostic criteria (156). In general, multicystic lesions with micropapillae or true papillae are regarded as IPMNs, whereas solitary cysts with flat epithelium represent retention cysts with PanIN.

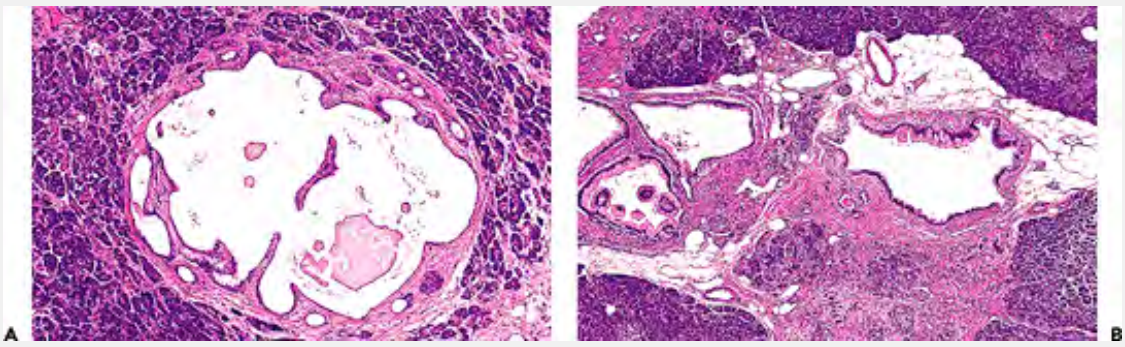

Figure 30.54 Duct ectasia. The dilated ducts may be lined by a

flattened cuboidal epithelium resembling normal ductal epithelium (A), or there may be involvement by PanIN (B). In the latter circumstance, the lesion merges morphologically with intraductal papillary-mucinous neoplasm.

Islet Cells

Islet hyperplasia is defined as an absolute increase in the size or number of islets relative to the normal islet volume at a given age. Individual compact islets larger than 250 Âµm in diameter are regarded to be hyperplastic (171). However, making an assessment that there is an increase in the total volume of islet tissue in the pancreas is difficult. There are a number of conditions, most associated with pancreatic atrophy, that can result in the appearance of increased numbers of islets when in fact the islet volume is not increased but rather the volume of exocrine elements has decreased (see below). Plus, the density of islets varies in different regions of the pancreas. Thus, some objective assessment of islet volume must be made for a diagnosis of islet hyperplasia, rather than just a casual observation of â€œnumerousâ€• islets. Conditions associated with islet hyperplasia in infancy include Beckwith-Wiedemann syndrome, maternal diabetes, erythroblastosis fetalis, and hyperinsulinemic hypoglycemia (55); cases have also been described in adults with hyperinsulinism (172). Islet hyperplasia may occur either by proliferation of islet cells or by neoformation of islet cells from uncommitted progenitors (42). The distribution of the different peptide cell types is usually maintained, although there may be a relative increase in the number of Î² cells, some of which may show hypertrophy.

Nesidioblastosis is a descriptor of the morphologic findings accompanying functional disorders of Î² cells associated with hyperinsulinemic hypoglycemia in the absence of an insulinoma (173,174,175,176). This condition generally occurs in neonates and

infants, where it is known as persistent neonatal hyperinsulinemic hypoglycemia (PNHH); a similar condition occurs rarely in adults. Morphologic abnormalities include hypertrophic Î² cells within the islets; close association of islet cells with small pancreatic ducts (ductuloinsular complexes), particularly in neonates; and abnormal aggregation of islets. Both focal and diffuse types are described (173). In focal nesidioblastosis, there is a localized nodular lesion that may resemble an insulinoma, but more often there is simply an aggregate of ill-formed isletlike clusters associated with small ductules (Figure 30.55).

Some of the nuclei within the lesion are enlarged. The islets in the remaining pancreas are normal. The diffuse form of nesidioblastosis shows islet abnormalities throughout the gland without discrete localized aggregation of islets. The principal finding is the presence of enlarged, hyperchromatic Î²-cell nuclei. The size of nuclei in Î² cells varies somewhat in normal neonates; but, in nesidioblastosis, there is a 40% increase in nuclear volume compared with age-matched controls. By immunohistochemistry, the islets in both focal and diffuse types of nesidioblastosis retain their normal complements of peptide cell types. Genetically, PNHH is associated with a number of different mutations in genes such as *ABCC8* and *KCNJ11* that encode the ATP-sensitive potassium channel (K_{ATP}) in the cell membrane of Î² cells, demonstrating that this disorder clearly has a functional basis and does not simply reflect an increase in Î²-cell mass (177,178,179,180).

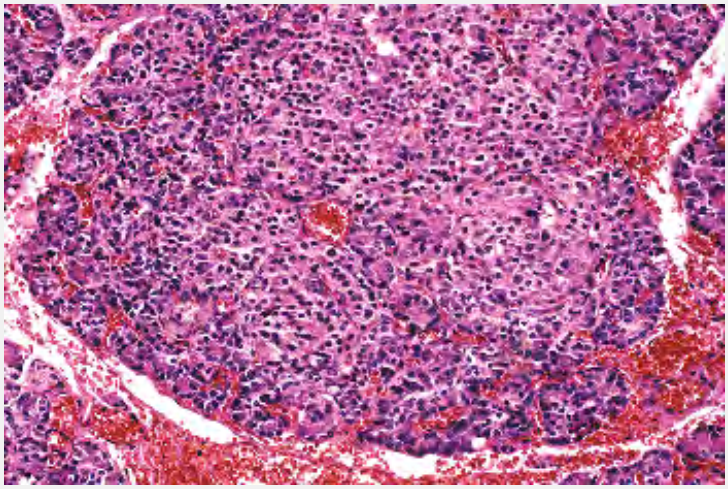

Figure 30.55 The pancreas from an infant with persistent neonatal hyperinsulinemic hypoglycemia shows the focal form of nesidioblastosis. There is localized aggregation of islets separated by thin bands of acini.

The apparent increase in number of islets that occurs secondary to exocrine atrophy has been termed islet aggregation and is not a result of hyperplasia. With the progressive atrophy that occurs in chronic pancreatitis, eventually most of the acini and many of the ducts disappear, leaving only residual islets embedded in fibrous or adipose tissue (Figure 30.56) (140). This phenomenon may be widespread in patients with significant chronic pancreatitis, or it may only involve one lobule of the gland. In addition to the clustering of islets, some degree of islet cell proliferation may occur (181); however, islet aggregation should be distinguished from true islet cell hyperplasia. The clustering of islets in regions of severe atrophy may resemble a solid tumorlike process with a nesting pattern, reminiscent of a pancreatic endocrine neoplasm (Figure 30.57). Individual islets may be found in the peripancreatic adipose tissue. The appearance of infiltrative growth is even more marked when the process involves the regions of the head of the pancreas containing

the diffuse islets; these islets lack the insular arrangement of the compact islets from the tail, appearing as small clusters, trabeculae, and individual cells when the exocrine elements undergo atrophy (Figure 30.58). In contrast to most pancreatic endocrine neoplasms, the border of foci of islet aggregation is ill defined. The surrounding pancreas often exhibits areas of pancreatitis that are less advanced, with incomplete acinar atrophy. In problematic cases, immunohistochemical labeling for the specific peptides may be helpful. In islet aggregation, the normal peptide cell types are present, in roughly normal numbers and distribution, although the relative proportions of Î± and PP cells may be increased (106,181). Although more than one peptide may be expressed in endocrine neoplasms,

it is exceptional for all of the normal peptides to be found in normal numbers, and there may be expression of peptides not found in normal islets (vasoactive intestinal polypeptide or gastrin). Bear in mind that the diffuse islets have a different normal peptide cell constitution (abundance of PP cells) from that of the compact islets (Figure 30.59). Another pseudoneoplastic property of islet cells in chronic pancreatitis is perineural invasion (Figure 30.60). Small clusters of islet cells may surround nerves, simulating the perineural invasion that is so common in pancreatic ductal adenocarcinoma. Fortunately, benign glands only exceptionally rarely exhibit perineural invasion. Immunohistochemical labeling for chromogranin may be used to distinguish benign perineural invasion by islet cells from adenocarcinoma.

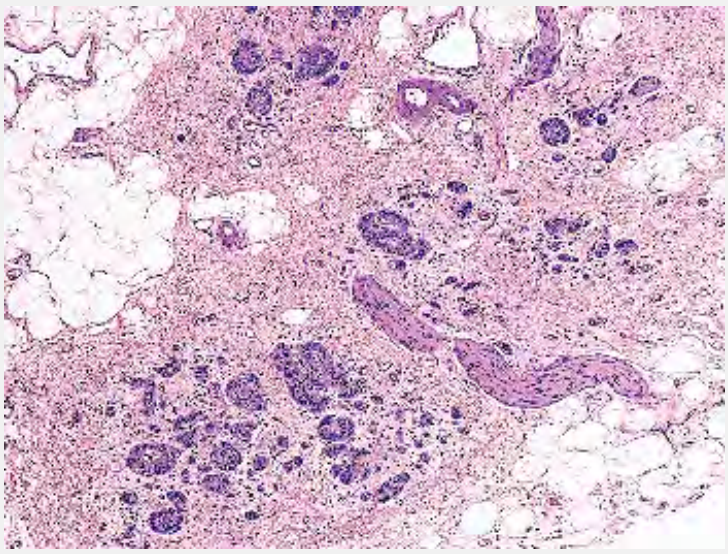

Figure 30.56 Islet aggregation involving compact islets. With extreme atrophy, there is complete loss of exocrine elements, leaving the clustered islets embedded in fibrous stroma.

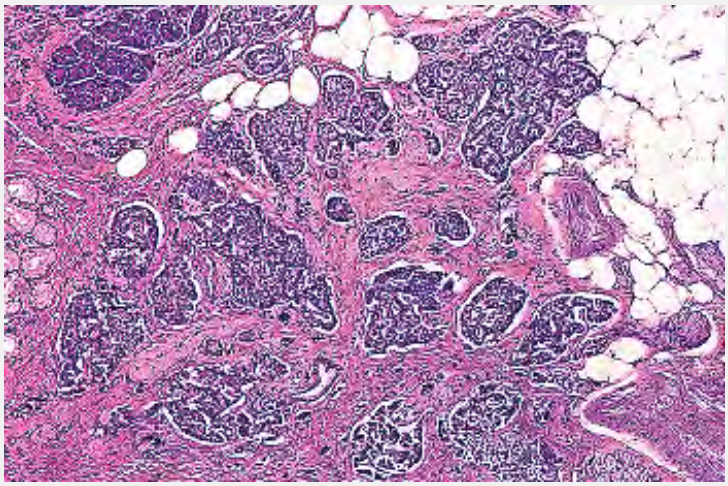

Figure 30.57 When advanced atrophy of exocrine elements occurs, aggregation of the remaining endocrine elements may simulate a neoplasm. The nests of cells may be poorly

circumscribed and separated by bands of fibrous tissue, with extension into peripancreatic adipose tissue.

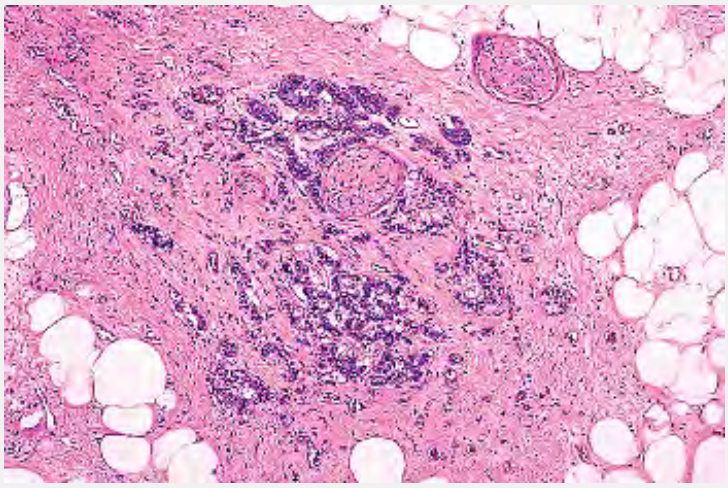

Figure 30.58 Exocrine atrophy in areas containing diffuse-type islets results in a pseudoinfiltrative pattern of individual cells and trabeculae.

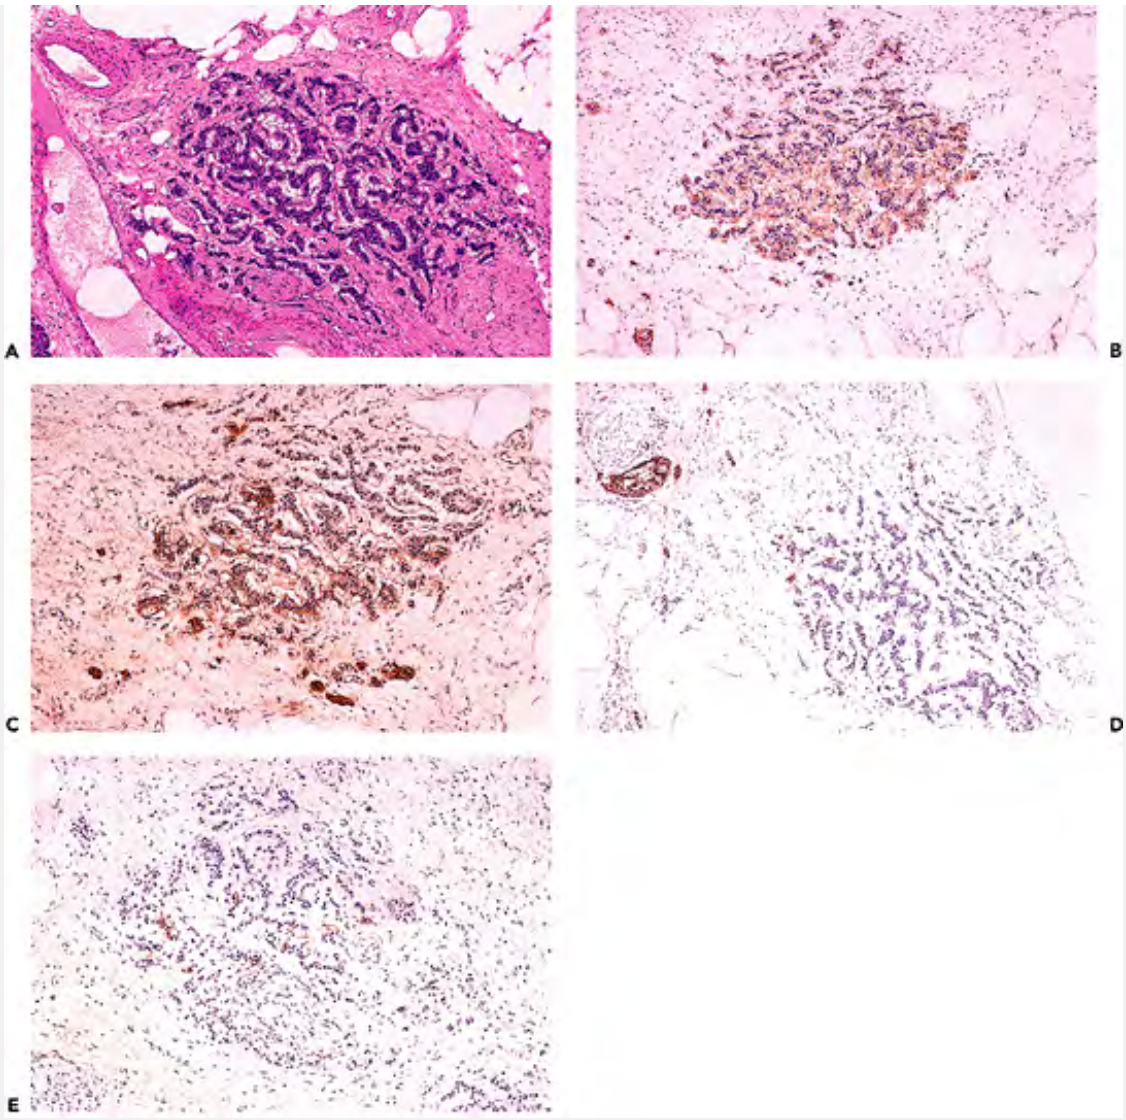

Figure 30.59 Immunohistochemistry may be helpful for distinguishing foci of islet aggregation from an endocrine neoplasm. In this focus (A) with a trabecular and infiltrative pattern, there is an abundance of PP cells (B) and Î² cells (C), with smaller numbers of Î± (D) and Î´ (E) cells, a composition typical of nonneoplastic diffuse type islets.

The appearance of dilated blood-filled spaces within the islets (Figure 30.61) has been referred to as peliosis insulis. Although reported in

a pancreas from a patient with

multiple endocrine neoplasia-I (MEN-I) and harboring multiple pancreatic endocrine neoplasms (182), peliosis insulis usually occurs in otherwise normal pancreata. It is of unclear etiology and significance. The blood-filled spaces are not observed to be lined by endothelium ultrastructurally.

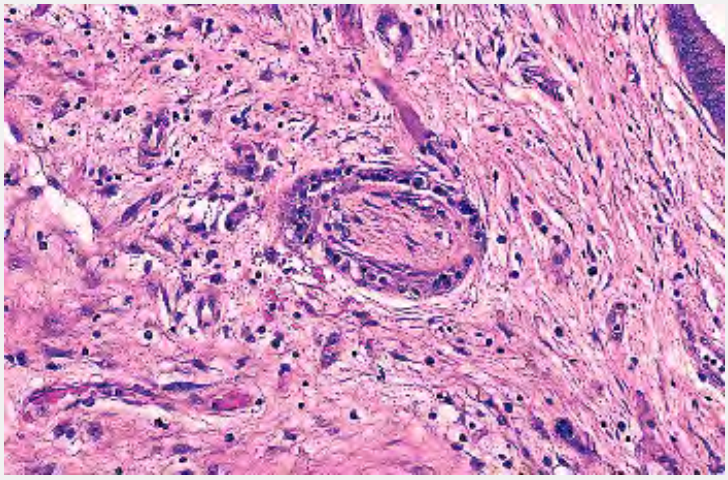

Figure 30.60 Perineural invasion by islet cells in chronic pancreatitis may simulate carcinoma.

Perivascular deposition of amyloid or amyloid-like material may be seen in islets of older individuals (Figure 30.62), especially in association with nonâ€“insulin-dependent (type II) diabetes mellitus (183). Insular amyloid is biochemically different from systemic amyloid, and there is no association between insular amyloidosis and systemic amyloidosis. In insular amyloidosis, the hyalinized stroma is limited to the islets. In patients with generalized fibrosis of the pancreatic parenchyma due to chronic pancreatitis or other causes, the islets also may be involved (insular fibrosis); however, the hyalinized stroma in these cases has no ultrastructural features of

amyloid (183).

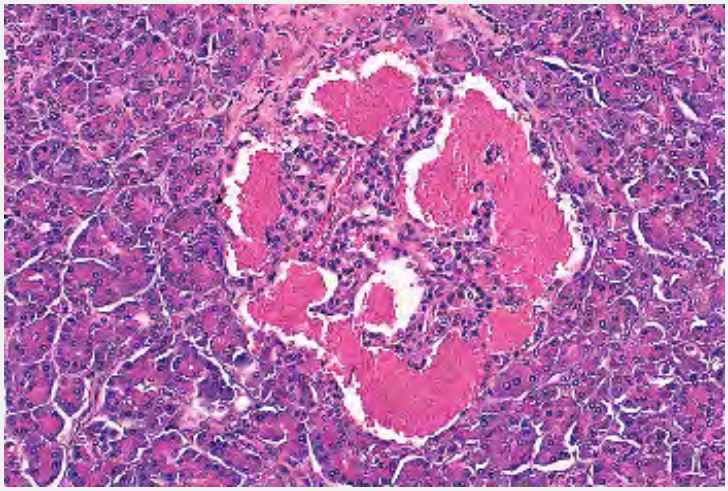

Figure 30.61 The appearance of dilated, blood-filled spaces within the islets has been called peliosis insulis. It is probably of no clinical significance.

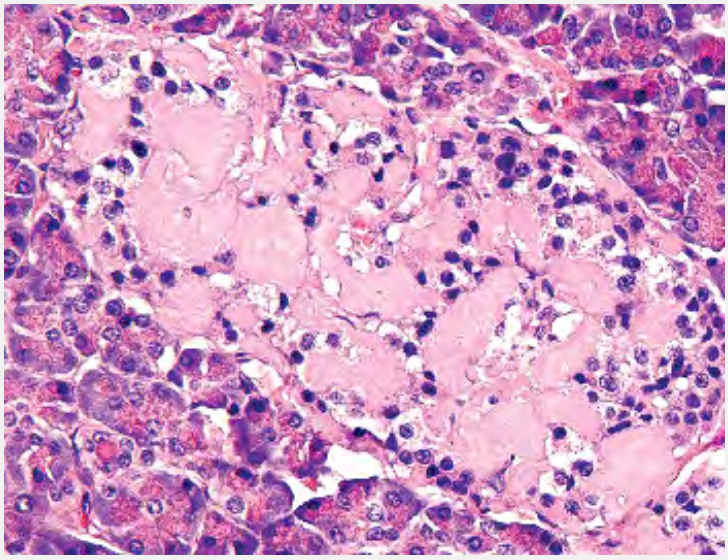

Figure 30.62 Amyloid-like hyalinization of the perivascular

tissue may be seen in the islets, especially in older patients with type II diabetes. The surrounding acinar tissue is not fibrotic.

Chronic Pancreatitis, Atrophy, and Fibrosis

Several different types of chronic pancreatitis exist, with etiologies including chronic alcoholism, ductal obstruction, autoimmune disorders, malnutrition, and genetic predisposition (184,185,186,187,188,189,190). Although the distribution of the disease within the pancreas varies with the different types, the histologic features of most types (except for autoimmune pancreatitis) are similar, especially at the end stages when fibrosis and atrophy are prominent (16). In fact, microscopic foci of fibrosis and atrophy (histologic chronic pancreatitis) are common incidental findings in pancreatic resection specimens or at autopsy, and the pathologic findings often reported as â€œfocal chronic pancreatitisâ€• are only loosely related to the clinical disease of chronic pancreatitis.

When chronic pancreatitis is localized, it may mimic pancreatic carcinoma clinically, radiographically, and grossly, and the resultant histological patterns also frequently simulate neoplasia. Early in the process, the fibrosis is largely around the periphery of the lobules, there is minimal acinar atrophy, and chronic inflammatory cells are evident (Figure 30.63A). The glands may be enlarged. However, as chronic pancreatitis progresses, the fibrosis involves the entire lobule, with marked distortion of the architecture. There is progressive exocrine atrophy, with eventual complete loss of acinar elements. The ducts become ectatic and irregularly shaped (Figure 30.63B). Ultimately, even the ducts are lost, leaving only the islets. In experimental pancreatitis induced by duct ligation, acinar atrophy occurs by necrosis and apoptosis (191,192), resulting in closely

packed lobules of ductular structures. Small ductules and islets remaining after acinar atrophy become encircled and distorted by the fibrous tissue (Figure 30.63C),

often acquiring a pseudoinfiltrative appearance. Ductuloinsular complexes may be found (Figure 30.64). As the gland is replaced by fibrous tissue, it decreases in size and acquires a woody consistency. Inflammatory cells are sparse at this stage and may be aggregated around small nerves (133). Duct ectasia, calcification, and intraductal calculi may occur (193), especially in pancreatitis of alcoholic etiology. The ducts may show PanIN, although the presence of intraepithelial neoplasia is not necessarily related to the chronic pancreatitis (142); and, other than the congenital type, chronic pancreatitis per se is only associated with a small increased risk for pancreatic cancer (194). It is possible that the chronic pancreatitis commonly accompanying ductal adenocarcinoma is secondary to ductal obstruction by the tumor rather than representing a preexisting condition.

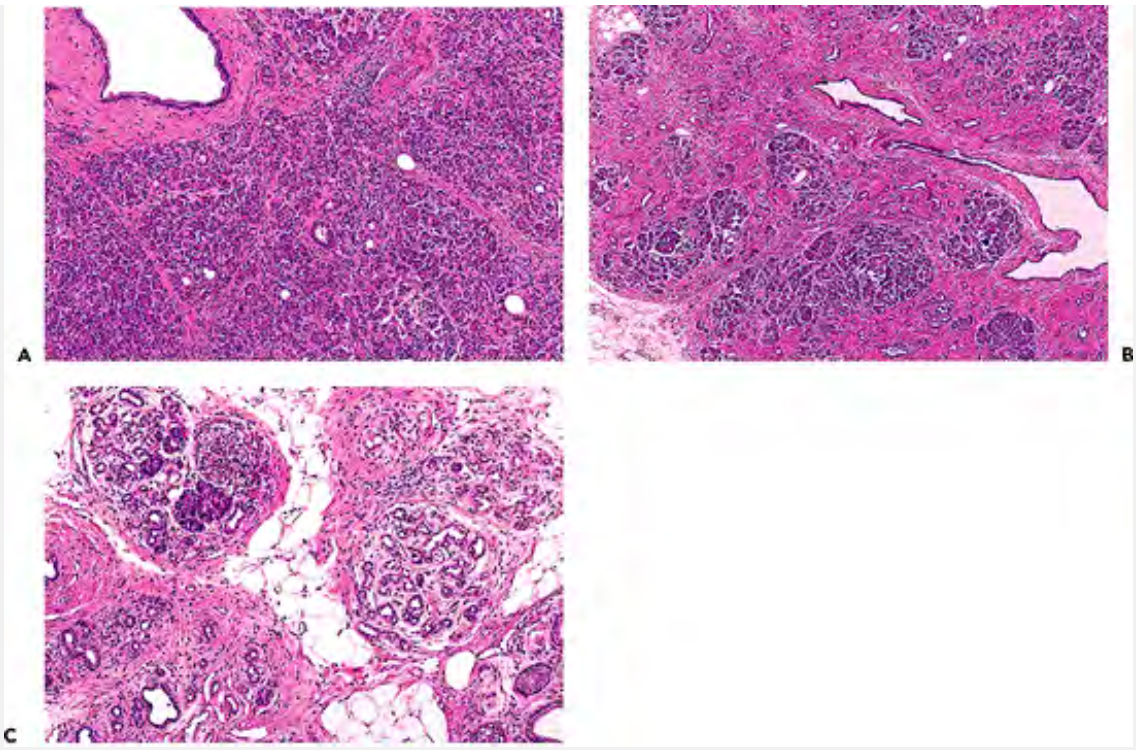

Figure 30.63 Progressive changes in chronic pancreatitis. A. In the early stages, the fibrosis is largely limited to the periductal and septal areas of the gland. The lobules show prominence of ductules. There are scattered aggregates of chronic inflammatory cells. B. As the pancreatitis progresses, the amount of fibrosis is increased, entrapping small lobules of residual acinar tissue. The ducts are ectatic. C. In the terminal stages, most of the acinar tissue is atrophic, leaving lobular aggregates of small ductules and islets within a fibrotic and fatty stroma.

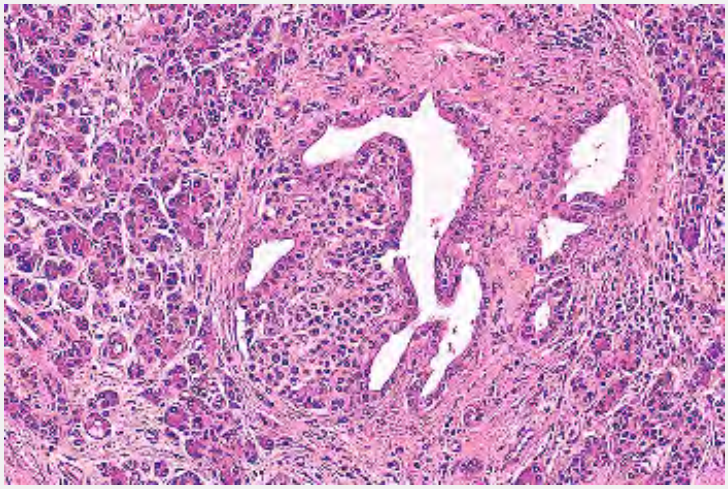

Figure 30.64 A ductuloinsular complex in an adult with mild chronic pancreatitis. Small ductules are surrounded by nests of endocrine cells, a finding that does not necessarily reflect true islet cell hyperplasia.

The distinction of chronic pancreatitis from infiltrating ductal adenocarcinoma on the basis of biopsies can be very challenging. The distorted ducts and ductules in areas of fibrosis closely resemble the pattern of ductal adenocarcinoma, and the fibrotic stroma may simulate the desmoplastic stroma often accompanying carcinoma. Features that support the interpretation of chronic pancreatitis include a retention of the lobular arrangement of the small collections of ductules, normal location of the glands, and uniformity of nuclear morphology from one cell to the next (Figures 30.65Aâ€“C). Features that conversely favor the diagnosis of carcinoma include haphazardly arranged individual angulated glands infiltrating the

stroma, glands in abnormal locations [adjacent to muscular arteries (122), in the perineurium, within vessels, or immediately apposed to

adipocytes], significant cytological abnormalities (variation in shape and size of nuclei from one cell to the next, macronucleoli, loss of nuclear polarity), and individual cells or small cell clusters in the stroma (Figures 30.65Dâ€“F, 30.66). It is helpful when two cytologically distinct populations of cells are found in the biopsy, since some of nuclear features of well-differentiated carcinomas are very subtle unless compared with a second population of clearly benign glands. Unfortunately, biopsy samples of the pancreas are frequently small, and it is uncommon for all of the characteristic features to be present. Even if carcinoma is present, it may only be represented by two or three glands. Furthermore, needle biopsy samples are sometimes subjected to frozen section examination, which may introduce artifacts complicating the interpretation. Even for the experienced observer, there may be cases having rare atypical glands that cannot be confidently diagnosed as benign or malignant. Performance of serial sections sometimes reveals additional diagnostic features. Immunohistochemistry also can be useful to document some of the abnormalities characteristic of carcinoma. Most benign glands do not express CEA, B72.3, CA125, or p53 at immunohistochemically detectable levels (92), and they will all show normal intact labeling for the Dpc4 protein. By contrast, most pancreatic cancers express CEA, 75% label for B72.3, 50 to 75% for p53, 45% for CA125, and 55% show complete loss of Dpc4 expression (Figure 30.67) (195). Expression of mesothelin also supports a diagnosis of carcinoma (196).

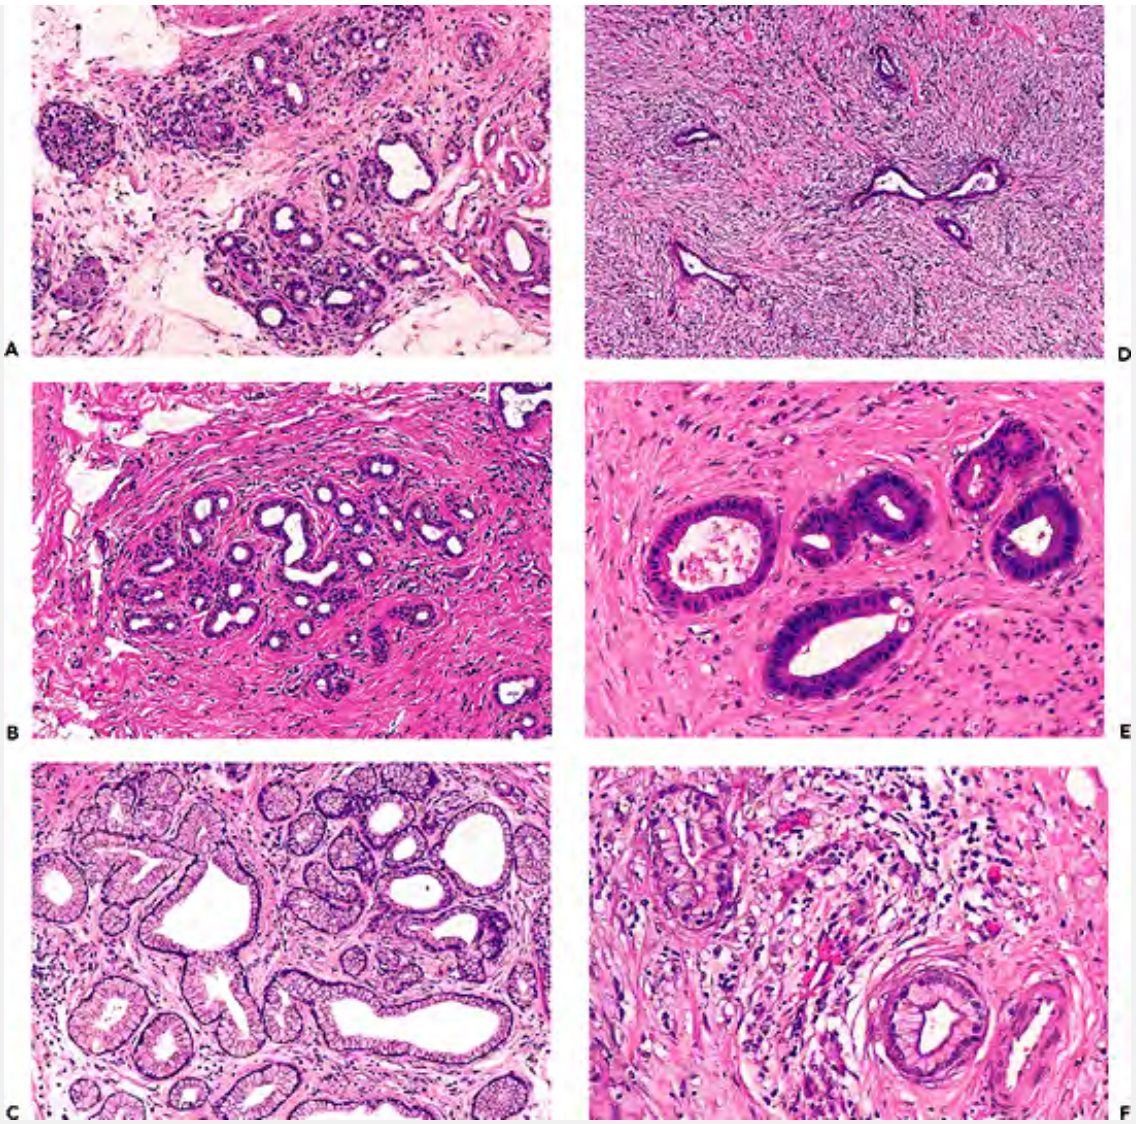

Figure 30.65 Comparison of ductules in atrophic chronic pancreatitis with well-differentiated ductal adenocarcinoma. A. In chronic pancreatitis, there is preservation of the lobular arrangement of small ductules, with larger branching ductules surrounded by collections of smaller tubular glands. Some residual islets of Langerhans are also present. B. At higher power, the cells are generally uniform, with round nuclei having a similar cytologic appearance from cell to cell. C. In areas showing mucinous metaplasia, there may not be as obvious a lobular arrangement. However, the glands retain a benign

cytologic appearance and have uniformly basally oriented nuclei. D. In infiltrating adenocarcinoma, the lobular arrangement of the glands is lost. There is a haphazard configuration of angulated glands within a desmoplastic stroma. E. In some instances, there may not be significant stromal desmoplasia, and the glands may retain rounded contours. However, there is variability in cytologic appearance from one cell to the next, with occasional macronucleoli, loss of polarity, and mitotic figures. F. Some individual glands of infiltrating carcinoma may be almost impossible to distinguish from benign ductules. This remarkably well-differentiated gland (*lower right*) contrasts with an adjacent gland showing marked loss of nuclear polarity. The abnormal location of the gland adjacent to a muscular artery is another clue that it is malignant.

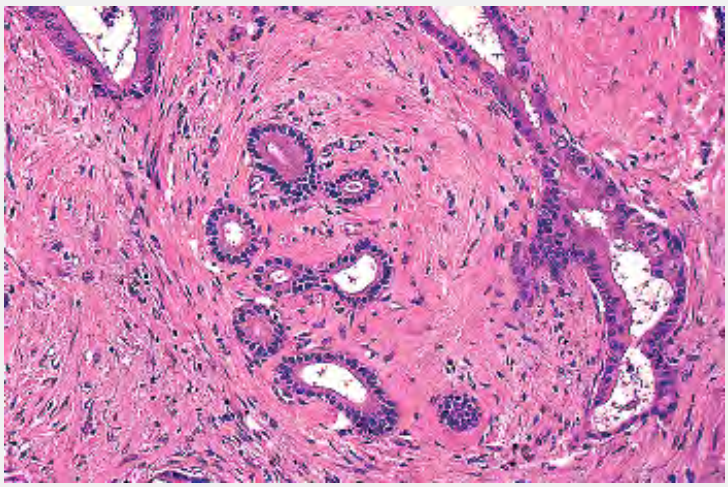

Figure 30.66 It is helpful to identify two populations of cells in specimens harboring an infiltrating adenocarcinoma. In this example, a lobular collection of benign ductules contrasts with irregularly shaped glands of adenocarcinoma.

Atrophy of pancreatic parenchyma due to long-standing ductal obstruction is often associated with infiltration by adipose tissue. Only rare islets may be found between lobules of fat in extreme cases (Figure 30.68). A primary form of fatty infiltration is Shwachman syndrome, an extremely rare autosomal recessive syndrome affecting the pancreas, bone marrow, and skeleton (197). An enlarged gland may result, but the amount of parenchymal tissue is reduced and exocrine insufficiency is present (16). The term *lipomatosis* has been applied to pancreata containing more than 25% adipose tissue (Figure 30.69). The distribution of the adipose tissue is generally not uniform. Lipomatosis is usually associated with parenchymal atrophy and is more common in older individuals (13). Other associations include adult-onset diabetes and generalized atherosclerosis, conditions that are also more prevalent in the elderly. Pancreatic lipomatosis is not associated with generalized obesity (13).

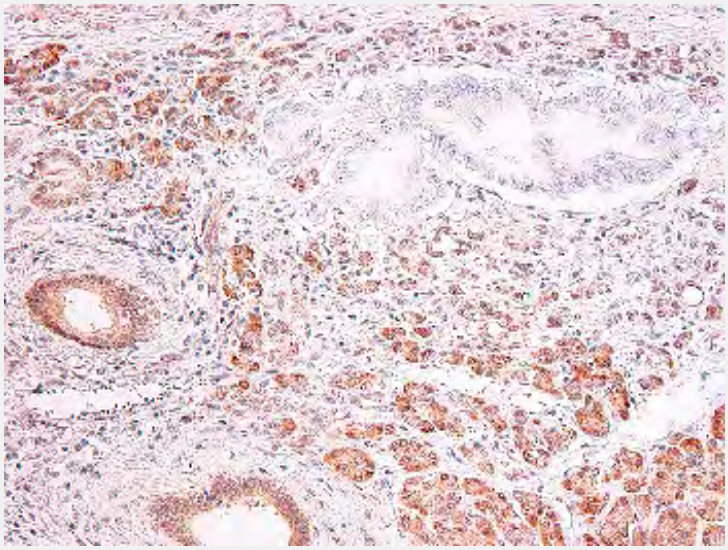

Figure 30.67 Immunohistochemisty for Dpc4 shows both nuclear and cytoplasmic labeling in normal acini and ducts, whereas the invasive carcinoma has complete absence of labeling.

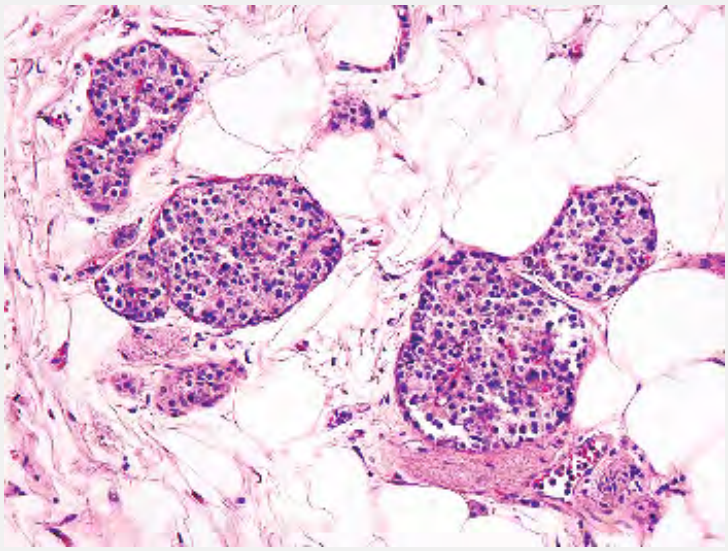

Figure 30.68 With extreme atrophy, the residual islets of Langerhans may be completely surrounded by adipose tissue.

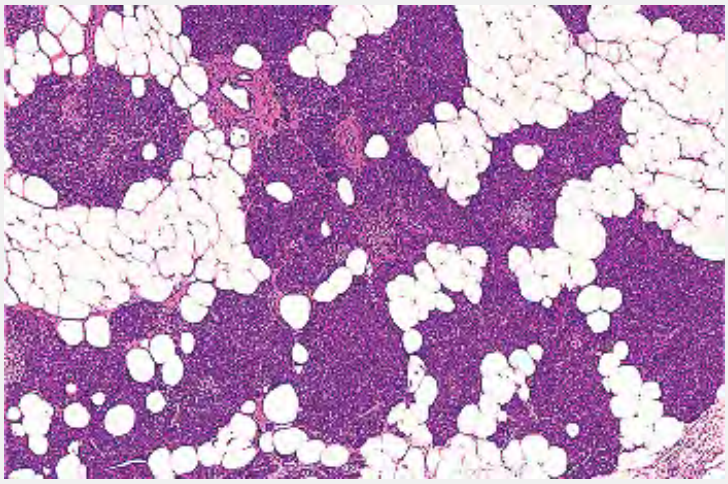

Figure 30.69 In pancreatic lipomatosis, adipose tissue comprises more than 25% of the volume of the gland. As in this case, the remaining parenchyma may not necessarily show

changes of atrophic chronic pancreatitis.

Lymph Nodes

Paul van der Valk

Chris J.L.M. Meijer

Introduction

The lymph nodes are an integral part of the immune system, a complex system whose job is to adequately deal with foreign substances (1). â€œDealing withâ€• here is taken in the broadest sense: it can mean either ignoring an antigen entirely (i.e., tolerance) or mounting a destructive reaction to the antigen, clearing it from the system. In certain areas of the body, an effective elimination is, of course, vitally important. This is certainly true for lymph nodes in areas where antigens serve no purpose and are therefore best eliminated. In contrast, in areas such as the gastrointestinal tract, reactivity against food antigens is not always advantageous, and tolerance is often the better response. As lymph nodes deal with antigens, their histology reflects the (re)activity of the immune system; the nature of the antigen determines whether a reaction will be mounted against it but also determines what effector cells will be employed. This will be reflected in the morphology of the lymph nodes, as will be discussed later.

As the entire body is continually confronted with antigens, lymph

nodes are required throughout the body and are concentrated in areas draining organs with environmental contact. The skin has numerous draining lymph nodes, partly grouped in areas where lymphatics converge, such as the axillary, cervical, and inguinal regions. The gastrointestinal tract and the airways have small collections of lymphoid cells in their mucosal surfaces (the so-called mucosa-associated lymphoid tissue, or MALT), as well as draining lymph nodes in the mesenteric or the mediastinal

and hilar regions (2,3,4,5). Drainage from extra-abdominal areas is through the para-iliac and para-aortic nodes. All these systems converge on a single lymphatic channel, the thoracic duct, which returns the lymphatic fluid to the bloodstream. The only organ where no lymphatics are found is the brain, which drains its extracellular fluid via the cerebrospinal fluid or the extra-parenchymatous Virchow-Robin space.

Under antigenic pressure, lymph nodes can become apparent in areas where they are usually not found. Whether this appearance is actually an enlargement of very small lymph nodes already present or de novo formation of a lymph node is uncertain.

Embryology/Developmental Changes

Relatively little is known about the embryonic development of lymph nodes. They seem to arise from the lymphatic sacs, which in turn develop from the venous system. From the sacs, a lymphatic plexus forms; and, as early as the first trimester, small collections of lymphoblasts can be found in association with this plexus (6). In the second trimester, differentiation into cortex and medulla begins to take place, gradually forming the familiar compartmentalized structure of the lymph node parenchyma. This process is probably also under the influence of nonlymphoid cells (such as macrophages and interdigitating dendritic cells) and mesenchymally derived cells (such as follicular dendritic cells and,

perhaps, fibroblastic reticulum cells). After the compartmentalization of the lymph node is completed, no other changes take place except those that follow antigenic challenge.

Gross Features

Reactive lymph nodes are mostly small structures, round or reniform in shape. When clinically detectable, they are usually enlarged due to some degree of stimulation. Normally, they do not exceed a diameter of 1 cm, although during immune reactions they can become considerably larger. A diameter of more than 3 cm, however, is unusual (though not unheard of) in benign lymph nodes and should raise the suspicion of malignancy. The cut surface of a lymph node is a pink-brown in color and homogenous. A white (â€œfish meatâ€•) aspect or distinct nodularity is suspicious for maligancy (lymphoma). In lymph node dissection specimens, the lymph nodes often consist of small rims of parenchyma enclosing fatty tissue. They can be difficult for pathologists to spot grossly; but, in those cases, their resistance to the palpating finger gives them away.

Anatomy

Blood Supply

Arterioles enter the lymph node through the hilus, branch, and then rapidly form a plexus of capillaries in the parenchyma. Subtle differences exist at the level of the basement membrane between the capillaries in the follicles and those in the paracortex. Laminin-5 is found exclusively in the basement membranes of the follicular compartment (7). It is also very likely that, at the level of the endothelial cells, differences in expression of surface markers (such as chemokine receptors) also exist, though these have not yet been formally demonstrated. Such differences likely play a role in the positioning of lymphocytes in the differing nodal

compartments.

Venous drainage channels accompany the arterioles. The postcapillary venules in the lymph nodes are special, as they are the main route for the entrance of lymphocytes homing to the lymph nodes. They will be discussed in more detail later.

Lymphatics

The lymph node is positioned in the lymphatic system. The afferent lymphatics enter the lymph node through the capsule, draining into the subcapsular sinus. This sinus is lined by endothelial cells, but the system of branching sinuses arising from it no longer has an endothelial lining. Further discussion of the different cell types in the sinuses follows below.

Light Microscopy: The Different Compartments, Histology, and Function

Examination of a sectioned lymph node at low power reveals more or less clearly defined areas or compartments (Figure 31.1A); most obvious are the follicles, generally rounded structures with pale centers and a dark rim. The centers often show a mottled appearance. The follicles are mainly present in the cortical area (i.e., the outer area of the lymph node just below the capsule). Occasionally follicles are found in the deeper regions. Between the follicles and extending to the deeper parenchyma is an ill-defined area, the paracortex or paracortical area, recognizable by its rather pronounced vessels, the epithelioid or high endothelial venules, the specialized postcapillary venules mentioned earlier. On occasion, this area shows a mottling not unlike that of the follicles (Figure 31.1B). In the medullary region of the lymph node, if present in the specimen, low power shows dark areas separated by lighter staining ones, often in a somewhat reticular pattern. The dark areas are the

medullary cords, where plasma cells and, with appropriate stains, mast cells are found. The lighter areas between these sheets of dark-staining small lymphocytes are the sinuses, filled with histiocytes whose ample pale cytoplasm imparts the lighter coloration to this region. The sinuses run through the entire parenchyma but are especially visible in the medullary zone and directly beneath the capsule.

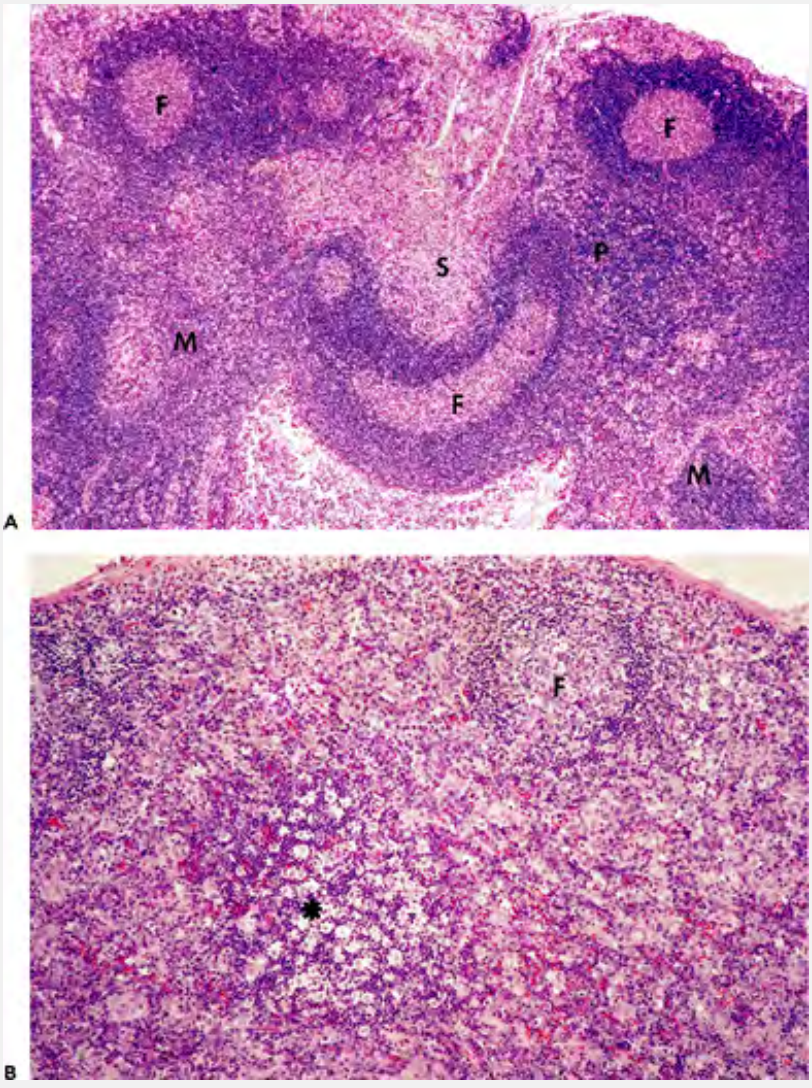

Figure 31.1 A. Low-power view of lymph node (periodic acid-Schiff stained, paraffin-embedded section). This â€œsmilingâ€• picture illustrates the four different compartments of the lymph node. In the upper corners and in the middle of the bottom (the â€œeyes and mouthâ€•) the follicles (*F*) are seen. The paracortical area (*P*) here is fairly small; usually there is more paracortex present. The less sharply defined sections where light and dark areas are juxtaposed represent the medullary cords (*M*, dark) and sinuses (*S*, light). B. Low-power view of another lymph node (H&E; paraffin-embedded section). In the upper right there is a follicle (*F*) recognizable. The rest of the picture shows paracortical area, with considerable influx of macrophages and interdigitating dendritic cells. In the center the typical mottling of the paracortex is seen (*).

These different areas can be easily recognized on low-power microscopy (Figure 31.1A), but it must be stressed that their representation varies greatly in different specimens and not rarely, for instance, the medullary cords are not found.

As humans are in constant contact with antigens, a lymph node is virtually always stimulated to some degree, and the increase in one area caused by this stimulation will often be at the cost of the volume of the other compartments (Figure 31.2). Such stimulation will not only increase the size of one compartment (and decrease the size of the others), but it will also cause a shift in the cellular composition. This usually means an increase in the proliferative fraction of each compartment, the blast cells (8). This adaptability to the constantly changing antigenic challenges explains the variety in â€œnormalâ€• lymph node histology: almost all lymph nodes that come under the microscope are stimulated to some degree. Each of the four different compartments, follicle, medullary cords, paracortical area, and sinuses, is discussed

separately.

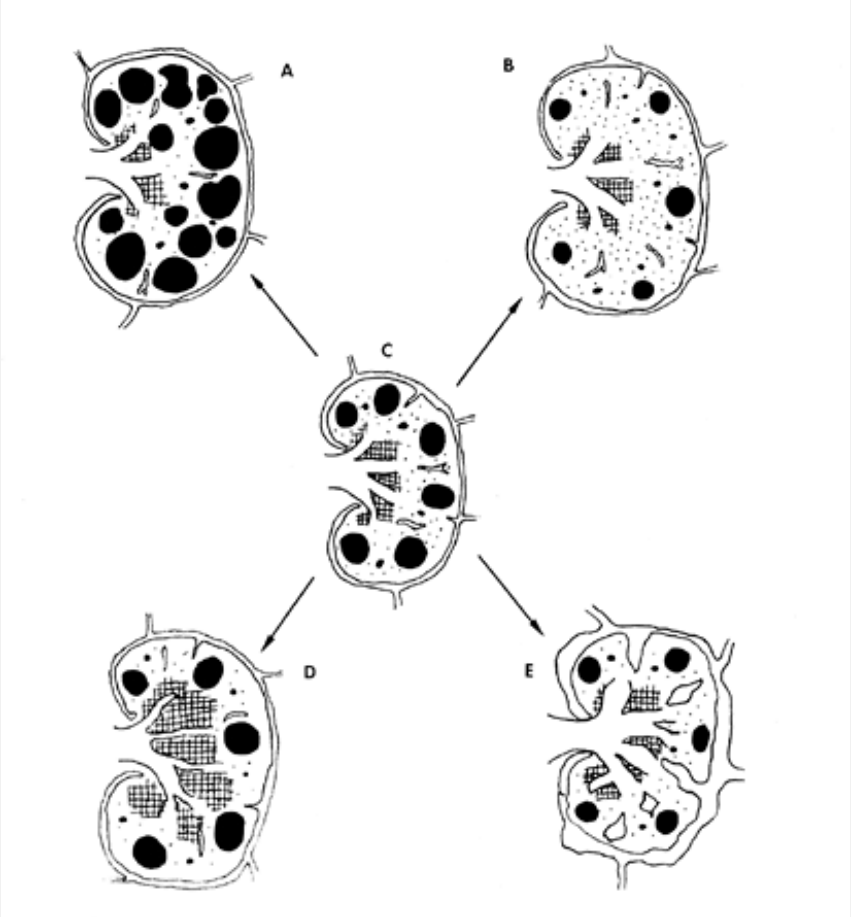

Figure 31.2 Schematic representation of the lymph node with enlargement of the four different compartments, respectively the follicular (A), the paracortical (B), the medullary (D) and the sinusoidal (E) compartments. C represents an unstimulated lymph node.

The Follicle

Distinction must be made between primary and secondary follicles. Primary follicles are aggregates of small, dark-staining lymphoid

cells. In these primary follicles, a germinal center can develop, turning them into secondary follicles. Thus, the mantle zone around the follicle center has the same characteristics as the original primary follicle. The outer portion of the mantle zone is somewhat less densely packed than the inner layer. This outer rim is sometimes called the marginal zone (9), largely based on a very loose resemblance to the splenic marginal zone and on the fact that marginal zone lymphomas tend to localize perifollicularly. However, if the marginal zone exists in the lymph node, it is difficult to distinguish except when it is expanded in benign or lymphomatous proliferations (10).

In the follicle center, an immunologic reaction takes place that is called, after its location, the follicle center cell reaction. It requires the cooperation of follicular dendritic cells (FDCs), lymphoid cells, and tingible body macrophages (Figure 31.3Aâ€“B). The function of the reaction is the generation of B cells that have been affinity-selected against an antigen (i.e., that produce an antibody with the best possible fit to the antigen) and that can function either as a direct precursor for antibody-producing plasma cells or as (long-term) memory cells.

Follicular Dendritic Cells

Follicular dendritic cells (FDCs; previously called dendritic reticulum cells) trap antigens on their surface and present them to B cells (11,12). Because these cells can retain antigen on their surfaces, it was postulated they provide a long-lasting reaction to that antigen, which may be important for immune memory (13); however, this is controversial, and other functions have been proposed (14). Follicular dendritic cells are difficult to recognize in light microscopic sections; they were first described by electron microscopy and later by enzyme and immunohistochemistry (Figure 31.3C) (12,15,16,17). They have a large but inconspicuous nucleus with very fine, almost vesicular chromatin and a small

nucleolus. Not infrequently, they are or appear binucleated, with the nuclei pressed together. The cytoplasm is largely invisible with the light microscope; but, in ultrathin sections and with immunohistochemistry, they appear to have many long and slender cytoplasmic protrusions. These are linked to the protrusions of other FDCs via (hemi)desmosomes, thus forming a round network with a fingerprint-like configuration. In this way, they are responsible for the shape of the follicle. Their origin is still a matter of debate; a derivation

from the mononuclear phagocyte system was proposed (18), as was an origin from the perivascular mesenchyme (19), possibly via a circulating mesenchymal stem cell (20).

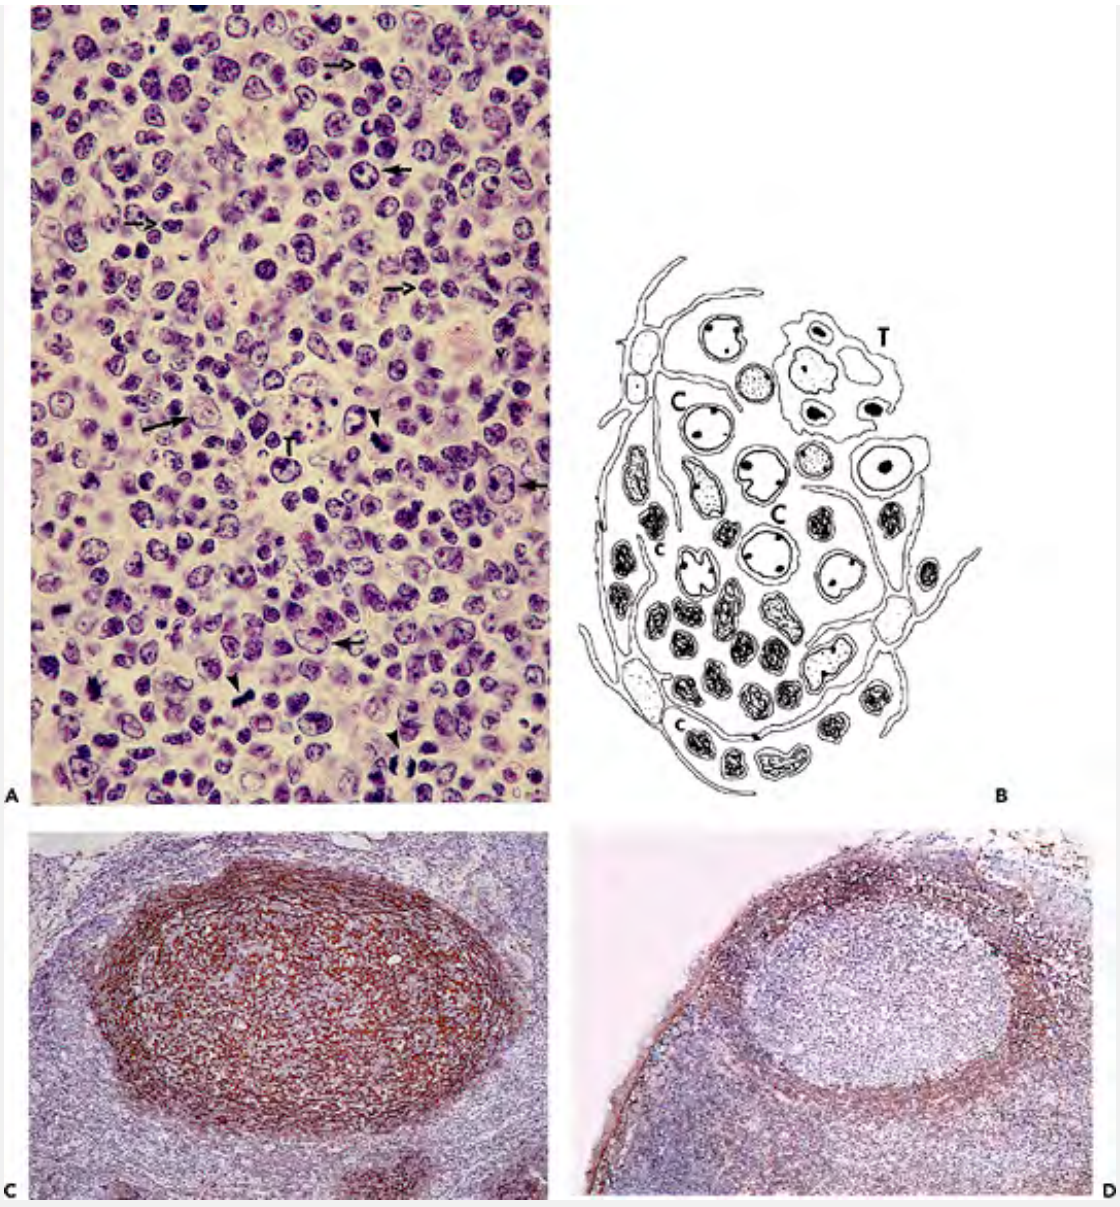

Figure 31.3 The follicular compartment. A. Giemsa-stained, plastic-embedded section, showing the pleomorphism of the follicle center. All typical elements are present: mitotic figures (*arrowheads*); a tingible body macrophage (*T*) with phagocytized debris, staining intensely black; blastic cells (*short arrows*); small follicle center cells (*open arrows*), and a follicular dendritic cell (FDC) (*long arrow*). B. Diagrammatic representation of a follicle, stressing the FDC morphology.

Other elements are tingible body macrophage (*T*) and blastic (*C*) and small (*c*) lymphoid cells. C. Frozen section stained with a CD35 antibody against the C3b-receptor on FDCs. Note the somewhat fingerprint-like pattern of the FDC lattice. D. Frozen section stained for IgD. The mantle cells are positive; the cells in the center are not.

Lymphoid Cells

The lymphoid cells of the primary follicle and the mantle zone have small, slightly irregular nuclei, with condensed, dark-staining chromatin. They have scanty cytoplasm and, consequently, are packed closely together. The outer rim of the mantle zone, the marginal zone equivalent of the lymph node, houses cells that are slightly bigger and less densely packed, but they have the same dark nuclei (9). All of these cells are B cells, staining with antibodies to CD20, 22, and 24. They also express IgM on their surface, and the mantle zone cells proper also express IgD simultaneously (Figure 31.3D) (17,21,22,23). In the germinal center, distinctive B cells can be found:

- Blast cells with large vesicular nuclei and several small but distinct nucleoli, often located at the nuclear membrane. When they are round, they have a small rim of basophilic cytoplasm, especially well-appreciated in cytologic preparations. These are the proliferative cells of the follicle; where they predominate, mitotic figures are easily found. Also, because of their basophilic cytoplasm, areas where they are in the majority appear dark (the dark zone of the follicle).
- After the blast phase of proliferation, the cells gradually become smaller and get more irregular nuclei. As they get smaller, they lose their nucleoli and the chromatin condenses. This leads to cells that are almost indistinguishable from the

mantle cells; small, irregular cells with dark-staining nuclei and virtually invisible cytoplasm. These cells are less densely packed, and the areas where they predominate (the light zones) appear a little lighter than the dark zones. Naturally, cells in transition between large round to small irregular are frequent, giving rise to a particularly polymorphic cellular picture, with a mixture of cells that are large, medium-sized, or small, round or irregular and with vesicular or condensed chromatin.

- A smaller portion of the cells are medium-sized to large, with a finely dispersed chromatin and inconspicuous nucleoli and scanty but intensely basophilic cytoplasm (lymphoblasts).
- Other lymphoid cells include occasional plasma cells and â€œimmunoblastsâ€• (i.e., very large blastic cells with big vesicular nuclei and single centrally placed nucleoli) and small, dark-staining lymphocytes (a little smaller than the small follicle center cells themselves), probably representing T lymphocytes. The number of these various cells varies considerably. On occasion, plasma cells can be quite numerous; also, T lymphocytes can outnumber the B lymphocytes in the follicle.

As follicle center cells are B cells, too, they react with the same markers as mentioned for the mantle and marginal zone cells (with the exception of IgD). In addition, they are mostly positive for the markers CD10 and Bcl-6, considered markers of follicle center cells (23).

Tingible-Body Macrophages

Tingible-body macrophages (TBMs) are large cells with abundant, pale cytoplasm. The cytoplasm contains phagocytized debris and apoptotic bodies from surrounding lymphocytes that have died in the selection process that takes place in the follicle (see Function

section, below). Tingible-body macrophages have large nuclei, with finely dispersed chromatin. Because their nuclear size is fairly constant, they can be used as an internal â€œyardstickâ€• to compare to the nuclear size of the surrounding lymphocytes, especially in lymphomas (nuclei as big or bigger than a TBM nucleus means a large-cell lymphoma). The cytoplasm of TBMs is often very clear, and therefore their presence causes clear/white spots in the tissue, a mottling colorfully described as the â€œstarry skyâ€• pattern. It should be noted that this highly characteristic feature, often used to distinguish between benign and malignant, is in fact a fixation artifact. In some fixatives, such as sublimate-formaldehyde or B5, this starry sky pattern is not seen!

Variations of the Follicular Pattern

From the above information, a characteristic pattern for the morphology of the follicle emerges: a more or less round or oval area, with a dark outer edge (the mantle zone) and a lighter center, that shows mottling and, upon closer inspection, a very polymorphic cytologic picture and many mitotic figures. Sometimes zonation is seen, with the dark zone directed inwards, the light zone directed more to the capsule of the node. As it is very dependent on how the follicle is cut in the section, this zonation is often not seen (15,24).

Variations occur in the shape of the follicles and in their composition. An important cause for variation is time: the pattern described above takes time to evolve. In the beginning, the follicle consists largely of blasts, with smaller follicle center cells appearing as the follicle center cell reaction runs its course (24).

In reactive conditions, follicles can become very large and coalesce; HIV lymphadenopathy is a good example of this phenomenon (25,26,27) (Figure 31.4). Their composition can also vary somewhat. Changes that occur with malignancy are discussed

later. With involution, the follicle can become hyalinized and atrophic, or it can be overrun by T lymphocytes, a phenomenon known as progressive transformation of the germinal center (15,28).

This can make the follicle difficult to recognize. It is only by their remnant round shape (and by special stains for FDCs) that they may be recognized as follicles. Fortunately, this somewhat alarming-appearing feature usually involves only a few follicles at the same time, so the presence of nearby normal follicles is reassuring.

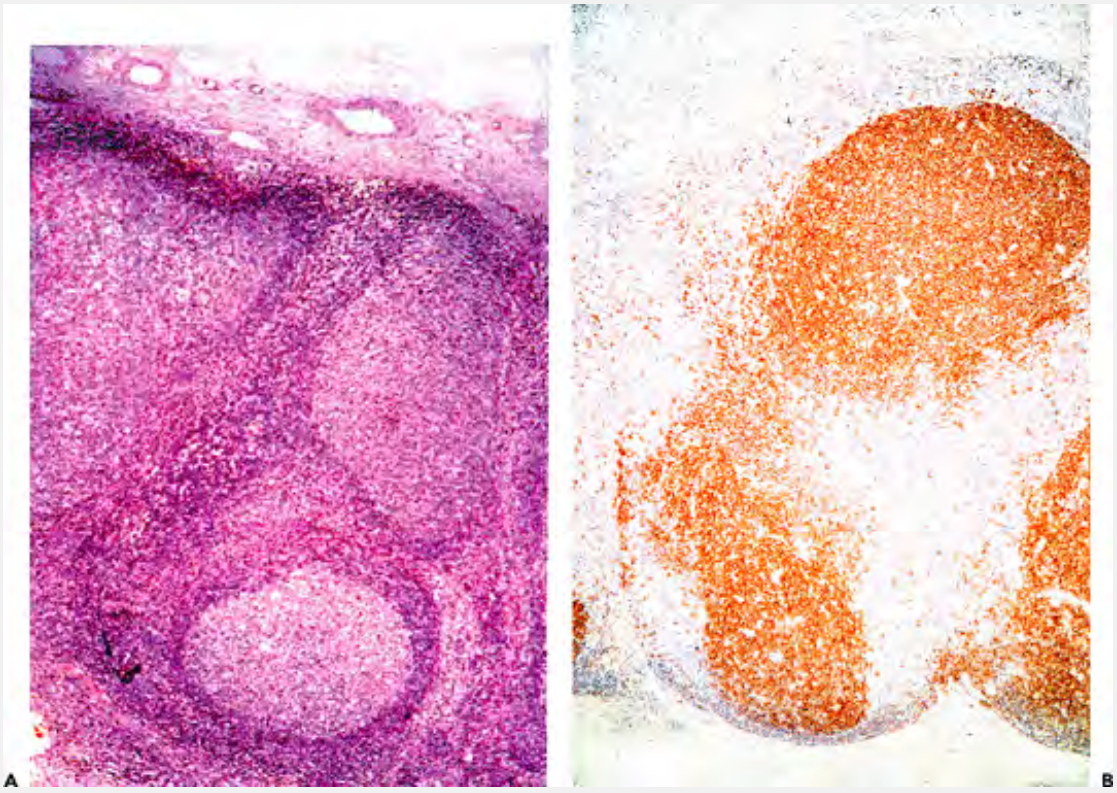

Figure 31.4 HIV-induced follicular hyperplasia. A. Very large and irregularly shaped follicles dominate the picture (H&E; paraffin-embedded section). B. Two follicles are seen, with ragged borders showing beginning follicular disintegration

(CD20 stain).

The Medullary Cords

The medullary cords are found in the hilar region of the lymph node, between the sinuses. The cellular composition of this compartment is described next (Figure 31.5).

Lymphoid Cells

Small lymphocytes make up the majority of cells in the medullary cords. They have small, more or less round nuclei and a scant-to-moderate amount of cytoplasm. In some cells, the chromatin is clumped and peripherally distributed in the nucleus, similar to the plasma cell nucleus, though the typical â€œclock faceâ€• chromatin of a mature plasma cell is not seen. Cells with this kind of chromatin tend to have more cytoplasm and sometimes even a perinuclear hof, clearly indicative of plasmacytoid differentiation. These are called lymphoplasmacytoid or lymphoplasmacytic cells. Immunologically, the cells can be identified with CD20 and, even better with CD79a, general B cell markers. Staining for immunoglobulins can sometimes show cytoplasmic IgM and light chains. Many of the cells with less cytoplasm and irregular nuclei are T lymphocytes (CD2-, 3-, 5-, and 7-positive), necessary to modulate or drive the process of antibody formation that takes place in the medullary cords. The blast cells of this process, the immunoblasts, are striking, though infrequent. They have large vesicular nuclei with a large, centrally located nucleolus and abundant basophilic

cytoplasm. Plasma cells are also present but in varying number. They are distinctive cells, with their small round nuclei having a â€œclock faceâ€• chromatin pattern due to small clumps of dark

chromatin at the nuclear membrane, like the numbers on a dial. The nucleus is eccentrically located in the cytoplasm, with a perinuclear hof or small zone of cytoplasmic clearing. The outer rim of the cytoplasm is deeply basophilic. Under some conditions, plasma cells accumulate immunoglobulins in their cytoplasm, forming so-called Russell bodies, globular structures that stain positive with PAS and that can indent the nucleus if they reach sufficient size. Plasma cells are CD20-negative but retain their CD79a expression and are, of course, positive for cytoplasmic immunoglobulins. Plasma cells will also (paradoxically) label for epithelial membrane antigen (EMA).

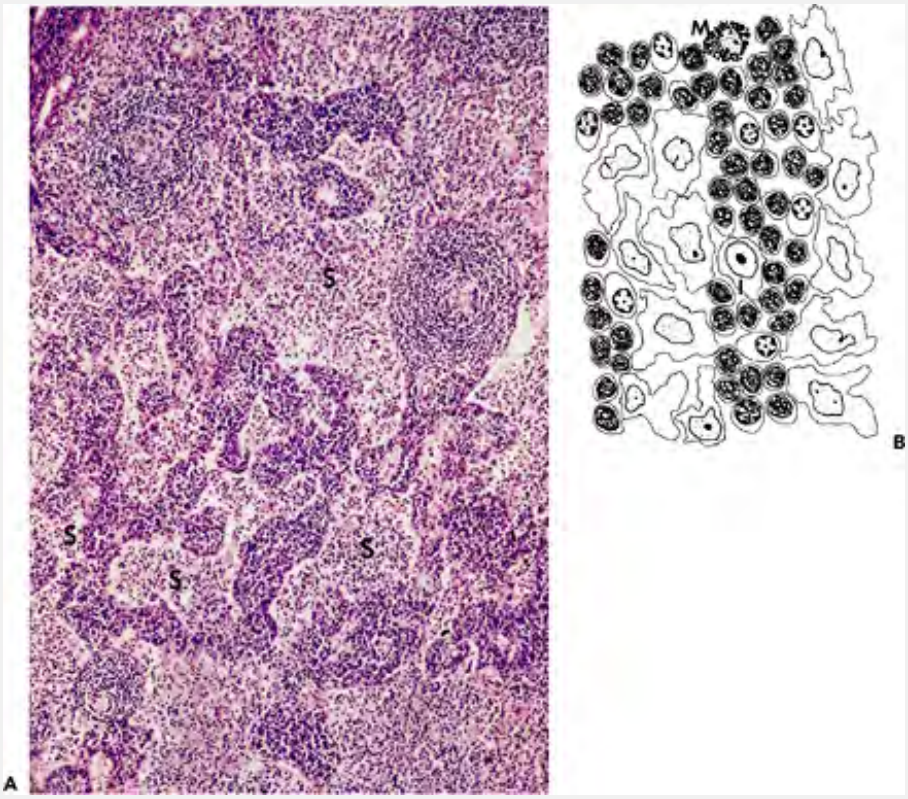

Figure 31.5 Medullary cords. A. The sheets and ribbons of dark-staining cells are the medullary cords, containing small lymphocytes and plasma cells; they are separated by the lighter staining areas, the sinuses (*S*) (H&E; paraffin-

embedded section). B. Schematic representation, also depicting an immunoblast (*I*) and a mast cell (*M*).

Macrophages

Macrophages are fairly scarce in the medullary cords. They have medium-sized to large irregular nuclei and abundant cytoplasm. They are not as avidly phagocytic as the TBMs from the follicle center, perhaps because they are differentiated more toward antigen-handling and presentation then for phagocytosis.

Other Cell Types

T lymphocytes were already mentioned. The mast cell is the other cell type that can be foundâ€”especially in the medullary cords, where they can be easily demonstrated with a metachromatic dye such as a Giemsa stain. Their characteristic purple granulation permits easy recognition. The granules generally obscure the nucleus.

The Paracortex

The paracortex, or paracortical area, was the last compartment to be described and named (29), probably because its boundaries are indistinct and the area best appreciated in less commonly used fixatives, such as Zenker's or sublimate-formaldehyde. Nevertheless, it has some typical structural elements that allow easy recognitionâ€”the epithelioid venules and the interdigitating dendritic cell (IDC) (Figure 31.6).

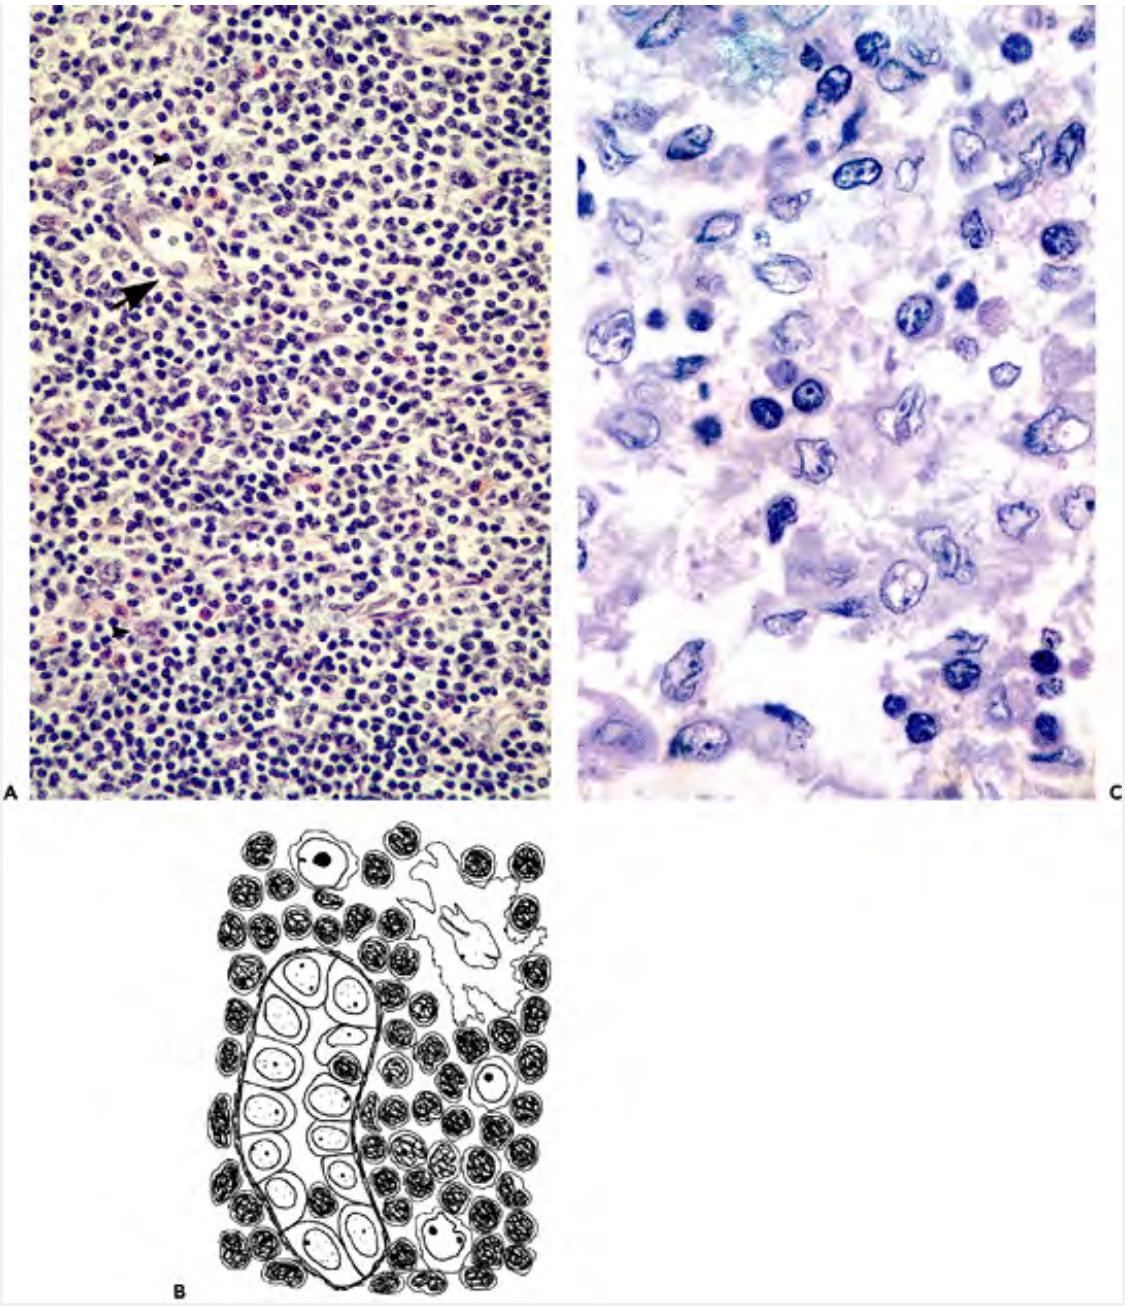

Figure 31.6 The paracortex. A. An epithelioid venule is seen (*arrow*); small lymphocytes dominate the picture, with an occasional blast present; interdigitating dendritic cells (IDCs), with their markedly irregular, grooved, and pale nuclei are scattered throughout the area (*arrowheads*) (H&E; paraffin-embedded section). B. Schematic representation. Note the

typical IDC. C. This section demonstrates an increase in IDCs, characteristically displaying their irregular pale nuclei and abundant cytoplasm (lymph node with dermatopathic lymphadenopathy)(Giemsa; plastic-embedded section).

Epithelioid (Postcapillary or High Endothelial) Venules

These highly distinct vessels are found only in the paracortex; they are lined with plump cuboidal or even cylindrical endothelial cells with fairly large oval nuclei, with vesicular chromatin and indistinct nucleoli. Sometimes the lumina of these vessels appear to be obliterated by the endothelium. These vessels have long since been recognized as the port of entrance for bloodborne lymphocytes to the lymph node parenchyma (30,31). Therefore, they play a crucial role in recirculation, distribution, and homing of lymphocytes in different lymphoid organs, a process mediated by specific homing receptors on the lymphocyte surface, that react with organ-specific ligands (or vascular addressins) on the endothelial cell surface (32,33,34,35) (Figure 31.7). In this process chemokines also play an important role (36,37).

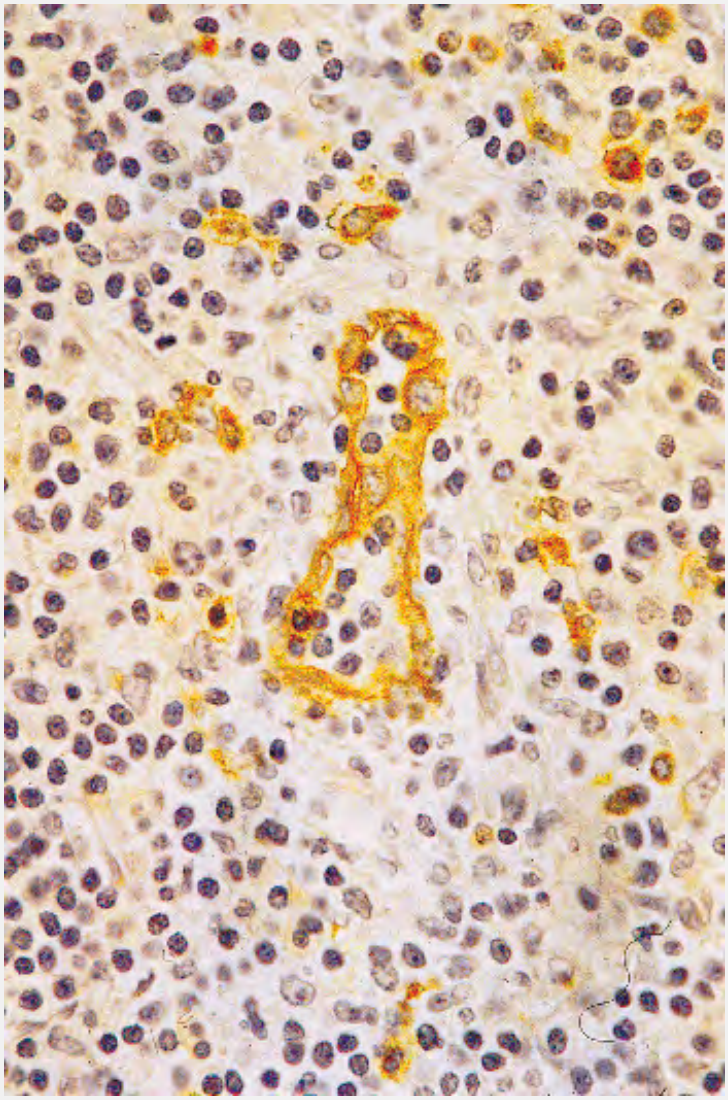

Figure 31.7 Paracortical area with a highlighted epithelioid venule. Lymphocytes are seen adhering to the endothelium and passing through the vessel wall (HECA 452 stain).

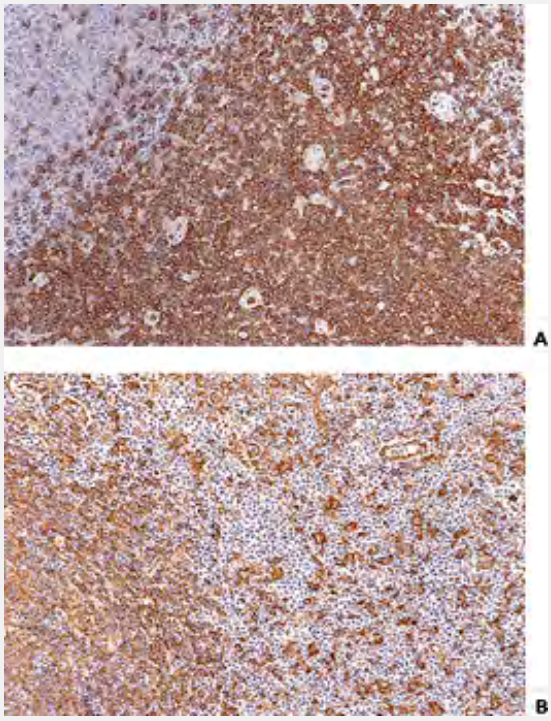

Figure 31.8 Immunohistochemistry of paracortex. A. The vast majority of the cells in the paracortex stain positive for CD3 (frozen section). In the upper left corner, a segment of a follicle (B-cell area) is seen. B. Here, the IDCs stain positive for HLA-DR (frozen section); they are larger and show more cytoplasm than the group of follicular (B) cells on the left.

Interdigitating Dendritic Cells

Interdigitating dendritic cells (IDCs) are large cells with large and bizarre nuclei having deep clefts and folds. The chromatin pattern is delicate, almost transparent, and nucleoli are inconspicuous. The cytoplasm is abundant, pale, and with ill-defined borders (Figure 31.6C). Electron microscopy shows protrusions, broad and veil-like, in contrast to the thin processes of the FDC. Contact points are lacking. Furthermore, IDCs have a typical organelle of

undetermined function: the tubulovesicular system (15). When present in large numbers IDCs cause a mottling of the paracortex.

The IDC is a bone marrow-derived cell, intimately related to the Langerhans cell of the skin, which it closely resembles, both morphologically and functionally (38,39,40,41). Both are antigen-presenting cells to T lymphocytes, important to initiate and/or maintain immune responses. Immunologically, these cells are best demonstrated in stains for S-100 protein or by HLA-DR, among the class IIâ€“negative T lymphocytes (Figure 31.8).

Lymphoid Cells

The cytology of the paracortex is somewhat variable; but, in the majority of cases, small T lymphocytes predominate. They have small, irregular nuclei with coarse chromatin and little cytoplasm. They are demonstrated with stains for CD2, 3 (Figure 31.8), 5, and 7 and are either CD4- or CD8-positive, with CD4-positive cells outnumbering the CD8-positive ones. Blast cells are present in varying numbers; they are large cells with vesicular nuclei of a varying shape.

Other Cell Types

The fibroblastic reticulum cell (FRC) is often found at the edge of the paracortex (15). It is a somewhat functionally enigmatic cell that forms reticulin fibers involved in the transport of cytokines and/or antigens through the parenchyma. This so-called FRC conduit system is an effective means of spreading important activating molecules throughout the entire lymph node (42).

The Sinuses

The sinuses are the structures carrying the lymphatic fluid from the afferent lymphatics through the lymph node to the efferent

lymph vessels. The afferent lymph vessels drain into the subcapsular sinus, a structure at least partly lined by endothelium. As the sinuses traverse through the lymph node, they lose their endothelial lining and acquire a â€œliningâ€• of macrophages (43). The macrophages in the sinuses are similar to macrophages elsewhere. They are large cells with large, irregular, and vesicular nuclei, a low nuclear-to-cytoplasmic ratio, and signs of phagocytotic activity.

Apart from the macrophages, which look the same here as elsewhere in the lymph node, small lymphocytes are also found in the sinuses (Figures 31.5A, 31.9A). In addition, occasional neutrophils or eosinophils can be found here as well.

Mention must be made of two other cell types. The first is the so-called sinus-lining cell, an ill-defined cell type that is primarily recognized with immunohistochemical stains for keratins. It is found in the area of the subcapsular sinus and has a coarsely dendritic morphology (44). Its nature is unclear; but, in evaluating lymph node sections for metastatic tumor, it is important to be aware of these cells and not confuse them with tumor cells. The second is the so-called immature sinus histiocyte, a misnomer as these are B lymphocytes (Figure 31.9B and C). These cells are primarily seen in certain reactive conditions in which they can partially fill the sinuses. They have small, more lymphoid appearing nuclei but have ample cytoplasm. Also called monocytoid B cells (another unfortunate name!), they are indeed B-lymphocytes, probably marginal zone cells (45,46).

Function

Each of the above-described compartments has a specific function, housing its own immunological reaction. Together these reactions make up the individual's immunologic integrity.

- In the follicle, the follicle center cell reaction takes place. In

this reaction the naÃ¯ve B lymphocytes are exposed to antigen (on the FDC surface), and they adapt their antigen receptor (the immunoglobulin) to make a perfect fit to the presented antigen by a process called somatic hypermutation. This involves rearranging their immunoglobulin receptor genes through a partially trial-and-error process. Thus, some of the changes are actually for the worse and decrease the fit. Such cells are ruthlessly eliminated through apoptosis (hence the many apoptotic cells in this compartment). Eventually though, a perfect fit is achieved, and the cell is rescued from elimination by expressing the anti-apoptotic Bcl-2 molecule. Normal follicles, where selection takes place, are therefore negative for Bcl-2. Typically, several clones are developing in a single follicle, making it an oligoclonal proliferation (47).

Through this complicated molecular biologic process of antibody selection, the follicle center cell reaction results in B cells that express high avidity antibodies on their surface. These cells can recirculate through the body as memory cells, spreading immune competence through the entire body and waiting for another encounter with the antigen; others go to the medullary cords or to the bone marrow to enter the plasma cell reaction and develop into plasma cells that produce antibodies for secretion.

- In the medullary cords, the plasma cell reaction takes place. As mentioned above, it leads to the formation of plasma cells and the secretion of antibodies. The antibody production in the lymph node does not substantially contribute to the level of circulating antibodies, but it may be locally important, for instance for fixing antibodies on FDCs.
- In the paracortex, we find the specific cellular response that generates antigen-specific effector T lymphocytes of the various subsets: helper cells, suppressor cells, regulatory cells, memory cells, and maybe more (32). The cellular

processes here are still poorly understood. It is likely that T-cell memory, cytokine production, and a number of other reactions take place in the paracortex, but little is known about this. Its role in the delayed-type contact hypersensitivity is well-recognized (29).

- The sinuses, with their abundant macrophages, are a filtering system, clearing foreign substances from the lymph. Given their ability to handle antigens, a function in antigen-presenting might be plausible, but little is known about this.

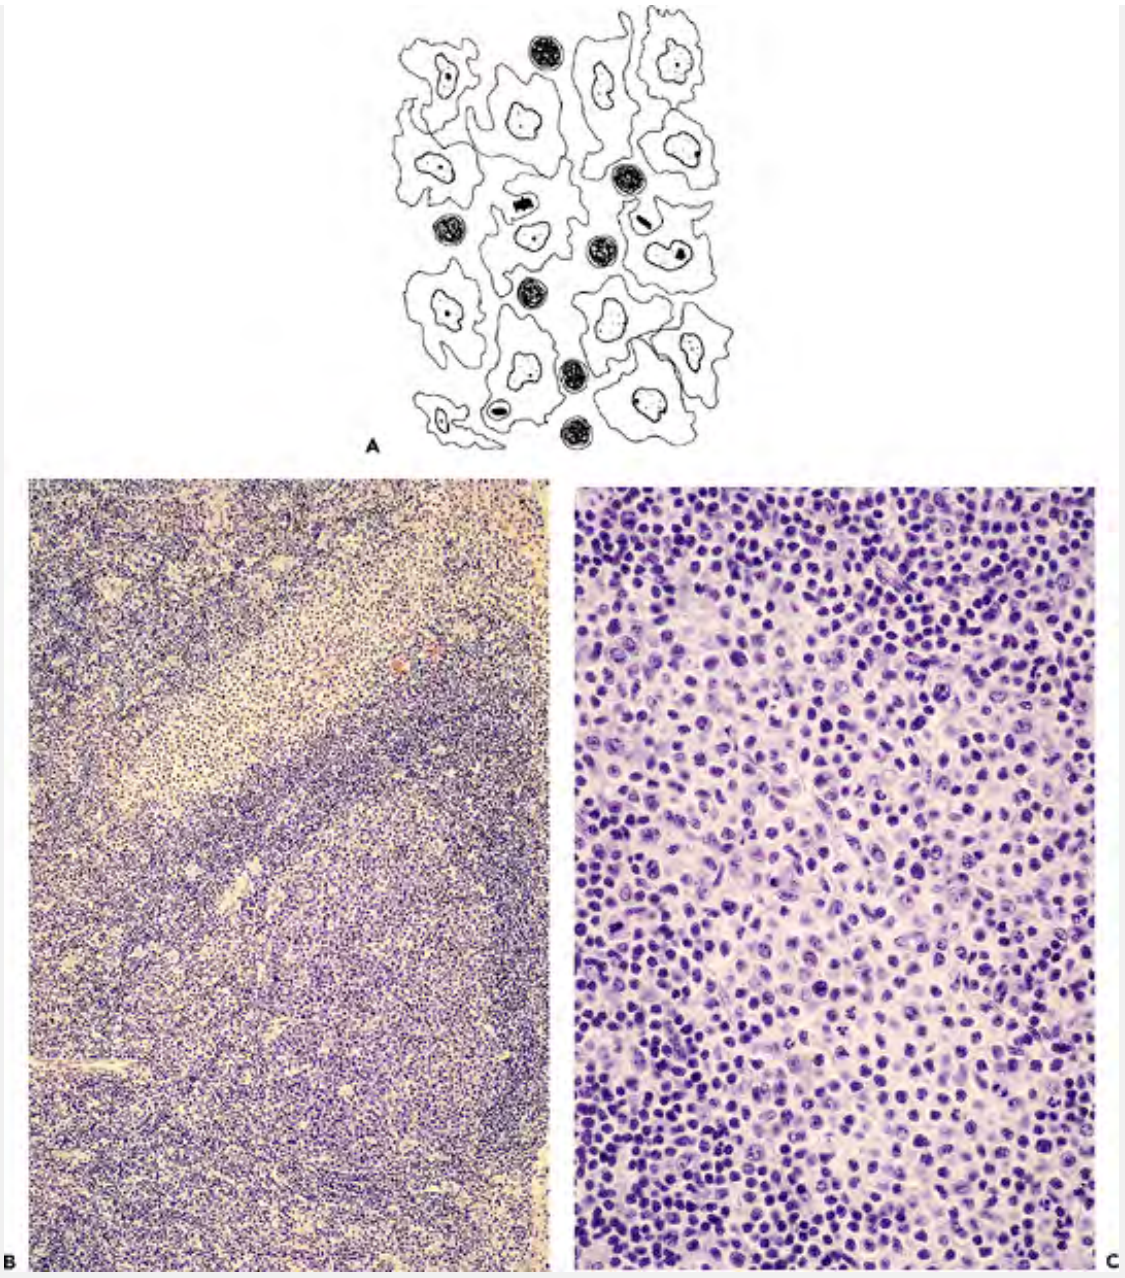

Figure 31.9 The sinuses. A. Schematic representation with predominance of macrophages and some lymphocytes. B. Low-power view of immature sinus histiocytosis, recognizable as the pale area to the upper left of the central follicle. C. Detail of B, showing the cells to be somewhat larger than the dark, small lymphocytes and having fairly abundant cytoplasm.

Changes in Compartments: Benign Versus Malignant

The differential diagnosis of benign and malignant lesions is important in the discussion of normal lymph node histology for two reasons: (a) it is naturally of the utmost importance for the surgical pathologist to decide between benign and malignant, and (b) it is often difficult to distinguish between these two. The first goes without saying; the second can be clarified somewhat.

Though a link between normal tissue and the tumors arising from them has been self-evident for epithelial neoplasms, the same insight for lymphomas and lymph node structure was slow to arrive. However, this has been firmly established through careful morphologic and immunologic studies. We now regard the (non-Hodgkin's) lymphomas as malignant counterparts of the normal immunologic reactions to antigens that take place in the different compartments of the lymphoid tissues (15,48,49,50). Lymphoma cells have similar morphologic, immunologic, and functional characteristics when compared with normal cells. This explains why a malignant process can resemble a reactive condition so closely. Table 31.1 relates some of the benign variations in normal histology to their malignant counterparts. As this chapter deals with normal histology and many excellent texts have been written on lymphomas, we will discuss this matter only briefly.

Follicular Changes

The most important issue here is the distinction between follicular hyperplasia and follicular lymphoma. The term *follicular hyperplasia* covers a large number of conditions, most of which are difficult to differentiate from each other on morphologic grounds. Thus, it occurs in: (a) lymph nodes in the vicinity of a (bacterial)

inflammation [e.g., tonsillitis but also in syphilis (51)]; (b) in autoimmune diseases, such as rheumatoid arthritis and systemic lupus erythematosus (52,53); (c) viral infections, such as HIV (25,26); and (d) in a number of idiopathic conditions, such as Castleman's disease, multicentric angiofollicular hyperplasia, reactive lymph node hyperplasia with giant follicles (54,55,56,57). (It is by no means clear that these are all separate entities.) Sometimes special stains can help in elucidating causation (spirochetal stains, p24 for HIV). In essence, the follicles are all more or less the same, so they are taken together here.

Table 31.1 Benign Compartmental Enlargement and Their Malignant Counterparts

Compartment	Benign	Malignant
Follicle	Follicular hyperplasia	Follicular lymphomas
Paracortex	Paracortical hyperplasia	T-NHL
	Dermatopathic lymphadenopathy	Mycosis fungoides
Medullary cords	Medullary hyperplasia	Lymphoplasmacytic lymphoma
	Reactive plasmocytosis	Plasmacytoma

Sinuses	Sinus histiocytosis	Malignant histiocytosis

The most important morphologic criteria arguing for a benign lesion, mentioned in the literature (15,53,58,59,60,61,62) are:

- Cellular pleiomorphism of the follicle center
- Presence of TBMs
- High number of mitotic figures
- Well-defined mantle zone
- Differences in size and shape of the follicles
- Low number of follicles per surface area and predominant cortical localization
- Well-developed and intact FDC networks in the follicle center
- Zonation of the follicles, with clear dark and light zone

Despite this impressive list of criteria it may not be possible in all cases, even by an experienced pathologist, to distinguish reliably between benign and malignant on morphologic features alone. Therefore, there are some additional roles from immunohistochemistry and molecular biology (63). Features of malignancy by these techniques include: (a) demonstration of light chain restriction by immunohistochemistry (expression of either Îº- or Î»- light chain by follicular lesions is considered proof of malignancy); (b) expression of Bcl-2 by follicle center cells; (c) demonstration of clonality by detection of rearrangement of immunoglobulin genes, either by Southern blotting or by polymerase chain reaction (PCR) analysis; and (d) demonstration of a t(14;18) translocation (perhaps not 100% proof but a very strong argument).

Even with these additional techniques, it is not possible to diagnose all cases with certainty. It is good to realize that the majority of the lymph nodes encountered by pathologists are quickly scanned and interpreted, and rarely cause diagnostic problems. However, a high index of suspicion is

probably a good general attitude, simply because of the occasional treacherous similarities between benign and malignant follicular processes.

Changes in the Medullary Cords

Two distinctions can be important when examining changes in medullary cords. The first is reactive plasmacytosis (Figure 31.10) versus plasmacytoma. Preserved lymph node architecture and the presence of plasma cell precursors strongly favor the diagnosis of a reactive condition (15). In rare doubtful cases, immunohistochemistry can clinch the diagnosis by demonstrating light chain restriction. Second, expansion of the medullary cords, a rare event in itself, can be mimicked by a lymphoplasmacytic lymphoma. In rare instances, this lymphoma does not efface the architecture but expands the medullary cords. If the expansion is sufficient to arouse suspicion, marker studies can settle this easily, again by showing light chain restriction. It is good to realize that demonstrating clonality in paraffin sections may be difficult due to diffusion artifacts. The intercellular fluid is rich in immunoglobulins, and these can diffuse into the cells of a specimen if fixation is delayed. Subsequent fixation will trap the polyclonal immunoglobulins inside the cells, potentially obscuring monoclonality. In practice, when a lesion is clearly monoclonal, this will be demonstrable; however, caution must be taken in interpreting immunoglobulin stains.

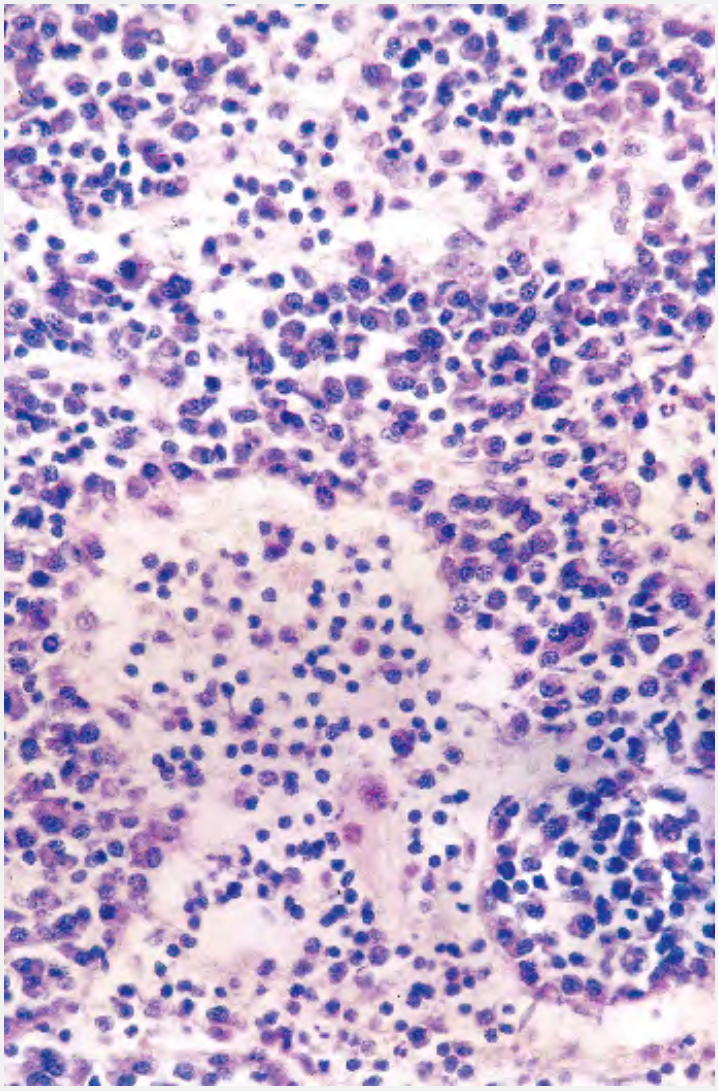

Figure 31.10 Reactive plasmacytosis. The medullary cords here consist almost entirely of plasma cells; sinuses are patent, a sign of preserved lymph node structure (H&E; paraffin-embedded section).

Changes in the Paracortex

Paracortical hyperplasia can take three forms, each with their own differential diagnostic considerations.

- *Expansion of the paracortex by predominantly small lymphocytes, usually with an increase in epithelioid venules.* Distinctive features, suggestive of malignancy are cellular monotony and destruction of lymph node architecture by the proliferation. Immunohistochemical features that may be supportive are: (a) demonstration of an aberrant phenotype (e.g., strong predominance of CD4 or CD8), loss of markers that are normally present (such as CD7 or CD5), or expression of markers normally not expressed by lymph node T cells (such as CD1); and (b) demonstration of clonality by molecular biology [i.e., Southern blotting or PCR analysis of the T cell receptor chains (64,65)].
- *Expansion with an increase of blasts.* This can be seen in viral infections or following vaccinations, as well as in some drug reactions (the antiepileptic drugs featured prominently here) (53,60,66,67). The changes can be histologically very alarming for malignancy. In some conditions, even necrosis can occur, such as in Kikuchi's histiocytic necrotizing lymphadenitis (68). On occasion, the changes can exhibit a nodular pattern (69). In such cases, a preserved architecture should raise the possibility of a benign condition, regardless of the histologic picture. Simple analysis with immunohistochemistry will reveal blasts of B-cell origin next to blasts of T-cell origin; also mitotic cells labelled by both B-cell and T-cell markers argue strongly for a benign proliferation and against a peripheral T-cell lymphoma. A differential diagnosis with Hodgkin's disease is also sometimes a consideration; Reed-Sternberg cells can be found in reactive conditions. Therefore, this differential can be very problematic. It should be kept in mind, however, that cases of Hodgkin's disease with intact lymph node architecture are rare. In short, this pattern can be extremely difficult to interpret; a combination of clinical history, morphology, immunophenotyping, and molecular biology (demonstration of

clonality) must bring about a final diagnosis.

- *Dermatopathic lymphadenopathy.* In this pattern, seen in lymph nodes draining skin areas with itching skin disorders, the paracortex is expanded by a marked increase in IDCs and Langerhans cells (70,71). It is mentioned here, because the skin lymphomas, mycosis fungoides, and the SÃ©zary syndrome, when they involve the lymph nodes, will do so in the background of a dermatopathic lymphadenopathy. This problem will

thus arise only in the setting of a patient known to suffer from one of these skin lymphomas. That does not make the problem easier in itself. The only way to arrive at the diagnosis is to make a careful search for the diagnostic large cerebriform mononuclear cells, which can be difficult to find (72,73). Their demonstration is clinically very relevant (74). Immunohistochemistry and molecular biology unfortunately are not helpful here (75).

Sinusoidal Changes

Sinusoidal changes are very common in lymph node specimens. Lymph nodes draining tumors or inflammatory areas often show sinus histiocytosis. Typical conditions showing a sinusoidal pattern include sinus histiocytosis with massive lymphadenopathy (76,77) and Langerhans cell histiocytosis (60,78). The former condition is a peculiar clinicopathological entity in which the histiocytes seem to engulf large numbers of lymphocytes in their cytoplasm without destroying them, a phenomenon dubbed emperipolesis. This is a highly characteristic finding. The latter can also cause a (mostly but not always benign) sinus histiocytosis. The typical features of Langerhans cells, with their deeply grooved nuclei and the admixture with eosinophils, are important clues. Immunohistochemistry with CD1 (and S-100) will prove the true

nature of the cells. Malignant conditions in the sinuses are almost always easily recognized on histology as frankly malignant. Metastatic carcinoma or melanoma, large-cell anaplastic lymphoma (79), and malignant histiocytosis (80) all can be difficult to distinguish from one another, but doubts about their malignancy are rare.

As mentioned above, the sinuses can be filled with immature sinus histiocytes or monocytoid B cells. A malignant equivalent is nodal marginal zone B-cell lymphoma (81). A predominant sinusoidal localization of such a lymphoma is rare but can occur. Demonstration of clonality is helpful and necessary in such cases.

Finally a particular sinusoidal pattern involving vessels can be seen on occasion, often as a reaction of the lymph node to ischemia or irradiation. This pattern is called vascular transformation of the sinuses and can show some histological variation, from a delicate vascular pattern to a more spindle-cell proliferation resembling Kaposi's sarcoma (82).

Combined Patterns

Follicular, medullary, paracortical, and sinusoidal patterns often occur simultaneously, and any combination is possible. As combined patterns are extremely rare in lymphomas, any combination argues for a benign condition. For example, *Toxoplasma* and Epstein-Barr virus infections often cause combined patterns. If suspicions of a malignancy arise, the same criteria as mentioned for the single patterns apply.

In addition a number of other patterns may occur, such as granulomatous patterns. As this chapter cannot aspire to completeness and this is not a treatise on benign conditions of the lymph node, they will not be discussed further.

Artifacts

A number of extrinsic and intrinsic factors can influence lymph node histology. Though they are not patterns, they can cause considerable difficulties in evaluating histology and are therefore mentioned here.

Technical Artifacts

Lymph node tissue is vulnerable and easily damaged in processing. Undue pressure on a specimen during dissection can cause considerable crushing artifact, to the point of obliterating morphology completely. *Specimens with extensive crushing artifacts should best not be evaluated.* Differences are already subtle, and no chance should be taken with poor material.

Another disturbing artifact is fixation related. It occurs especially in large specimens or if processing is too quick. If the fixation time in formalin is too short, only the outer edge of the specimen is fixed. The central part will not be reached by the formalin and will be fixed in the alcohol of the dehydrating series. This causes a marked difference in the histologic appearance of outer and inner segments. The inner segment shows loss of cohesion, and cells appear more shrunken and hyperchromatic (Figure 31.11). Great care should be taken in evaluating such specimens.

Intrinsic Artifacts

Though the lymph node architecture described above is found in all nodes throughout the body, in some areas typical changes can be found, mostly the result of repeated inflammation or reactions. These changes are most often seen in inguinal nodes and take the form of deposits of fibrotic material that can distort the normal architecture. This should be kept in mind when evaluating such specimens. Similarly, in retroperitoneal lymph nodes, hyalinization can be found.

Handling of Lymph Node Specimens

In an area where morphologic differences are (very) subtle, additional techniques can be decisive in making a diagnosis. In the past, this meant having snap-frozen material

available to do marker studies and/or Southern blotting. However, at the moment, all commonly used markers in characterizing lymphoid tissues and their tumors are applicable on formalin-fixed, paraffin-embedded material. In addition, though Southern blotting is still the most sensitive and reliable technique, PCR analysis with multiple primers is a good alternative for molecular biologic evaluation of gene rearrangements and translocation.

Nevertheless, it is still good policy to ask clinicians to send in lymph node specimens fresh and to snap-freeze a part of the specimen. It is no longer necessary to use a special fixative for immunohistochemistry (Bouin's fixative, sublimate-formaldehyde, B5, Sensofix, zinc-containing fixatives, among others); most of these are toxic and damage DNA to such a degree that molecular biologic analysis becomes impossible. It can be helpful to make touch imprints, by *carefully* pressing the cut surface of a specimen against a slide. The cytological picture can be helpful, especially in cases where the histology is not so good.

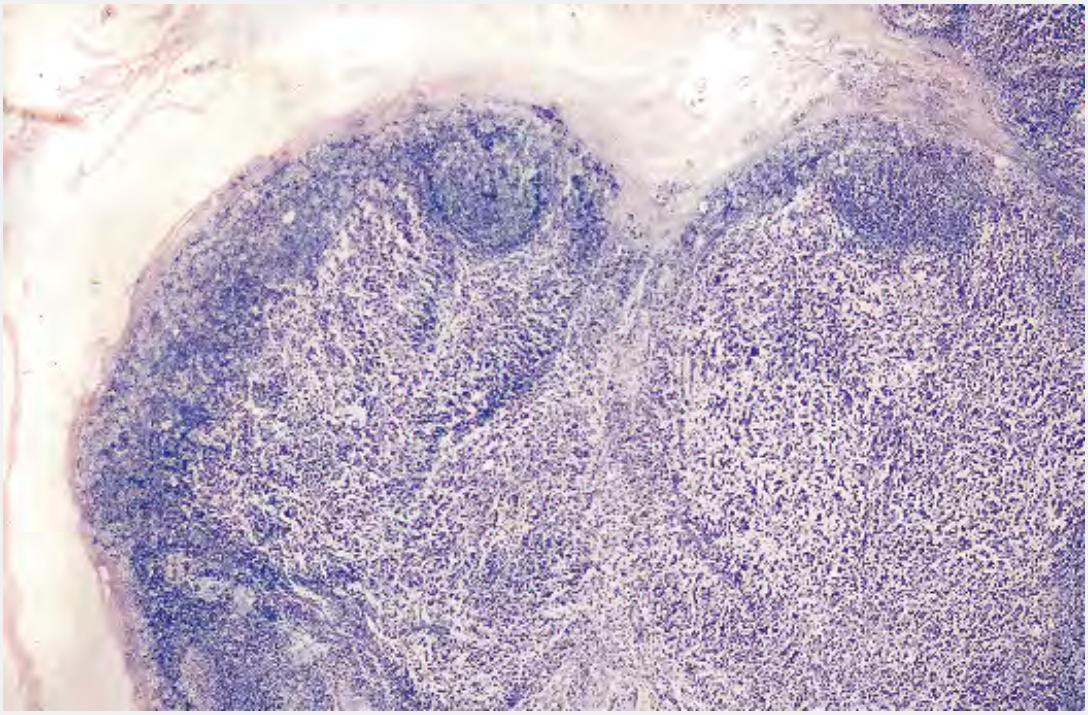

Figure 31.11 Fixation artifact. Edge of the specimen is properly fixed; the center, fixed in alcohol during the dehydration procedure, shows loss of tissue structure.

Electron microscopy is not particularly helpful in diagnosing lymphoid lesions, whether benign or malignant. For very rare lesions, tumors of dendritic cells for instance, this may be of assistance, and it is a small effort to slice off a very small and thin fragment for fixation in glutaraldehyde. However, and this is a general principle, *if a specimen is small, any manipulation is a risk of damaging the cells in the lesion severely and should be kept to a minimum or even avoided altogether.*

If circumstances so dictate, consider sending a piece of tissue to the microbiology department for culture.

For research purposesâ€”and if the size of the specimen allows itâ€”a cell suspension can be made. Routine use of cell

suspensions to perform marker analysis is not to be encouraged. One loses the morphologic control of the lesion and its cells, which is extremely important.

Special Techniques and Procedures

Immunohistochemistry can hardly be described as a very special technique, given its omnipresence in pathologic diagnostics. It is, however, not always used properly. Therefore, we will stress the basic rules for this important additional technique.

- *Always use positive and negative controls.* Given the problems with endogenous peroxidase, alkaline phosphatase, or biotin activity/presence and the very real possibility of technical mistakes, they are absolutely essential.
- *Use panels of antibodies.* Because no single antibody is absolutely specific for one molecule and cross-reactions can be very confusing, it is sound policy to use a well-constructed panel in which individual staining results will confirm each other. Panels for classification of lymphoid lesions have been reported (83,84); they are primarily in use for classification of lymphoma but are also useful for benign lymphoid lesions and distinguishing between benign and malignant.
- *Use the morphology.* Immunohistochemistry is an additional technique; one should always be extremely cautious if morphology and immunohistochemistry are at odds. Also, morphology can direct the interpretation of the immunohistochemistry, for instance by looking at the immunophenotype of those cells that are considered the tumor cells. In lymphoid lesions, there are always a lot of admixed cells that are also of lymphoid origin. The best example is that of a paracortical expansion where the blasts prove to be of B-cell origin with the immunohistochemistry, a strong argument for a benign process.

- *Use your common sense.* This goes without saying. It is curious, however, how often this essential piece of advice is ignored!

By and large, similar advice goes for the use of molecular biology in the evaluation of lymphoid lesions. Controls, common sense, and the use of several primer pairs or techniques to confirm test results are equally as important here as they are for immunohistochemistry. The demonstration of clonality must be considered a (strong) argument for malignancy; however, not all clonal lesions are malignant and certainly will not behave in a malignant fashion, the obvious example being monoclonal gammopathy of undetermined significance (85). Again, the data must be interpreted in their entire context.

Even lineage determination (e.g., by demonstration of immunoglobulins or T-cell receptor rearrangements) is not absolute. The terms *lineage infidelity* and *lineage promiscuity* already suggest that there are exceptions to the rule that only B cells rearrange immunoglobulin genes and only T cells rearrange T-cell receptor genes (86,87,88,89,90). Obviously, additional techniques are invaluable in the analysis of lymphoid lesions, but only if they are properly used!

Spleen

J. Han J. M. van Krieken

Attilio Orazi

Introduction

Historically, the human spleen has attracted attention from poets as a producer of melancholy. Galen (131â€“201 AD) called the human spleen an enigmatic organ, a notion that has persisted for a long time. In the seventeenth century, Malpighi described, macroscopically, the splenic lymphoid follicles as white pulp against a background of red pulp. In 1857, Billroth published one of the first histologic studies of the human spleen in which he divided the red pulp into cord tissue and venous sinuses (1). Still, until the second half of the twentieth century, the spleen was considered a rather useless reservoir for blood cells and was hardly studied. In the 1970s, by using electron microscopy, Weiss was able to elucidate the fine structure of the organ, which gave insights into the red pulp function (2 ,3). During the same period, Nieuwenhuis, Ford, and Keuning performed immunologic function studies on rat spleen (4 ,5 ,6), and Veerman published a detailed description of the white pulp of the rat spleen (7). A complete summary of the organization and functions of the spleen is provided by Weiss in 1988, in the sixth and last edition of his *Textbook of Histology* (Cell and Tissue Biology) (8).

Nevertheless, many pathologists still lack a clear understanding of the

normal histology and functions of the human spleen. This is due to several reasons. The organ is extremely vulnerable to autolysis, which often makes histologic findings in postmortem specimens difficult to interpret and of limited teaching value. Surgically removed spleens are suitable, if processed without delay. However, since the number of splenectomies performed in most institutions is relatively scarce, it is not surprising that pathologists may feel uncomfortable when interpretating splenic pathology as a result of a lack of familiarity with splenic histologic features.

Another source of confusion with respect to the structure and function of the human spleen is in the terminology and definitions applied to this organ, which are still largely based on studies of animal spleens. The human and

animal spleens do not have an identical architecture; for example, in the human spleen, the periarteriolar lymphocyte sheath and the marginal sinus as described in rodent spleens are not present. Furthermore, certain definitions (e.g., of the marginal zone) vary widely from author to author (9 ,10).

The next problem is the large variations that occur in the â€œnormalâ€• spleen. The spleen is a compartimentalized organ (Table 32.1). Stimulation of one of the many functions of the spleen can lead to morphologic changes in the compartment that is mainly responsible for that function. The normal spleen therefore can show wide variation. As one of us has shown in a previously published study, it is essential to define a normal control population if one undertakes histologic studies in the spleen in specific disorders (11). For example, a morphometric analysis showed that spleens removed incidentally during abdominal surgery (i.e., for highly selective vagotomy or early gastric cancer) differed from traumatically ruptured spleens; we therefore excluded the latter from our â€œnormalâ€• group. All these problems sometimes make it difficult to differentiate physiologic from pathologic changes.

Part of this chapter is based on a previous study, performed by one of the authors, of methylmethacrylate sections of more than 400 surgically removed human spleens and our immunohistochemical experience using frozen (12 ,13) and/or paraffin-embedded tissue.

White pulp

T-cell area

Irregular area of small lymphocytes containing lymph vessels bordering arteries

Predominant CD4 lymphocytes

Paracortex containing lymph vessels

B-cell follicle

Round area of small lymphocytes surrounded by medium-sized lymphocytes (a germinal center may be present)

Production of Ig-producing cells and probably memory cells

Follicle

Perifollicular zone

Area between white and red pulp containing many erythrocytes and lacking a normal sinusoidal structure

Place of retarded blood flow with interaction of blood cells, cells, antigens, and antibodies

Medulla (?)

Red Pulp

Sinuses/cord tissue with sheathed capillaries

Tissue containing a meshwork of sinuses (with interrupted basement membrane) and capillaries, partly sheathed

Removal of particles from blood cells. Possible place of interaction of new antigens with reticulum cells

Sinus: partly high endothelial venule

Sheathed capillary: medullary sinus

Nonfiltering area

Area of red pulp tissue lacking capillaries and containing lymphocytes

Probably place of onset of immune reaction

Medulla or compartment of primary follicles

Perivascular rim

Spleen Compartment	Description	Function/Composition	Equivalent in Lymph Node
		Small area along the vessel tree containing lymphocytes and plasma cells Probably connected to lymphatics	Medulla (?)

Table 32.1 Summary of Splenic Histology, Function, and Relationship to Lymph Node Compartments

Prenatal and Developmental Changes

During embryogenesis, the spleen can be recognized from about the fifth week of gestation, and blood vessels appear in it by the ninth week. Red and white pulp cannot be distinguished until the ninth month. The functional role of the spleen during prenatal development varies widely from that of the adult spleen, and this is reflected in the microscopic anatomy of the organ. Hematopoiesis was considered to take place in the fetal spleen (and liver) and to contribute largely to blood cell formation in the fetus until the sixth month of gestation, but it has been shown that, in fact, the spleen functions at most as a site of maturation for hematopoietic precursors derived from the peripheral blood (14 ,15). In adults, one may see foci of hematopoietic cells (extramedullary hematopoiesis) in the spleen in many reactive conditions (e.g., sepsis), as well as in disorders of the bone marrow associated with myelofibrosis. Extramedulary hematopoiesis as seen in the spleen is also referred to as myeloid metaplasia.

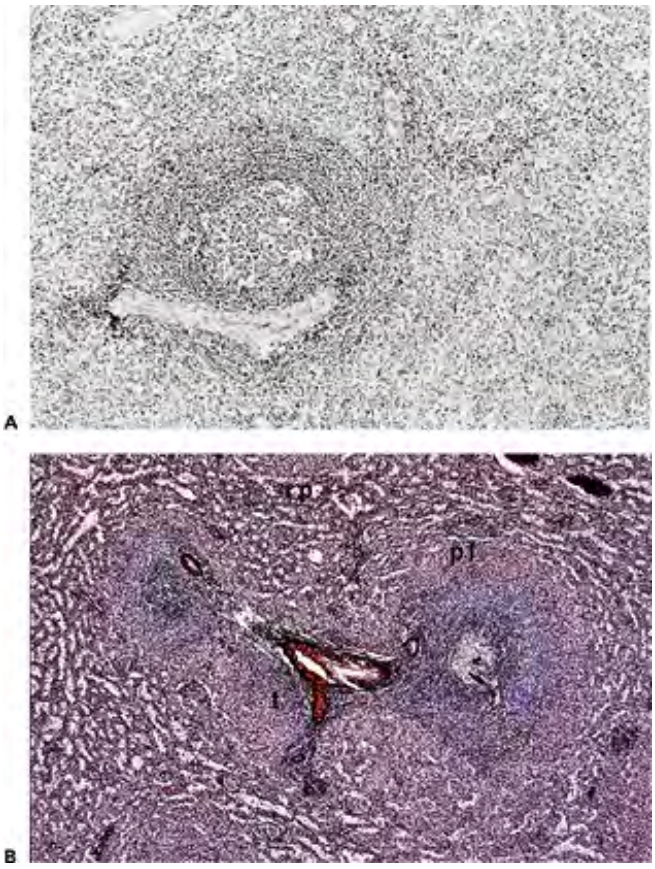

Figure 32.1 Spleen removed in idiopathic thrombocytopenic purpura. A. Formalin-fixed paraffin embedding (H&E, original magnification Ã—40). B. Methylmethacrylate embedding (methenamine-silver/H&E, original magnification Ã—40). Overview of red and white pulp showing central arteriole with T-cell area, a primary follicle, and a secondary follicle containing a germinal center. Note the absence of the marginal zone around the T-cell area and the presence of the erythrocyte-rich (pink) perifollicular zone surrounding both the T- and B-cell compartment of the white pulp. Note the lack of detail on the structure of the red pulp and the difficult discernable perifollicular zone in standard H&E section. (*rp,* red pulp; *pf,* perifollicular zone)

The immune system develops during fetal growth, and this development continues after birth (16). This functional maturation is reflected by the morphology: until birth the splenic white pulp does not contain

follicles and marginal zones. There are immature B cells in clusters and T cells scattered throughout the organ. Their numbers increase with the developmental age of the fetus; and, from the end of the second semester onward, B- and T-cell areas can be recognized (17 ,18). Phagocytosis can be demonstrated at the twelfth week of gestation (14 ,15).

Developmental changes of the spleen are very familiar. The presence of accessory spleens (so-called splenculi, small extra pieces of spleen tissue with the complete and normal histology of the red and white pulp) can be found in at least 25% of autopsies. In disorders being treated with splenectomy, these splenculi may lead to recurrence of the disease.

Rare but well known is the polysplenia associated with immotile cilia syndrome (19). In this syndrome, left-right orientation of thoracal and abdominal organs may be abnormal, and the spleen at the right side is often divided into many small pieces, generally having normal function. This is not to be confused with acquired splenosis, in which many small fragments of spleen are present after trauma. Congenital asplenia, which is exceedingly rare, is associated with abnormalities of the cardiovascular system.

Apoptosis

In the development of the spleen, apoptosis does not seem to play an important role, but the lymphoid compartment, as in other lymphoid tissues, shows extensive apoptosis, especially in the germinal centers of the B-cell follicles. This is illustrated in Figure 32.1 , where the â€œstarry skyâ€• phenomenon can be observed. The starry sky cells are macrophages that phagocytose remnants of lymphocytes that are dying through apoptosis, generally because they

have an unsuccessful gene rearrangement of the antigen receptor or because of the fact that the produced immunoglobulin recognizes autoantigen. This physiologic process is important in the protection

against autoimmune diseases. The Bcl-2 protein that protects against certain forms of apoptosis (see Chapter 1), which is expressed in most B and T cells, is lacking in germinal center B cells, rendering them susceptible for apoptosis. In follicular lymphoma the t(14;18) translocation leads to aberrant expression of Bcl-2 in the tumor cells. This is sometimes helpful in the recognition of follicular lymphoma in the spleen for the following reasons. Because the spleens of patients over about 20 years of age only rarely contain active germinal centers, the distinction between a primary follicle and follicular lymphoma can be difficult. Furthermore, the involvement of the spleen by follicular lymphoma is often nodular but does not lead to the disturbance of the architecture that is so noticeable in the lymph nodes involved by follicular lymphoma. Because spleens are often received after fixation, immunoglobulin light chain restriction is not possible by immunohistochemistry, immunofluorescence, or flow cytometry.

Apoptosis also plays an important role in mantaining a normal number and function of T cells. In cases of autoimmune lymphoproliferative syndrome (a pediatric disorder due to a genetic defect of FAS or FAS ligand that is associated with splenomegaly and autoimmunity), a decreased rate of apoptosis in T lymphocytes is responsible for the marked degree of lymphoid hyperplasia seen in the T-cell rich areas of the spleen.

Gross Features/Organ Weight

The human spleen is a bean-shaped organ surrounded by a smooth capsule covered by the peritoneum. In contrast to several species, the capsule does not contain smooth muscle fibers and therefore does not have the capability of undergoing contraction in response to acute blood loss. The spleen in animals such as dogs and cats has an important red blood cell reservoir function. By undergoing rapid contraction, the spleen can squeeze out its red blood cell reservoir and, by doing so, produce a rapid increase in the amount of circulating blood. The surface may be covered with fibrotic or even calcified

plaques, the cause of which is unknown. It is not uncommon to find several grooves at the outer surface that have no clinical significance. The weight of the spleen is highly variable (20). In adults, the spleen generally weighs 150 to 250 g; but, in the elderly, the spleen is often substantially smaller, even when there is no apparent hypofunction.

On the cut surface, the red and white pulp can be discerned, the latter consisting of small (less than or equal to 2-mm) nodules. It is important to realize that involvement of the spleen in malignant lymphoma often is observed foremost in the white pulp (21), which becomes enlarged but often not to a great extent. Therefore, the spleen should be cut up into small sections (less than or equal to 5 mm).

Anatomy

Blood Supply

Blood reaches the spleen via the splenic artery, a large branch of the celiac artery, and enters the spleen through four to six branches; their number and location is, however, highly variable. Venous outflow occurs via four to six venous branches. These combine, within the lienorenal ligament to form the splenic vein, which drains into the portal vein (22). This is why portal hypertension can produce â€œcongestiveâ€• splenomegaly. The blood flow within the spleen is highly specialized and relates to the different functions of the spleen.

Nerves

The spleen is innervated by nonmyelinated fibers from the major splanchnic nerves and the celiac plexus (23). These nerve fibers run along the splenic artery. Innervation in human spleens is less extensive than in cat and dog spleens, and this might be related to the important reservoir function of the spleen in these animals, as previously mentioned.

Lymphatics

No afferent lymphatic vessels are present in the spleen. Its lymph drainage occurs via hilar lymph nodes and lymph nodes in the gastrosplenic ligament. The lymph then flows through lymphatics along the splenic artery to the celiac lymph nodes along the celiac artery. The lymphatics in the spleen are described below.

Light Microscopy

Vascular Tree

After entering at the hilus, the splenic artery branches like a tree (24). Within the splenic parenchyma, these arterial branches, called trabecular arteries, are accompanied by veins and lymph vessels and surrounded by collagenous fibers. These vessels containing fibrous structures are usually referred to as trabeculae or septa, a term which is inappropriate to describe what in essence are perivascular collagen cuffs. Real, albeit short, true septa are also present in the spleen. These are connected to the capsule, lack inside vessels, and only extend for a short length into the splenic tissue. Foci of condensed reticular fibers devoid of vessels are found throughout the red pulp. The condensed reticulum

appears to be in direct continuity with the reticular meshwork of the surrounding red pulp; they may represent areas of collapse or involution of the red pulp tissue.

Trabecular arteries branch to form central arteries and arterioles that are no longer accompanied by veins and are surrounded not by a collagenous cuff but rather by lymphatic tissue predominantly composed of T lymphocytes. This lymphatic compartment, which is usually referred to as periarterial or periarteriolar lymphoid sheath (PALS) is present around the vessels and becomes smaller toward the capillary ending. The arterioles are usually described as branching into

penicillary arterioles, which run in parallel. In humans, however, this phenomenon seems to be restricted to involuted specimens in which the disappearance of tissue between arterioles has left them lying close to each other.

Branching of arterioles and capillaries often occurs at right angles, as can frequently be seen in sections. Reconstructions based on serial sections have shown that the terminal end of the capillary forms a peculiar and specifically splenic structure (25 ,26) (Figures 32.2 ,32.3). These structures are known by several names, determined partly by the species in which they have been studied, for example, sheathed capillaries, HÃ¼lsekapillaren, ellipsoids, or periarteriolar macrophage sheaths. In humans, they are present in the red pulp and the perifollicular zone and are generally referred to as sheathed capillaries. The sheathed capillary is surrounded by a â€œsheathâ€• of mononuclear phagocytes and rare reticulum cells. Because autolysis is so rapid, visualization of the sheathed capillaries in particular is dependent on adequate tissue processing. The endothelial lining of the capillary ends abruptly in a string of concentrically arranged macrophages. Blood cells coming from an arteriole have to pass through the sheathed capillary on their way to the lumen of the sinus, which they reach by slowly percolating through the cord macrophages and red pulp stroma (open circulation), and then via the slits in the basement membrane of the sinus (3 ,27). Although no direct anatomic connection between the arteriolar ends and the sinuses has been demonstrated, a proportion of the arteriolar branches may end in close opposition to walls of the sinuses, allowing a more rapid circulation (close circulation) of at least a portion of the blood flow. The red pulp sinuses are considered as the first part of the splenic venous tree.

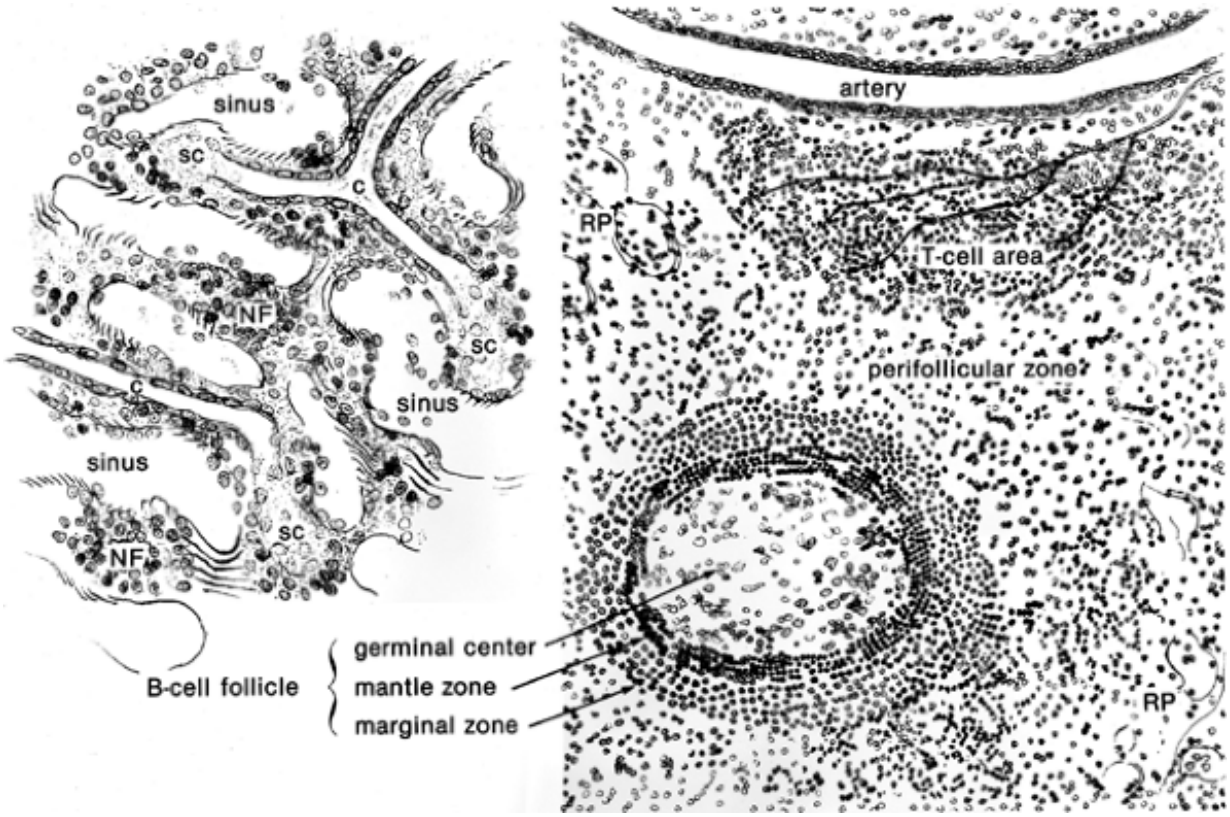

Figure 32.2 Schematic impression of red (*left*) and white (*right*) pulp, showing the main compartments and structures of the human spleen. The capillaries (*c*) end as sheathed capillaries (*sc*) without direct communication with the sinuses. The nonfiltering areas (*NF*) are bordered by sinuses and are devoid of (sheathed) capillaries. The perifollicular zone surrounds the white pulp (follicle and T-cell area) and lacks fully developed sinuses. Note the zoning in the B-cell but not in the T-cell compartment. The T-cell area contains a lymphatic plexus. (*Left,* original magnification Ã—250; *right,* original magnification Ã—100.)

The localization of the sheathed capillaries at the end of the arterial tree seem perfect for their functioning as a filtering unit.

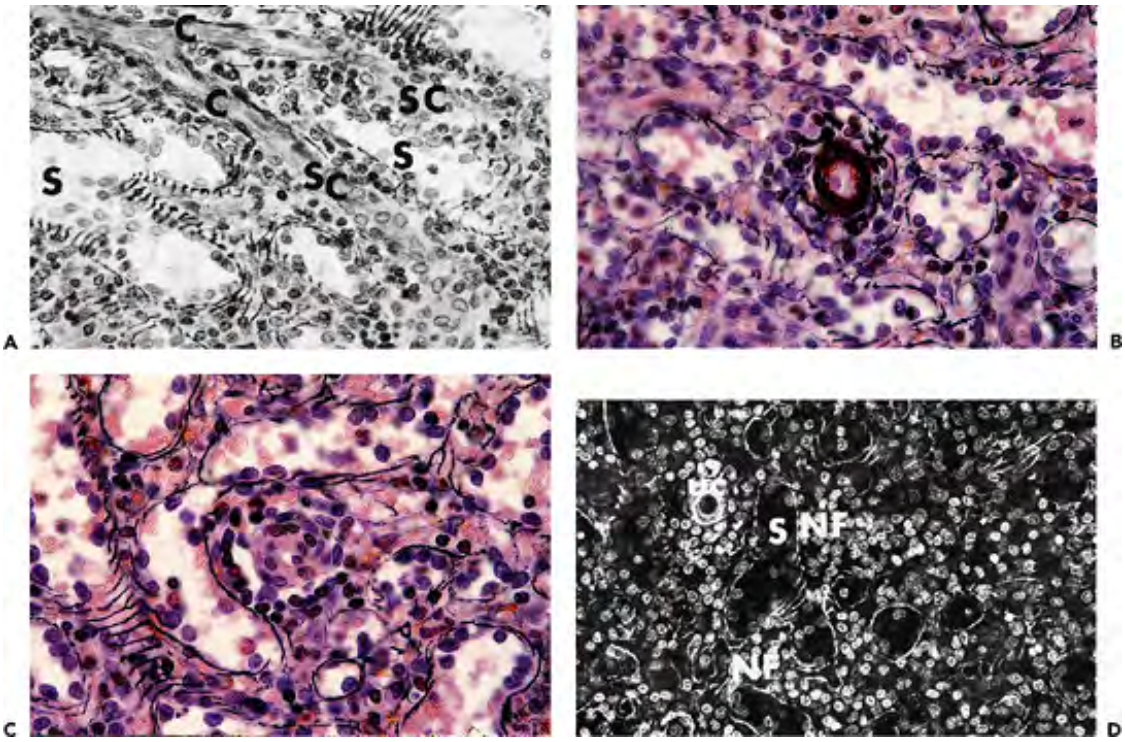

Figure 32.3 A. Traumatically ruptured spleen. Methylmethacrylate embedding (methenamine-silver/H&E, original magnification Ã—400). Capillary transitioning into sheathed capillary. Note the proximity to, but lack of connection with, the sinuses. (*C,* capillary (unsheathed); *SC,* sheathed capillary; *S,* sinus) B. Same specimen as in A (original magnification Ã—1000). Detail of unsheathed capillary. C. Same specimen as in A (original magnification Ã—1000). Detail of sheathed capillary. D. Same specimen as in A (original magnification Ã—250). Detail of the red pulp showing sinuses in cord tissue. Note the nonfiltering areas devoid of capillaries and completely surrounded by sinuses. (*Uc,* unsheathed capillary; *S,* sinus; *NF,* nonfiltering area)

Within the sinusoidal meshwork, there are large sinuses that open directly into veins running along the arteries in the collagenous cuff.

Small efferent lymph vessels can be found in the T-lymphocyte compartment of the white pulp in about two-thirds of the spleens. They are not seen in the surrounding perifollicular zone. A reconstruction

from serial sections showed that these lymph vessels form a network around arterioles and eventually follow the arterial tree to the hilar region (9 ,28).

Red Pulp

Seventy-five percent of the volume of the spleen is made up of red pulp (26). The two-dimensional picture given by conventional histology sections suggests that the red pulp is largely composed of cordal macrophages, interconnected by their cytoplasmic processes to form a reticular meshwork that provides structural support to the venous sinuses. Serial sections have shown, however, that the red pulp contains also a loose reticular framework, is rich in capillaries, and contains the terminal ends of the penicillary arterioles (Figure 32.3D). The sinuses account for about 30% of the red pulp (26). The sinus endothelial cells are surrounded by almost circular strands of discontinuous basement membrane that is predominantly composed of collagen IV and laminin, known as the ring fibers (Figure 32.4). The ring fibers are both interconnected among themselves and anchored to the dendritic processes of the cordal macrophages and splenic (fibroblastic) reticulum cells. Stromal fibers and reticulum cells running throughout the red pulp cords also contribute to provide structural support to this splenic area (the reticular meshwork of the red pulp).

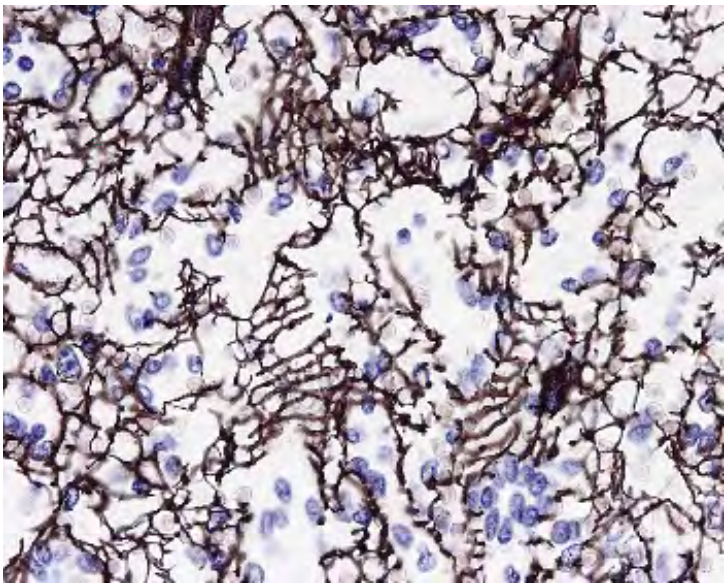

Figure 32.4 Normal spleen with red pulp stained with an antibody against collagen IV showing the ring fibers surrounding the sinuses (original magnification Ã—250).

A subpopulation of reticulum cells that express nerve growth factor receptor is found predominantly in periarteriolar location (29). These cells, most likely representing adventitial reticulum cells similar to those present in the adventitia of blood vessels, also have been observed within the stroma of bone marrow and lymph nodes (30). Myoid reticulum cells (smooth muscle actinâ€“positive, or SMA-positive) are found scattered throughout the red pulp. These cells are, however, much more concentrated within the marginal zone of the lymphoid follicles and in the PALS (31 ,32 ,33). Whether the SMA-positive red pulp cells correspond to fibroblastic reticulum cells that have undergone myofibroblastic differentiation, or are a truly separate population, is unclear at this time. The red pulp sinuses themselves form a complex network of their own with many interconnections and bulblike extensions with blind ends, the latter of which project into the cord tissue [see Figure 4 of van Krieken et al. (26)].

The sinuses are lined by elongated, flat endothelial cells with typical bean-shaped nuclei having a longitudinal cleft; these cells are also

known as littoral cells. Immunoperoxidase studies have shown positivity for endothelial markers and, unique among other endothelial cells, to CD8 (Figure 32.5) and often CD68 and CD21. Parts of the endothelial lining react also with a monoclonal antibody that also immunostains high endothelial venules in the lymph node (van Krieken JHJM, unpublished observation).

The preponderant function of red pulp is blood filtration. However, in serial sections, one might notice that a fair amount of the red pulp tissue does not include capillary endings, including sheathed capillaries, and that these areas are surrounded only by sinuses. Small aggregates of lymphocytes (both B and T) and mononuclear phagocytes are present (Figure 32.3), which means that these nonfiltering areas of the red pulp should be regarded as a previously unrecognized splenic lymphoid compartment in addition to the white pulp. Morphometrically, the size of this lymphoid, nonfiltering red pulp compartment seems to be comparable to that of the white pulp (26). Newly formed white pulp follicles might originate from the small lymphoid aggregates of these nonfiltering areas.

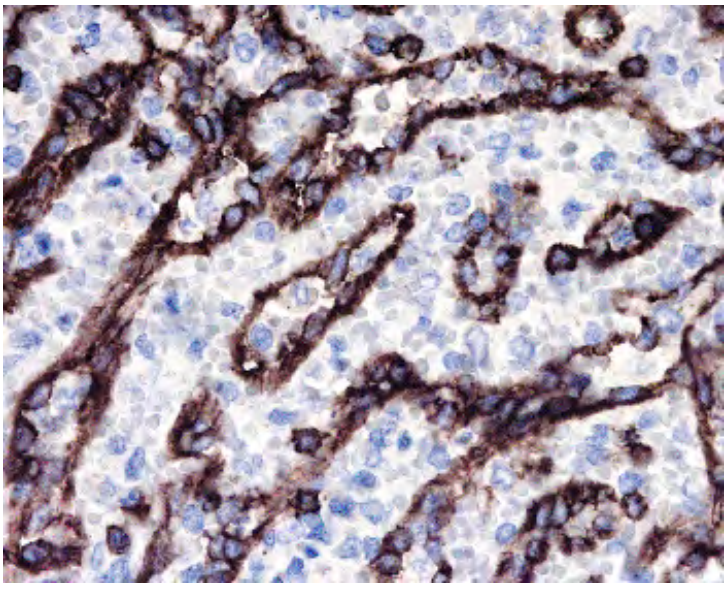

Figure 32.5 Normal spleen, red pulp stained with anti-CD8 showing the positive sinus endothelial cells (original magnification Ã—400).

Blood cells can only reach these areas by passing through large stretches of red pulp tissue or, which seems more likely, via influx from the sinus by passing through the sinus endothelium. A retrograde return of lymphocytes from the venous sinus lumen back into the splenic tissue is known for the rat spleen, where lymphocytes migrate through the walls of what is called the marginal sinus into the white pulp. This type of sinus is histologically not discernable in the white pulp of the human spleen. In humans, the role played in the rat by the marginal sinus in the exchange of lymphocytes between the sinusoidal circulation and the splenic lymphoid compartment might be played by the previously described blind-ended bulblike extensions of the red pulp sinuses, representing a splenic endothelial component with high endothelial venulelike characteristics. This hypothesis is supported by the observation that, in humans, splenic follicles are surrounded by a perifollicular zone, a distinct splenic compartment containing erythrocyte-filled vascular spaces. The perifollicular zone sinuses differ from the typical red pulp sinuses in their enhanced expression of CD34. Recent evidence has suggested that this zone may represent the entry compartment for recirculating lymphocytes into the white pulp since it is capable of supporting influx and local proliferation of lymphoreticular cells, particularly CD4-positive T lymphocytes (33).

It has been recently suggested that the entry of these cells may be dependent on the presence in the perifollicular area of specialized reticulum cells with an endothelial-like phenotype secreting lymphokines and guiding the T cells into the PALS (33).

White Pulp

The white pulp consists of B- and T-cell lymphoid compartments (11) (Figure 32.1). The B-cell compartment mainly consists of the splenic lymphoid follicles. These are composed of a germinal center (only found in secondary follicles) directly surrounded by a ring of small lymphocytes, called the mantle zone or corona, which in turn is surrounded by the marginal zone that contains medium-sized

lymphocytes (Figure 32.6). The germinal centers have similar features to those found in other lymphoid organs. They are formed by a scaffold of follicular dendritic cells that express CD21, CD23, CD35, and the low-affinity nerve growth factor receptor. The B cells of the germinal centers express CD20, CD19, CD10, and CD79a but not CD5. They have a high proliferation activity with Ki-67 and do not express Bcl-2. The T lymphocytes present within germinal centers are predominantly CD4-positive; tingible-body macrophages are CD68-positive. Mantle zones consist predominantly of CD5-positive small lymphocytes that are IgM-, IgD-, Ki-B3â€“, and DBA.44-positive and alkaline phosphataseâ€“negative (Figure 32.7). The marginal zone lymphocytes are, in contrast, positive with alkaline phosphatase and are IgD-, Ki-B3â€“, and DBA.44-negative (34). The marginal zone also contains a population of macrophages that are functionally distinct from the cord histiocytes of the red pulp, which, at least in animal models, seem to be important in maintaining the anatomic structure of the marginal zone by attracting newly differentiated marginal zone B lymphocytes into it. These cells move into the marginal zone area from the germinal center, where they derive from a common follicular/marginal zone precursor B cell (35).

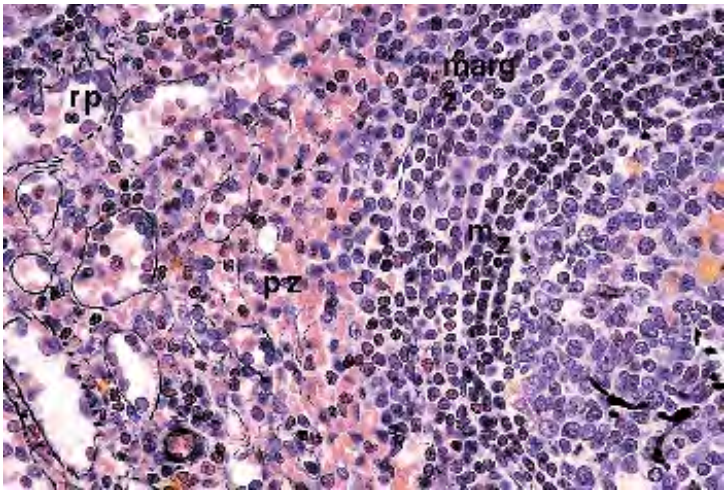

Figure 32.6 Same specimen as in Figure 32.3 . A secondary follicle (germinal center to the right) borders the red pulp. (*mz,* mantle zone; *margz,* marginal zone; *pz,* perifollicular zone; *rp,* red pulp; original

magnification Ã—100)

The reticulin framework of the marginal zone is characterized by the presence of numerous SMA-positive reticulum cells arranged in a concentric meshwork pattern. The marginal zone SMA-positive cells continue into the T-cell zones, where reticulum cells, exhibiting the same immunophenotype, form the reticular framework of the PALS. Cells with SMA positivity are also seen, although less frequently, in the perifollicular zone and throughout the red pulp. These cells become more prominent in the presence of red pulp congestion, such as seen in cases of fibrocongestive splenomegaly (Figure 32.8) (29 ,36). Contractile capability may be important for a scaffoldlike reticular structure capable of being reversibly stretched around lymphoid follicles as they expand and contract within the PALS.

In the rat spleen, the mantle and marginal zones are separated by a marginal sinus that can easily be seen by light microscopic examination. It plays an essential role in the splenic immune function as the site of entry of lymphocytes and antigens (37). This dividing sinus is not discernible in humans, at least by light microscopy. Recently, by using electron microscopy, a marginal sinuslike structure was described (38), although, surprisingly, it seems to be absent in active follicles (39). However, neither the exact location nor functional properties of this structure are known.

The light microscopic differences with rodent spleens has led to confusion in the definition of follicular structures

of the human spleen. The term *marginal zone* has been used with different meanings (11 ,40 ,41 ,42). Some investigators use the term to refer to the ring of medium-sized lymphocytes that surrounds the outer border of the mantle zone; few others have included the mantle zone, still others only the bordering area between the red and white pulp, and sometimes even the zone surrounding the T-cell areas (PALS). We prefer to reserve the term *marginal zone* for the unique

splenic structure that encases from the outside the IgD- and IgM-positive small lymphocytes of the mantle zone (in the secondary follicle) or of the primary follicle. We refer to the bordering area between the red and white pulp as the perifollicular zone. The same definitions are used in the extensive Japanese literature on the histology of the human spleen. However, the Japanese investigators call our marginal zone the inner marginal zone and refer to the perifollicular zone as the outer marginal zone. Because of the totally different architecture and cell population of these two structures, we find it preferable to use different names.

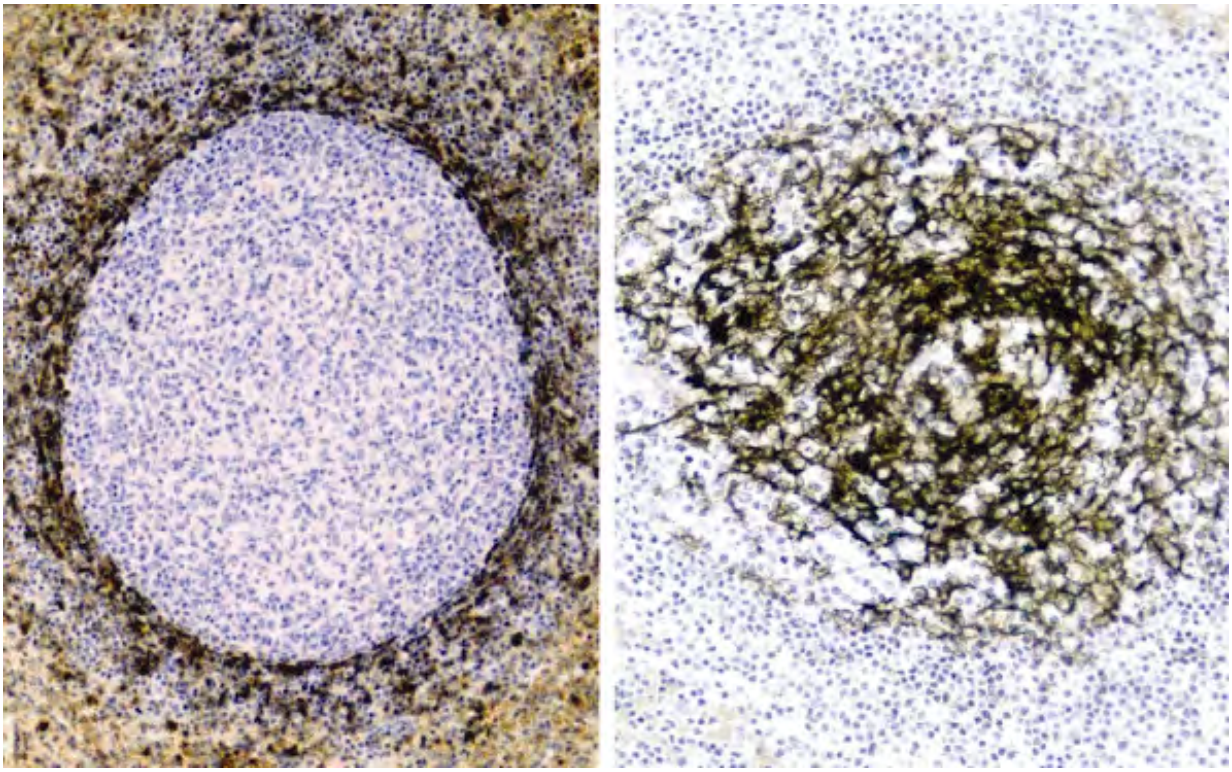

Figure 32.7 Normal spleen showing the positive mantle zone cells for DBA.44 (*left,* original magnification Ã—40) and the dendritic cells stained for CD21 (*right,* original magnification Ã—40).

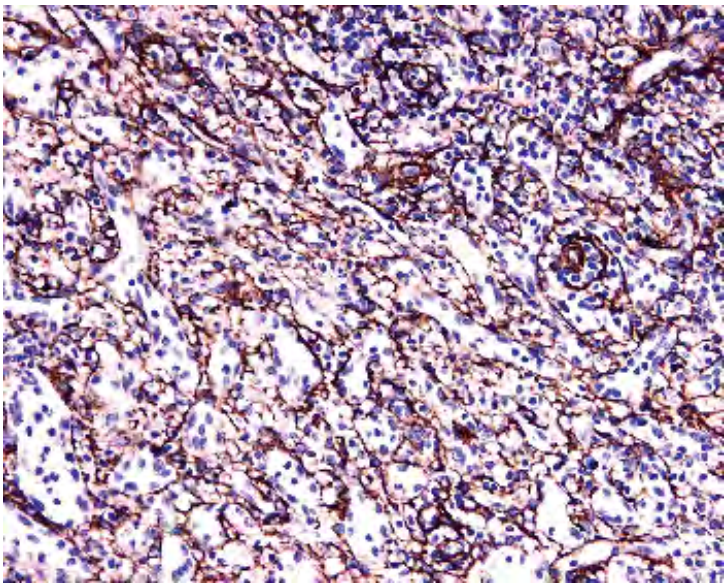

Figure 32.8 Spleen in fibrocongestive splenomegaly showing increased expression for smooth muscle actin (original magnification Ã—100).

The T-cell areas lie around arterioles but are not as regularly arranged as in the PALS seen in the rodent spleen (Figure 32.9). The arterioles are not constantly covered by these cylindrical lymphoid cuffs; they can be seen â€œnakedâ€• traversing follicles and even germinal centers.

In humans, the PALS are rather irregular aggregates of small polymorphic T lymphocytes, most of which express CD4 reactivity (T-helper/inducer lymphocytes). The T-cell areas are also surrounded by a perifollicular-like zone. The follicles sometimes border T-cell areas, with which they share a common perifollicular zone.

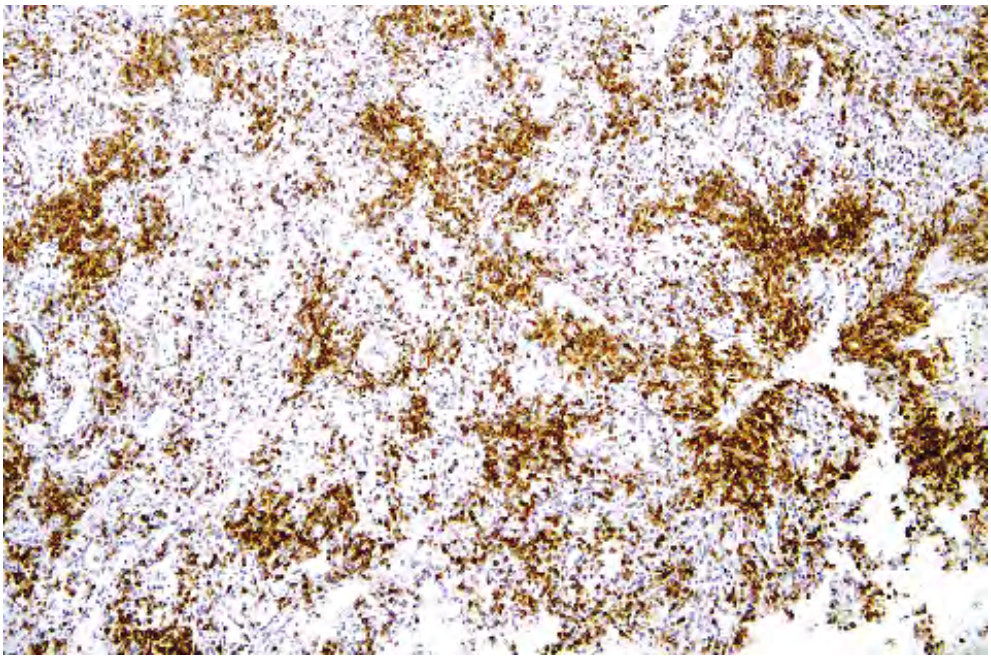

Figure 32.9 Normal spleen stained with anti-CD3 antibody (original magnification Ã—40) showing the somewhat loosely organized T-cell compartment.

Perifollicular Zone

The perifollicular zone (PFZ) is a specialized compartment of the red pulp that is associated with its own reticular stroma; PFZ is found both at the outside of the white pulp marginal zone (in the follicles) and at the periphery of the T-cell areas (PALS). In the PFZ, the reticular fibers are more widely spaced than in the rest of the red pulp (Figures 32.2 and 32.6). In silver-stained plastic sections, the PFZ can be identified by the paucity of basal membrane strands and by the presence of a vascular pattern that is different from the one seen in the rest of the red pulp. At the outer border of this area, red pulp sinuses are more widely spaced than elsewhere, and a rich network of capillaries, including sheathed capillaries, is present. The PFZ contains a considerable numbers of erythrocytes and leukocytes.

The PFZ zone at the outside of the white pulp stands out in silver-

stained sections but may be poorly visible in routine hematoxylin- and eosin (H&E)-stained sections. However, since the PFZ contains a large number of erythrocytes, it can be recognized by its deeply congested appearance around the densely packed lymphocytes of the T- and B-cell areas (Figure 32.1A). The erythrocytes are seen more regularly in PFZ than in the red pulp sinuses; the red pulp sinuses outside the PFZ often appear to be less filled with these cells than the cord tissue.

The PFZ, which makes up about 8% of the spleen, contains a mixture of blood cells comparable with that of the peripheral blood. It has been suggested that this area is responsible for the passage of the about 10% of the splenic blood, which is known to have a retarded flow (11).

Flow Cytometry

The spleen has been only rarely investigated by flow cytometry. Recently, we have looked at the immunophenotypic characteristics of the human spleen lymphocytes and have established reference values for those cells in normal and reactive spleens (43). Altough the results obtained showed B- and T-antigen patterns of expression comparable to those seen in other lymphoid organs, a few differences were noted (Table 32.2). In contrast to the thymus and bone marrow, the spleen contains only very rare Tdt-positive lymphoid precursors. Within the Bcell subsets, the spleen shows a frequency of CD19-positive/CD20-negative B cells that is higher than in the peripheral blood or lymph node. This corresponds to the presence, in the spleen, of a sizable proportion of early plasma cells (CD138-negative) as well as more mature plasma cells. Other findings included a significant population of CD20/CD5â€“positive B cells, accounting for approximately 10% of the B lymphocytes; the presence of CD4/CD8 ratio of 1.2:1 (lower than in the blood but similar to the one seen in lymph node) and a mean number of Î³/Î´-positive T cells (of all CD3-positive cells) of 6% in normal and 10% in reactive spleens. While in the peripheral blood, NK/T cells account for less than 6% of the CD3-positive circulating lymphocytes, our study showed a relatively high frequency of these

cells in the spleen. Similar results have been observed in the liver by others and support the concept that spleen and liver lymphocytes have specific, although yet unknown, immunoregulatory functions (43).

Ultrastructure

Electron microscopy (especially scanning electron microscopy), including the use of microcasts from the vasculature, has elucidated largely the functional microanatomy of the spleen. These studies have shown the routes that blood cells take through the spleen and have also clearly illustrated the pitting function of the spleen (removal of inclusions in erythrocytes) exerted by the sinusoids. In spleen examined in a diagnostic-oriented setting, however, there is hardly if ever the necessity of using ultrastructural studies.

Function

The human spleen has several important functions. However, splenectomy in general does not lead to impaired health, except for an increased risk of overwhelming postsplenectomy infections caused by encapsulated bacteria (e.g., pneumococci). The reason for this is that many functions of the spleen, at least in adults, can be taken over by other organs.

In humans, the spleen is involved in the primary immune response to bloodborne antigens and polysaccharide antigens; it also acts as a regulator of immune reactions elsewhere in the body. It contains a specific environment that facilitates the binding of antibodies and antigens; cells or microorganisms covered by antibodies are trapped and destroyed in the spleen, as are erythrocytes that have decreased flexibility and lowered osmotic resistance (1 ,44 ,45 ,46 ,47 ,48 ,49 ,50).

Each of these functions takes place in a specific splenic compartment, which is capable of undergoing rapid changes in its size and

composition, even under physiologic conditions. Therefore, the main splenic functions to be considered include blood filtering, immunologic function, hematopoiesis, and reservoir.

Filter Function

The location and specialized anatomy of the spleen is especially suitable for its function as a filter of the blood. Normal blood cells are capable of traversing the barrier of macrophages of the sheathed capillary, the red pulp cord macrophages, and the sinus endothelium (collectively, the filtering unit of the spleen) at a speed comparable to that of the blood in the capillary bed of other organs. However, in cases in which the flexibility of the red blood cell is diminished (e.g., by aging, intoxication, or congenital defects), the macrophages of the splenic filtering unit can eliminate the abnormal cell by ingesting it. The filtering function includes a process known as pitting, a term which is used to describe the removal of inclusions, such as nuclear remnants known as Howell-Jolly (H-J) bodies, from erythrocytes without destroying the cell. The presence of H-J bodies in circulating

erythrocytes in the peripheral blood indicates the presence of splenic hypofunction (e.g., splenectomized patients).

In addition to red blood cells, the macrophages of the spleen can readily take up bacteria, antigens, and immune complexes. The spleen is capable of filtering out reticulocytes, platelets, hematopoietic stem cells, lymphocytes, and dendritic cells from the blood and provides the proper microambient conditions for their further differentiation. Also, it sequesters monocytes from the blood and facilitates their transformation into splenic macrophages (8).

Immunologic Function

The spleen plays a more important role in the development of the immune system, but even in adults the spleen is still involved in B- and T-lymphocyte production and differentiation. The spleen receives B and T cells from the recirculating lymphocyte pool and sorts them into dedicated compartments such as the follicles and the PALS, where they can interact with antigens and antigen-presenting cells and become capable of mounting effective immune responses.

The marginal zone is a component of the B-cell follicle and is a remarkably larger compartment in the spleen than elsewhere (e.g., tonsils). Although the exact physiologic function(s) of the marginal zone is still unclear (42), its main immunologic role relates to the thymus-independent rapid response to bloodborne microorganisms; since these are rapidly trapped in the spleen and brought directly into contact with numerous immunocompetent cells, the spleen is well situated for this task.

Hematopoiesis

In rodents, the spleen has a large hematopoietic function, but this is not the case in humans. As described above, the hematopoietic function is only present in the fetal spleen; in the adult spleen, hematopoiesis

does not occur (15). Hematopoietic cells encountered in the adult spleen originate from circulating, marrow-derived, progenitors/early precursors that become entrapped in the spleen and are capable of undergoing further differentiation. When this â€œphysiologicâ€• phenomenon reaches pathologic relevance by causing splenomegaly, it is termed splenic myeloid metaplasia or extramedullary hematopoiesis. Although splenic myeloid metaplasia can be seen in many different conditions, the most striking examples of this condition can be observed in patients with chronic idiopathic myelofibrosis (15).

Reservoir Function

The human spleen contains about 300 mL of blood. This is a relatively small amount, in contrast to that seen in a dog or cat. In these animals, the spleen functions as an important blood reservoir; and in situations where more blood is needed, its rapid contraction can increase substantially the amount of circulating blood cells. It is highly doubtful that this function occurs at all in humans, whose splenic capsule lacks a significant component of smooth muscle fibers. The spleen, however, does function as a reservoir for factor VIII of the clotting system, platelets, granulocytes, and iron.

Aging Differences

In infancy and childhood, the immune system is not yet fully developed, and this is also reflected in the histology of the spleen. The marginal zone is observed as a separate compartment only after four months of age; moreover, the marginal zone B cells in the spleen of infants have a different phenotype (lack CD21; IgD- and IgM-positive) compared with adult marginal zone B cells (51). An important age difference, in our experience, is the regular occurrence of germinal centers in the white pulp of normal spleens in patients younger than 20 years; older patients have been shown to have only rare secondary follicles (9). The often mentioned age-dependent atrophic change has only been documented in patients in their eighth decade of life (11).

Hyalinization of vessels in the spleen is seen frequently, even in very young children and, therefore, does not represent a pathologic finding (52).

Differential Diagnosis

In the spleen, compartmentalized lymphoid tissue (white pulp) is interwoven by the filtering red pulp. Each splenic compartment reacts to external stimuli with physiologic changes in its composition and histology. As in the lymph node, the line between pathologic and impressive but essential physiologic reactions is vague. The amount of white pulp, for instance, varied from 5 to 22% of the total splenic tissue in a normal control group (11).

As previously mentioned, normal blood cells can pass undamaged through the barrier of macrophages of the sheathed capillary and the red pulp cord tissue as well as the sinus endothelium (i.e., the filtering unit of the spleen) at a speed comparable with that of the blood flow in the capillary bed of other organs. However, when the flexibility of the blood cells is diminished (e.g., by aging, intoxication, or congenital defects), the red pulp macrophages can ingest the abnormal cells. In this process, the sheathed capillaries seem to lose their macrophages, which spread out into the surrounding red pulp or enter the sinuses to be transported to the liver. In cases characterized by chronic stimulation of the filtering function, it can be demonstrated that the amount and length of the capillaries increase in parallel with the hypertrophy of the red pulp, whereas the sheathed capillaries are less readily seen in the sections (26). In idiopathic thrombocytopenic purpura (ITP), remnants of

phagocytosed thrombocytes can be seen as periodic acid-Schiff (PAS)-positive fragments in cord macrophages. If blood cells are covered by immunoglobulins or immunocomplexes, parts of the cell membrane can be removed by the sinus endothelium by â€œpitting and culling,â€• giving rise to a spherocyte. This happens in a fashion similar to the

removal of nuclear remnants, as previously described (15).

In septicemia, the filtering compartment may show morphologic findings (activation and hyperplasia of macrophages) indistinguishable from those seen in cases of acute or chronic hemolysis; these changes are most likely induced by the presence of circulating immunocomplexes, fragmented cells, or antibody-coated cells. In these conditions, postmortem autolysis of the activated macrophages can lead to early disintegration of the red pulp cells and stroma. The septic spleen at autopsy thus probably represents an artifact that can be the result of, but is not specific for, sepsis; it, especially, should not be diagnosed as splenitis. True splenitis, in which the spleen contains an inflammatory response to a local noxious agent such as in typhoid fever or tropical diseases, is rare in the Western hemisphere. Lymphoplasmacytoid cells and plasma cells normally rim arteries and arterioles and extend along red pulp capillaries. This perivascular cellular rim also may contain some macrophages or small epithelioid granulomas, the significance of which is unclear. The perivascular presence of plasma is a normal finding and by no means justifies a diagnosis of splenitis, nor does the diffuse influx of granulocytes throughout the red pulp in specimens resected during prolonged surgery.

The effects of chronic venous congestion are not clear. In our preliminary studies in patients dying with chronic cardiac disease, the so-called effect of chronic cardiac congestion on the lymphoid and filtering compartments appears more likely to be the effect of concomitant infections or is therapy mediated. In chronic venous congestion due to portal hypertension, the sinuses are normal in size but contain fewer buds and appear rigid. The amount of cord tissue and the number of capillaries are both decreased; in the cord tissue, an increase of reticular fibers (fibrocongestive splenomegaly) and increased expression of smooth muscle actin in reticulum cells is seen (26 ,36). Infarcts in the splenic tissue are microscopically more irregularly defined and poorly demarcated than could be expected macroscopically due to the intricate distribution of the splenic vessels.

In three-dimensional reconstructions, capillaries from different arterioles are seen to cross each other with overlapping territories.

Primary tumors of the spleen are rare. Metastatic carcinoma seems especially to occur in neuroendocrine tumors, including small cell carcinoma of the lung, with a conspicuous tendency for intrasinusoidal spread. Malignant lymphomas exhibit a homing pattern to specific splenic compartments dependent on the type of lymphoma, similar to that observed in other lymphoid organs (21). In nonlymphomatous hematopoietic malignancies involving the spleen, their distribution pattern is similar to that observed in the bone marrow: extramedullary erythropoiesis and megakaryopoiesis are found primarily along and within the sinuses of the red pulp, whereas myelomonopoiesis is found in proximity of the capillaries within the cord tissue. Blastic infiltration seen in cases of acute leukemia can be found anywhere in the spleen.

Specimen Handling

The spleen is quite vulnerable and, due to the large numbers of macrophages and granulocytes, may undergo rapid autolysis. Proper and rapid fixation is therefore important, and this goal is not reached when the entire organ is put into formalin. For proper handling, the specimen has to be received fresh, and handling has to be rapid. The organ is weighed and the surface examined. After that, the organ is cut into small slices of 0.5 cm. Then the cut surface is inspected carefully for nodules larger than normal white pulp. Ideally pieces should be frozen for flow cytometry, cryostat section immunohistochemistry, or other techniques. When no abnormalities are seen, at least three or four blocks are taken out randomly and processed for microscopic examination.

Histologic Technique

Routine paraffin embedding leads to shrinkage and loss of cellular detail. Because routine H&E staining often does not yield sufficient

information, the use of appropriate histology techniques, such as plastic embedding (53), methenamine-silver/H&E stain (54), or at least, PAS and Gomori's reticulin stains, is necessary for an adequate morphologic analysis of the splenic microarchitecture (Figure 32.10).

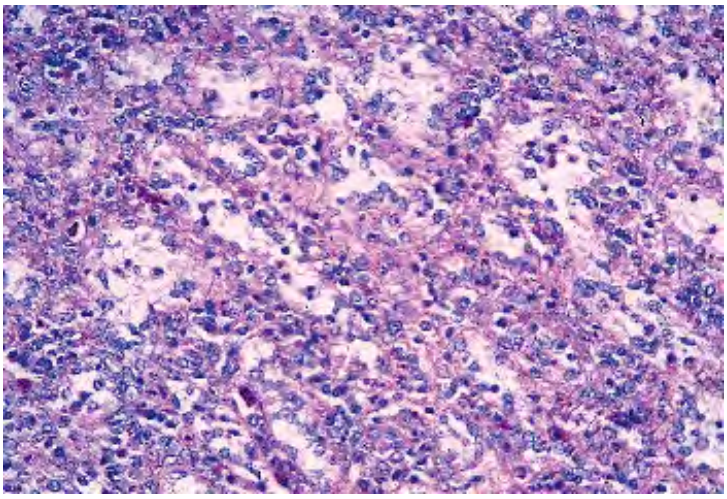

Figure 32.10 Same specimen as in Figure 32.1 . Detail of red pulp showing with some difficulty the structure of the sinuses (PAS stain, paraffin-embedded, original magnification Ã—200).

Special Procedures

The spleen is only rarely removed for diagnostic purposes. Staging laparotomy is no longer part of the required diagnostic workup of a patient with Hodgkin's disease. Therefore, splenic pathology may be seen as an unsuspected incidental finding in a patient splenectomized for other reasons (e.g., chronic idiopathic thrombocytopenia, trauma). Not uncommonly, splenic lymphoma may be discovered as an incidental finding. A high degree of suspiciousness of the grossing pathologist is necessary in these case since, for optimal lymphoma diagnosis, it is often necessary to apply techniques that require fresh/frozen tissue, such as flow cytometry, frozen tissue immunohistochemistry, molecular analysis, and/or cytogenetics (Figure 32.8).

In view of the frequent lack of fresh specimens, clonality assessment in a spleen is usually done by immunohistochemistry applied to paraffin-embedded tissue, looking for a restricted pattern of immunoglobulin light chain expression in B cells. This is one of the most important â€œspecial techniquesâ€• used in routine diagnostic laboratories. In addition, clonality can also be established by using a polymerase chain reactionâ€“based technique for detecting immunoglobulin gene rearrangement, which can also be succesfully applied to paraffin-embedded tissue (55).

Immunohistochemistry can also be necessary to characterize other hematopoietic and nonhematopoietic tumors, the latter primary or metastatic, which can occur (although infrequently) in the spleen. In storage disorders such as Gaucher's disease, electron microscopy can be of additional value, although biochemical analysis is considered by most experts as the most practical and specific approach.

Conclusion

The human spleen has always been a somewhat enigmatic organ. Studies of its histology must be based on carefully selected, surgically excised â€œnormalâ€• spleens. The organ should be processed immediately and appropriately for optimal results.

Previous studies by one of us of a large series of spleens with adequate histologic techniques and with reconstruction based on serial sections has shown that the spleen is a highly compartmentalized organ (Table 32.1). Each compartment has its own structure and cell populations and often a separate function. The old division into red and white pulp is probably oversimplified and should be expanded.

Human and animal spleens are different in many important structural aspects; data extrapolation from animal studies to humans is therefore problematic and often unwarranted.

Bone Marrow

S. N. Wickramasinghe

Introduction

The bone marrow is a large and complex organ that is distributed throughout the cavities of the skeleton. The total mass of the bone marrow of an adult has been estimated to be 1600 to 3700 g, exceeding that of the liver. About half this mass consists of hematopoietically inactive fatty marrow (which appears yellow) and the remainder of hematopoietically active marrow (which appears red). Although essentially hematopoietically inactive, even fatty marrow contains a few scattered microscopic foci of hematopoietic cells. The functions of hematopoietic marrow include: (a) the formation and release of various types of blood cells (hematopoiesis), mast cells, osteoclasts and some endothelial progenitor cells; (b) the phagocytosis and degradation of circulating particulate material such as microorganisms and abnormal or senescent red cells and leukocytes; and (c) antibody production. Recent studies indicate that, in addition to hematopoietic stem cells, the marrow contains mesenchymal stem cells that can differentiate under appropriate conditions into adipocytes, hepatocytes, osteoblasts and osteocytes, chondrocytes, skeletal and cardiac muscle cells, kidney cells and neural cell lineages, but the

interpretation of some of the data is still being debated (1). The nonhematopoietic marrow serves as a large store of reserve lipids. The various functions of hematopoietic marrow are based on a high degree of structural

organization. However, this organization is labile, altering rapidly in response to many stimuli.

Techniques for Studying the Marrow

The microscopic structure of the human bone marrow can be studied during life by performing a trephine biopsy of the posterior superior iliac spine or anterior iliac crest. This provides a core of bone and associated marrow. The biopsy specimen is commonly fixed in 10% neutral buffered formalin for 6 to 18 hr (depending on its width) but may be fixed in Zenker's solution for a minimum of 4 hr or in B5 (formalin and mercury chloride) for 4 hr. The fixed specimen is decalcified in 10% formic acid and 1% formalin or in one of a number of other decalcifying reagents. It is then processed in the usual manner and embedded in paraffin (2,3,4). Decalcification and paraffin embedding result in some shrinkage of marrow tissue, loss of the activity of cellular enzymes, and, sometimes, blurring of nuclear staining. In addition, certain decalcification procedures cause leaching of the iron stores (i.e., of the hemosiderin present within macrophages). However, the reactivity of some antigens with antibody is retained.

Table 33.1 Some Monoclonal and Polyclonal Antibodies that can be used in Immunohistochemical Studies on Sections of Decalcified, Paraffin-Embedded Trephine Biopsies of the Marrow

Antibody	Antigen	Cellular Specificity in Normal Tissue
Anti-CD34, QBEND10	CD34	Hematopoietic stem and progenitor cells, endothelial cells
Leu-M1	CD15	Neutrophil granulocyte series[a], monocytes
Antilysozyme	Lysozyme	Neutrophil granulocyte series[a], monoblasts, monocytes, macrophages
NP57	Neutrophil elastase	Neutrophil promyelocytes and myelocytes (strong), neutrophil metamyelocytes and granulocytes (weak), monocytes
Antimyeloperoxidase	Myeloperoxidase	Neutrophil granulocyte

		series[a]
Antilactoferrin	Lactoferrin	Neutrophil myelocytes to granulocytes
PG-M1, KPâ€“1	CD68	Monocytes, macrophages
Antiglycophorin A or C	Glycophorin A or C	Erythroid series
Antihemoglobin A	Hemoglobin A	Erythroid series
Antifactor-VIIIâ€“related antigen	von Willebrand factor	Megakaryocytes, endothelial cells
Y2/51	CD61, GP IIIa	Megakaryocytes, platelets
PD7/26, 2B11, antileucocyte common antigen	CD45	T and B lymphocytes, macrophages, granulocytes (weak)
UCHL 1	CD45 RO	T lymphocytes
Anti-CD3	CD3	T lymphocytes

L26	CD20	B lymphocytes, activated B lymphocytes
Anti-CD79a (JCB117)	CD79a	B lymphocytes
Anti-Ig light chain (Îº or Î»)	Light chain	Plasma cells, immunoblasts, B lymphocytes (weak)
Anti-Ig heavy chain	Heavy chain	Plasma cells, immunoblasts, B lymphocytes (weak)
Leuâ€“7	CD57	Natural killer cells, some cytotoxic T lymphocytes
AA1	Mast cell tryptase	Mast cells
Kiâ€“67, MIBâ€“1	Kiâ€“67 nuclear protein	Proliferating cells

[a]Other than normal myeloblasts

Histologic studies also can be performed on aspirated marrow. Two

methods are in use. The first is to allow the marrow to clot before fixation and subsequent processing to paraffin. The clot sections obtained usually show only a few marrow fragments within a large mass of clotted blood. The second approach is to concentrate the marrow fragments by filtration or some other procedure before processing. This approach yields better preparations than do clot sections.

Sections of paraffin-embedded marrow fragments or decalcified bone cores are cut to a thickness of 3 to 5 Âµm and are routinely stained with hematoxylin and eosin (H&E), with the Giemsa's stain, by a silver impregnation technique for reticulin, and by Perls' acid ferrocyanide method for hemosiderin (Prussian blue reaction). They may also be stained by the periodic acid-Schiff (PAS) reaction for glycogen or glycoprotein. A Leder's stain for chloroacetate esterase may be performed on sections of marrow fragments but works poorly on decalcified specimens (2). A limited range of antibodies can be used for immunohistochemical studies on formalin- or B5-fixed, paraffin-embedded sections of trephine biopsy specimens, using an immunoalkaline phosphatase or immunoperoxidase method. The most useful antibodies and the cell types they recognize are given in Table 33.1 (5,6,7,8,9,10,11).

The cores obtained by trephine biopsy also may be fixed in a mixture containing formaldehyde, methanol, and glucose phosphate buffer and embedded in methyl methacrylate without decalcification (4,12,13,14,15). Semithin sections (1â€“3 Âµm thick) of the undecalcified methyl methacrylateâ€“embedded material then may be cut using a special heavy-duty microtome. Such sections show cellular features in much greater detail than do paraffin-embedded sections but have no antigenic or enzymic reactivity. On the other hand, if the core is appropriately fixed and embedded in glycol methacrylate (a water-miscible plastic) or a mixture of methyl and glycol methacrylate, a number of antigen epitopes and enzyme activities are preserved (16,17,18).

Methyl methacrylateâ€“embedded semithin sections may be stained (after removing the methacrylate) with H&E or gallamine blueâ€“Giemsa for cellular detail, Gomori's stain for reticulin fibers, PAS stain, Berlin blue stain for iron, and Ladewig's and Goldner's stains for osteoid, calcified bone, and connective tissue (14,15,19,20,21). Trephine biopsy cores that are embedded in a mixture of methyl methacrylate and glycol methacrylate may be used for the demonstration of chloroacetate esterase, acid phosphatase, peroxidase, nonspecific esterase, and alkaline phosphatase, as well as for the immunohistochemical detection of some antigens (16,17).

For immunohistochemical studies with the widest range of antibodies, frozen sections of trephine biopsy cores must be used (22,23). However, such sections show less cytologic detail than paraffin-embedded sections and tend to become distorted, making interpretation difficult. The distortion when cutting frozen sections can be reduced using a special supporting medium such as Histocon (Polysciences; Warrington, Pennsylvania), which does not impair antigenic reactivity.

The trephine biopsy core can be used to prepare several imprints by gently touching it with glass slides before fixation for histology. The imprints so obtained are used for detailed investigations into the morphology and other characteristics of individual marrow cells. However, such studies are best performed on smears of aspirated marrow. In adults, marrow is aspirated from the posterior superior iliac spine or the iliac crest. In children, marrow is usually aspirated from the posterior superior iliac spine and, in the case of patients less than 1 year of age, also from the upper end of the medial surface of the tibia just below and medial to the tibial tuberosity. The imprints from the trephine biopsy core and marrow smears are usually stained by a Romanowsky method such as the May-GrÃ¼nwald-Giemsa (MGG) stain and also by Perls' acid ferrocyanide method. The smears also may be briefly fixed under conditions that preserve enzyme activity and antigenic sites and used to perform

cytochemical and immunocytochemical studies. The details of these techniques and their value in hematologic diagnosis have been discussed by Hayhoe and Quaglino (24). Antibodies useful in immunocytochemical studies of appropriately fixed smears include those listed in Table 33.1, as well as several others such as those against CD2 (a pan-T marker), CD19 (a pan-B marker), and CD41 or CD42b (megakaryocyte lineage markers).

A thorough study of the marrow requires examination of both marrow smears and tissue sections. Marrow smears are the best preparations for the study of cellular detail but provide little information on intercellular relationships and the organization of the marrow. Histologic sections provide this information and are therefore superior to marrow smears for the detection of tumor infiltration, granulomas, amyloidosis, and necrosis of the marrow. They are essential for studying the distribution and quantity of extracellular reticulin and collagen fibers and may show vascular lesions (e.g., in thrombotic thrombocytopenic purpura and polyarteritis nodosa).

When electron microscopic studies are to be performed, an aliquot of a marrow aspirate is mixed with heparinized Hanks' solution. A few marrow fragments are then removed without delay and placed in a solution of 2.5 to 4% glutaraldehyde in 0.1 M phosphate buffer (pH 7.3). Alternatively, 1-mm pieces of the trephine biopsy core are fixed in glutaraldehyde for 1 hr, after which the marrow is gently teased out of the bone using a dissecting microscope.

In this chapter, unless otherwise stated, the descriptions of cells in marrow smears apply to smears stained by a Romanowsky method. The electron microscopic data relate to ultrathin sections stained with uranyl acetate and lead citrate. Such sections were prepared from marrow fragments that were fixed in glutaraldehyde and postfixed in osmium tetroxide.

General Features of Hematopoiesis

Blood cells are produced in the embryo and fetus and throughout postnatal life. In the developing fetus and growing child, the total number of hematopoietic cells and blood cells increases progressively with time. By contrast, the hematopoietic systems of healthy adults are examples of steady-state cell renewal systems. In such systems, a relatively constant rate of loss of mature blood cells from the circulation is balanced by the production of new blood cells at the same rate. The number of hematopoietic cells and blood cells therefore remains constant.

New blood cells are eventually derived from a small number of hematopoietic stem cells (25), which are estimated to constitute 1 in 10^4 nucleated marrow cells. These cells have two properties: (a) the ability to mature into all types of blood cell and (b) an extensive capacity to

generate new stem cells and thus to maintain their own number (self-renewal). In humans, the existence of pluripotent hematopoietic stem cells with both the above properties has been demonstrated by the success of bone marrow transplantation. The marrow also contains primitive cells that form â€œcobblestoneâ€• foci of myelopoiesis under stromal cells in long-term marrow cultures (limited to 8â€“20 weeks); these do not have the capacity for extensive self-renewal or for long-term lymphopoiesis and are therefore considered to be more differentiated than stem cells. The pluripotent stem cells (25,26,27) give rise to lymphoid stem cells and multipotent myeloid stem cells. They may also give rise to endothelial cells (28). The lymphoid stem cells mature into all types of lymphocytes. The myeloid stem cells mature into neutrophil, eosinophil, and basophil granulocytes, monocytes, erythrocytes, platelets, mast cells, and osteoclasts. The immediate progeny of the lymphoid and myeloid stem cells are usually termed hematopoietic progenitor cells. The myeloid progenitor cells are committed to one, two, or a few hematopoietic differentiation pathways (i.e., are unipotent, bipotent, or oligopotent) and have only a limited capacity

for self-renewal. The most immature of the myeloid progenitor cells are oligopotent. Such cells undergo a progressive restriction of their differentiation potential such that the most mature progenitor cells are committed to only a single line of differentiation. Hematopoietic progenitor cells have been identified and characterized by their ability to form colonies containing cells of one or more hematopoietic lineages in vitro and are therefore called colony-forming units (CFUs) or colony-forming cells (CFC). These generate colonies containing a mixture of granulocytes, erythroblasts, macrophages, and megakaryocytes and are, therefore, termed CFU-GEMM. There is some indirect evidence for the presence of tripotent hematopoietic cells (CFU-E mega baso) that give rise to erythroblasts, megakaryocytes, and basophil granulocytes. Bipotent hematopoietic progenitor cells that give rise to colonies containing granulocytes and macrophages are termed CFU-GM. There are also bipotent progenitor cells generating colonies containing a mixture of erythroblasts and megakaryocytes (CFU-E mega). The unipotent progenitor cells that give rise to neutrophil granulocytes, eosinophil granulocytes, basophil granulocytes, macrophages, erythroblasts, and megakaryocytes are described as CFU-G, CFU-eo, CFU-baso, CFU-M, CFU-E, and CFU-mega, respectively. These develop into the most immature of the morphologically recognizable blood cell precursors in the marrow. Thus, CFU-G develop into myeloblasts, CFU-eo into eosinophil promyelocytes, CFU-baso into basophil promyelocytes, CFU-M into monoblasts, CFU-E into pronormoblasts, and CFU-mega into megakaryoblasts. The stem cells and progenitor cells are found in both the blood and the marrow but cannot be identified on morphologic criteria. The characteristics of the various types of morphologically recognizable hematopoietic cell found in the marrow are described later in this chapter. The relationships between the different categories of cell involved in hematopoiesis are illustrated in Figure 33.1.

Small numbers of bone marrow-derived hematopoietic stem cells and early hematopoietic progenitor cells circulate in the blood and these

can â€œhomeâ€• to the marrow.

Two processes are involved in the formation of all types of blood cells. These are the progressive acquisition of the biochemical, functional, and morphologic characteristics of the particular cell type (i.e., differentiation) and cell proliferation. The latter results in the production of a large number of mature cells from a single cell committed to one or more differentiation pathways. Differentiation occurs at all stages of hematopoiesis, and cell proliferation occurs in the hematopoietic stem cells, progenitor cells and, except in the megakaryocytic lineage, in the more immature morphologically recognizable precursor cells. The nearly mature blood cells seem to enter the circulation mainly by passing through the endothelial cells of the marrow sinusoids.

Regulation of Hematopoiesis

Hematopoietic stem cells and early progenitor cells show low-level expression of transcription factors and genes specific to several hematopoietic lineages (multilineage priming). Commitment to a single lineage involves enhancement of transcription factors controlling the gene expression programs specific to that lineage and permanent silencing by those transcription factors of gene programs required for differentiation down other lineages.

The mechanisms underlying the commitment of a stem cell to differentiate are not yet fully understood (29,30). According to one model, the probability of a stem cell undergoing self-renewal or differentiation is a stochastic process. Environmental signals (soluble factors, cell-cell and cellâ€“extracellular matrix interactions) mediated by specific receptor-ligand interactions operate only by influencing stem cell and progenitor cell apoptosis (and, thus, survival) and proliferation. Another model proposes that all decisions taken by stem cells and progenitor cells are determined by environmental signals. Bone marrow stromal cells (e.g., macrophages, nonphagocytic reticular or fibroblastoid cells,

adipocytes, endothelial cells) play a major role in generating such signals; they provide niches for the attachment of stem cells and their progeny, are a source of the extracellular matrix involved in such attachment, and secrete various membrane-bound and soluble stimulatory hematopoietic growth factors and inhibitory cytokines (29,31,32).

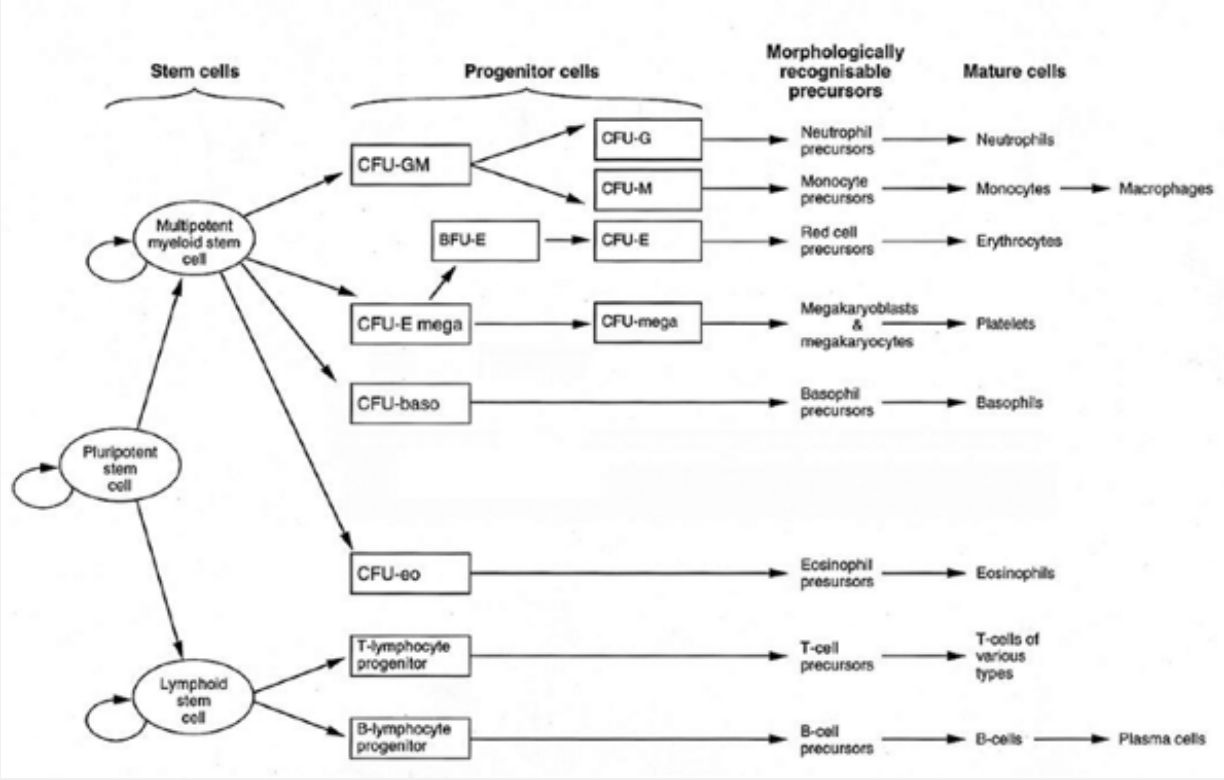

Figure 33.1 Model of hematopoiesis showing the relationships between the various types of stem cell, progenitor cell, and morphologically recognizable precursor cell. (*BFU,* E, erythroid burst-forming units; *CFU,* colony-forming units; *E,* erythroblasts; *GM,* granulocytes and macrophages; *eo,* eosinophil granulocytes; *baso,* basophil granulocytes; *mega,* megakaryocytes; *G,* neutrophil granulocytes; *M,* macrophages)

Stem cells and early hematopoietic progenitor cells interact via specific cell surface receptors with multilineage hematopoietic growth factors. The latter include stem cell factor (Steel factor, kit ligand), interleukin-1 (IL-1) and IL-6 for the pluripotent stem cells, and stem cell factor, thrombopoietin, IL-3 (multi-CSF) and granulocyte-macrophageâ€“colony stimulating factor (GM-CSF) for the multipotent myeloid stem cells. The regulation of later progenitor cells and the morphologically recognizable hematopoietic cells is dependent both on multilineage growth factors and lineage-specific growth factors such as G-CSF, M-CSF, IL-5 (influencing CFU-eo), thrombopoietin and IL11 (influencing CFU-mega), and erythropoietin (mainly influencing late BFU-E and CFU-E). The growth factors influencing lymphocyte progenitor cells and precursors include IL-2, IL-4, IL-5, IL-6, IL-7, and IL-11 for the B lineage and IL-2, IL-3, IL-4, IL-7, and IL-10 for the T lineage.

Hematopoietic growth factors are glycoproteins and influence the survival, proliferation, and differentiation of their target cells via second messengers. In their absence, the target cells undergo programmed cell death (apoptosis). Some growth factors such as G-CSF and GM-CSF not only regulate hematopoiesis but also enhance the function of the mature cells. Most hematopoietic growth factors are produced by bone marrow stromal cells and T lymphocytes, either constitutively (e.g., M-CSF production by fibroblastoid cells and endothelial cells) or after their activation by various signals. Thus, fibroblastoid cells and endothelial cells that have been activated by macrophage-derived IL-1 or tumor necrosis factor (TNF) and endotoxin-stimulated macrophages produce M-CSF, GM-CSF, G-CSF, IL-6, and stem cell factor. Antigen- or IL-1â€“ activated T cells produce IL-3, IL-5, and GM-CSF.

The main organ of erythropoietin production in postnatal life is the kidney, and the probable site of synthesis appears to be peritubular cells. About 10% of the erythropoietin is produced in the liver, which is the main organ of synthesis in the fetus. There is an oxygen

sensor in the peritubular cells of the kidney, and the production of erythropoietin is inversely proportional to the degree of oxygenation of renal tissue. A limited amount of data suggest that there also may be paracrine or autocrine erythropoietin production in the bone marrow. The erythropoietin receptor is upregulated at the late BFU-E and CFU-E stages, and signalling through this receptor is required to prevent apoptosis.

In addition to the stimulatory cytokines mentioned above, inhibitors (negative regulators) of hematopoiesis are produced by macrophages, fibroblastoid cells, and endothelial cells. These include transforming growth factor-Î²1 (TGF-Î²1), which inhibits multilineage progenitor cells, early erythroid progenitors, and megakaryocytes; TNF-Î±, which inhibits the proliferation of granulocyte precursors; interferon-Î±, which inhibits megakaryocyte progenitors; and macrophage inflammatory protein-1Î± (MIP-1Î±), which inhibits the proliferation of stem cells.

Hematopoiesis in the Embryo and Fetus: Development of the Bone Marrow

Studies in experimental animals have shown that hematopoietic stem cells responsible for embryonic (primitive) hematopoiesis develop in the yolk sac. Those responsible for fetal and postnatal (definitive) hematopoiesis are considered to arise in the aorto-gonad-mesonephros region by some investigators and the yolk sac by others (33,34,35). The stem cells migrate through the blood stream to colonize the fetal liver and other fetal tissues.

In the human embryo, erythropoietic cells first appear within the blood islands of the yolk sac about 19 days after fertilization (36,37). A few megakaryocytes are found in these blood islands during the sixth and seventh weeks of gestation. Yolk sac erythropoiesis is megaloblastic and results in the production of nucleated red cells

(Figure 33.2) that contain three embryonic hemoglobins (25), namely, hemoglobins Gower I ($\hat{I}\P_2\hat{I}\mu_2$), Gower II ($\hat{I}\pm_2\hat{I}\mu_2$), and Portland I ($\hat{I}\P_2\hat{I}^3_2$), and, in later embryos, hemoglobin F ($\hat{I}\pm_2\hat{I}^3_2$).

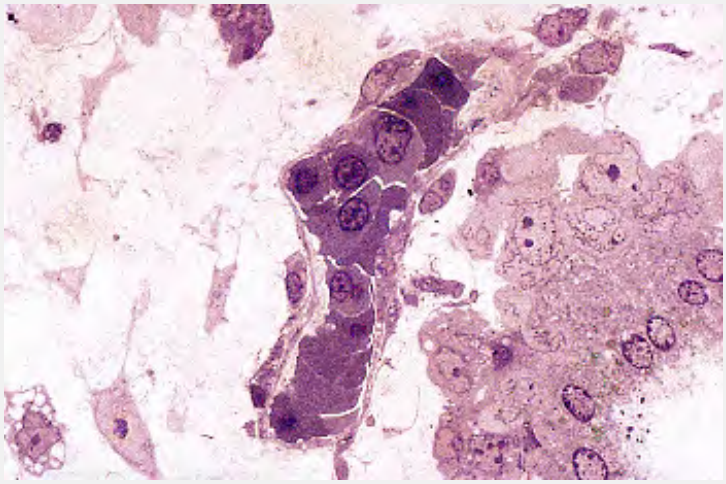

Figure 33.2 Semithin section of a plastic-embedded chorionic villus biopsy sample obtained at 7 weeks of gestation, showing a blood vessel containing nucleated embryonic red cells (toluidine blue).

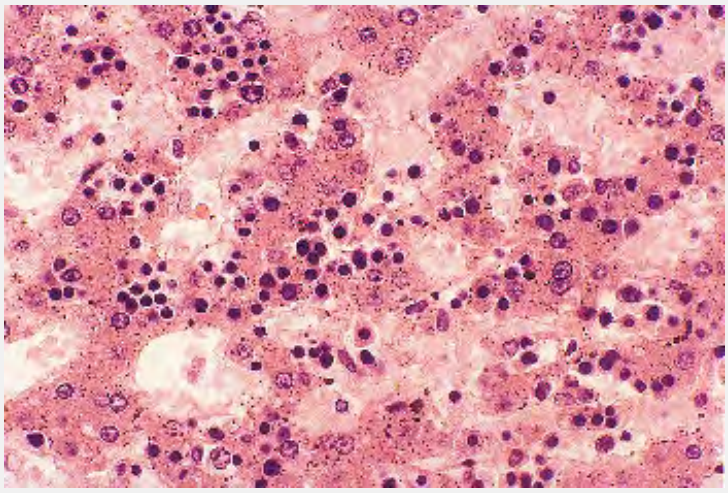

Figure 33.3 Fetal liver tissue obtained postmortem showing erythropoietic activity. The erythroblasts are found extravascularly, both within the hepatic cords and between the cords and the sinusoidal endothelial cells. The brown material within hepatocytes is formalin pigment, a common postmortem fixation artifact. (H&E.)

Hematopoietic foci develop in the hepatic cords during the sixth week of gestation, and the liver becomes the major site of erythropoiesis in the middle trimester of pregnancy (38,39). During this period, about half the nucleated cells of the liver consist of erythropoietic cells (Figure 33.3). A few granulocytopoietic cells and megakaryocytes also are found in this organ. Fetal hepatic erythropoiesis is normoblastic and gives rise to nonnucleated red cells containing hemoglobin F. These red cells are considerably larger than the red cells of adults. The number of erythropoietic cells in the liver decreases progressively after the seventh month of gestation; a few cells persist until the end of the first postnatal week.

Marrow cavities are formed as a result of the erosion of bone or calcified cartilage by blood vessels and cells from the periosteum (37). The first marrow cavity to develop is that of the clavicle (at about 2 months gestational age). After the formation of the marrow cavities, the vascular connective tissue present within them becomes colonized by circulating hematopoietic stem cells. The latter generate erythropoietic cells during the third and fourth months of gestation, the order of appearance of erythropoietic cells being the same as the order of formation of the marrow cavities. After the sixth month, the bone marrow becomes the major site of hematopoiesis (40). Erythropoiesis in fetal bone marrow is normoblastic and results in the production of nonnucleated red cells, which contain hemoglobins F and A ($\hat{I}\pm_2\hat{I}^2_2$) and which are larger than adult red cells. The fetal bone marrow is the predominant site of intrauterine granulocytopoiesis and megakaryocytopoiesis. In this tissue, the

myeloid/erythroid ratio (i.e., the ratio of the number of neutrophil precursors plus neutrophil granulocytes to the number of

erythroblasts) remains constant at about 1:4 after 6.5 months of gestation (40).

Postnatal Changes in the Distribution of Red Marrow and in the Type of Hemoglobin

At birth, all the marrow cavities contain red, hematopoietic marrow. Furthermore, the red marrow contains only a few fat cells. After the first four years of life, an increasing number of fat cells appears between the hematopoietic cells, particularly in certain regions of the marrow, and these regions eventually become yellow and virtually devoid of hematopoietic cells (41,42). Zones of yellow, fatty marrow are found just below the middle of the shafts of the long bones between the ages of 10 and 14 years and, subsequently, extend in both directions, distal spread being more rapid than proximal spread. By the age of about 25 years, hematopoietic marrow is confined to the proximal quarters of the shafts of the femora and humeri, the skull bones, ribs, sternum, scapulae, clavicles, vertebrae, pelvis, and the upper half of the sacrum. Although the distribution of hematopoietic marrow remains essentially unaltered throughout adult life, its fat cell content increases slightly with increasing age and more substantially after the age of 70 years, in association with a gradual expansion of the volume of the marrow cavities.

The percentages of hemoglobins F and A in the blood of full-term neonates are, respectively, 50 to 85% and 15 to 50%. The proportion of hemoglobin F decreases postnatally at different rates in different individuals, but adult levels of less than 1% are reached in nearly all children by the age of 2.5 years.

Because young children have red marrow containing few fat cells in

virtually all their marrow cavities, a rapid increase in hematopoietic tissue in this age group is presumably accommodated mainly by a reduction in the proportion of marrow space occupied by sinusoids. If the increase in the rate of hematopoiesis is substantial and prolonged (e.g., in congenital hemolytic anemias), there is an increase in the total volume of the marrow cavities and the reestablishment of extramedullary hematopoiesis in organs such as the liver, spleen, and lymph nodes (43). The expansion of the marrow cavities leads to skeletal abnormalities, such as frontal and parietal bossing, dental deformities, and malocclusion of the teeth. It also causes thinning of the cortex, which may lead to fractures after minor trauma. In adults, increased hematopoiesis is initially associated with the replacement of fat cells in red marrow by hematopoietic cells and also with the spread of red marrow into marrow cavities normally containing yellow marrow (43). If the increase in hematopoiesis is marked, extramedullary hematopoiesis may develop.

Structural Organization of Hematopoietic Marrow

The marrow cavities of most bones contain trabeculae of cancellous bone. The inner surface of the cortex and the outer surfaces of the trabeculae are lined by the endosteum, which consists of a single layer of cells supported on a delicate layer of reticular connective tissue. In most areas of the endosteum, the cells consist of very flat bone-lining cells (endosteal lining cells), but in some areas they consist of osteoblasts or osteoclasts. The marrow, which is located between the trabeculae, is supplied with an extensive microvasculature and some myelinated and nonmyelinated nerve fibers. It does not have a lymphatic drainage (44). The space between the small blood vessels contains a few reticulin fibers and a variety of cell types. The latter include fat cells, precursors of red cells, granulocytes, monocytes and platelets, lymphocytes, plasma

cells, macrophages (phagocytic reticular cells), nonphagocytic reticular cells, and mast cells (4,45).

Blood Supply

One or more nutrient canals penetrate the shafts of the long bones obliquely. Each canal contains a nutrient artery and one or two nutrient veins. After entering the marrow, the nutrient artery divides into ascending and descending branches, which coil around the central longitudinal vein, the main venous channel of the marrow. The ascending and descending arteries give off numerous arterioles and capillaries that travel radially toward the endosteum and often open into a plexus of sinusoids (25). The sinusoids drain through a system of collecting venules and larger venous channels into the central longitudinal vein, which in turn drains mainly into the nutrient veins. In the diaphyses of long bones containing yellow fatty marrow, the nutrient artery gives off relatively few branches until it reaches the lower edge of the red marrow, where it breaks up into numerous vessels that penetrate the hematopoietic tissue. Many blood vessels of various sizes supply the marrow within flat and cuboidal bones, entering the marrow cavity via one or more large nutrient canals, as well as through numerous smaller canals.

There are interconnections between the blood supply of the bone marrow and bone through an endosteal network of blood vessels. This network communicates both with the periosteal vessels via fine veins passing through the bone and with branches of the nutrient artery. Furthermore, studies in experimental animals have shown that many capillaries derived from the nutrient artery enter Haversian canals but swing back into the marrow and open into sinusoids or venules (46,47). There has been much speculation as to whether blood reaching the marrow from the bone contains one or more

hematopoietic factors derived from the bone or endosteal cells.

Figure 33.4 Electron micrograph of part of the wall of a sinusoid from normal bone marrow. There are three tight junctions (*small arrows*) at the area of contact between two adjacent endothelial cells. Several pinocytotic vesicles (*large arrow*) are present both at the luminal and abluminal surface of one of the endothelial cells, and a single pinocytotic vesicle is present at the outer surface of the adventitial cell.

The sinusoids of human bone marrow have thin walls consisting of an inner complete layer of flattened endothelial cells with little or no underlying basement membrane and an outer incomplete layer of adventitial cells (48). The endothelial cells are characterized by the presence of numerous small pinocytotic vesicles along both their luminal and abluminal surfaces (Figure 33.4). The nucleus is flattened and contains moderate quantities of nuclear

membraneâ€“associated condensed chromatin. The cytoplasm also contains ribosomes, rough endoplasmic reticulum (RER), mitochondria, some microfilaments, a few lysosomes, and occasional fat droplets. Adjacent endothelial cells overlap and may interdigitate extensively. These areas of contact are characterized by (a) a strictly parallel alignment of the membranes of the interacting cells with a narrow gap between the opposing membranes and (b) short stretches in which the membranes fuse together, forming tight junctions (not true desmosomes). There is an increased electron density of the cytoplasm immediately adjacent to and on both sides of the tight junctions (Figure 33.4). Some endothelial cells show alkaline phosphatase activity. Endothelial cells contain no stainable iron except when the iron stores are increased. They produce extracellular matrix, stem cell factor, IL6, GM-CSF, IL-1Î±, IL-11, and G-CSF and are thus intimately involved with the regulation of hematopoiesis. Endothelial cells of the sinusoids allow the bidirectional migration of progenitor cells and hematopoietic stem cells through them by a mechanism involving specific binding molecules.

Adventitial cells project long peripheral cytoplasmic processes, which may be closely associated with some extracellular reticulin fibers. Some of these processes lie along the sinusoidal surface, and others protrude outward between hematopoietic cells. Thus, adventitial cells are a type of reticular cell (i.e., form part of the cytoplasmic network or reticulum of the marrow stroma). The cytoplasm of adventitial cells contains ribosomes, RER, some pinocytotic vesicles, a few electron-dense lysosomes, occasional fat globules, and numerous microfilaments that are often arranged in bands. The latter are usually situated within the peripheral cytoplasmic processes. The cytoplasm of some adventitial cells appears very electron lucent. Adventitial cells stain strongly for alkaline phosphatase.

Nerve Supply

In the case of a long bone, the nerve supply enters the bone marrow mainly via the nutrient canal but also through a number of epiphyseal and metaphyseal foramina. Bundles of nerve fibers travel together with the nutrient artery and its branches and supply the smooth muscle in such vessels or, occasionally, terminate between hematopoietic cells (49).

Extracellular Matrix (Connective Tissue)

Normal marrow contains a scanty incomplete network of fine branching reticulin fibers between the parenchymal cells (Figure 33.5). A higher concentration of thicker fibers is found in and around the walls of the larger arteries and

near the endosteum; such fibers are continuous with the fibers in the parenchyma. Other extracellular matrix components produced by stromal cells include fibronectin, vascular cell adhesion molecule (VCAM)-1, vitronectin, thrombospondin, and proteoglycans such as heparan sulphate and chondroitin sulphate.

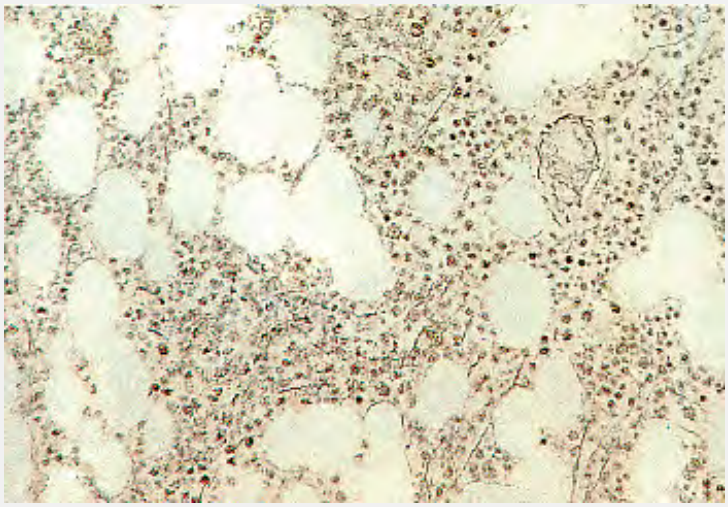

Figure 33.5 Section of a decalcified, paraffin-embedded trephine biopsy core from a hematologically normal adult, showing a scant

network of fine reticulin fibers. The upper right-hand quadrant of the photomicrograph shows a circular arrangement of fibers associated with a blood vessel. (Silver impregnation of reticulin.)

Stromal Cells

The stromal cells comprise (a) osteoblasts, bone marrow fat cells (adipocytes), and nonphagocytic reticular cells (including myofibroblasts), all of which are derived from mesenchymal stem cells within the marrow; (b) osteoclasts, macrophages, and mast cells that are derived from the myeloid hematopoietic stem cell; and (c) endothelial cells (discussed above) that are derived either from the hematopoietic stem cell or a more primitive marrow cell that also gives rise to hematopoietic stem cells (28). Some stromal cells are intimately involved in the regulation of hematopoiesis.

Osteoblasts and Osteoclasts

Osteoblasts are present in the endosteum in areas of deposition of osseous matrix (osteoid). In histologic sections, osteoblasts are cuboidal or pyramidal and have eccentric nuclei. Their cytoplasm is markedly basophilic and contains a large round pale zone. Osteoblasts are frequently found in a continuous layer, usually one or two cells thick, and appear like an area of epithelium. They become surrounded by the osteoid they produce and thus eventually become osteocytes. Osteoclasts are large multinucleate cells involved in bone resorption and are often found in shallow excavations on the surface of the bone, termed Howship's lacunae. Osteoblasts arise from progenitor cells closely associated with the endosteal lining cells. Although it is usually considered that osteoblast progenitor cells are not derived from hematopoietic stem cells, recent studies in mice indicate that osteoblasts and hematopoietic cells arise from a common primitive marrow cell (50). Osteoblasts produce cytokines

such as IL6, G-CSF, and GM-CSF that influence hemopoiesis (51). Osteoclasts originate from the myeloid hematopoietic stem cells. The relationship between the osteoclast progenitor cell and other hematopoietic progenitor cells (e.g., CFU-GEMM, CFU-GM, CFU-M) is not yet clear (52).

Romanowsky-stained normal marrow smears may contain groups of osteoblasts or individual osteoclasts. In such preparations, osteoblasts have an oval or elongated shape and are 20 to 50 Âµm in diameter. They have abundant basophilic cytoplasm, often with somewhat indistinct margins, and a single small eccentric nucleus with only small quantities of condensed chromatin and with one to three nucleoli. The cytoplasm contains a rounded pale area corresponding to the Golgi apparatus, which often is situated some distance from the nucleus (Figure 33.6). Osteoblasts stain positively for alkaline phosphatase activity. They superficially resemble plasma cells, but the latter are smaller, contain heavily stained clumped chromatin, and have a Golgi zone situated immediately adjacent to the nucleus. Osteoclasts appear as giant multinucleate cells with abundant pale blue cytoplasm containing many azurophilic (purple-red) granules (Figure 33.7). The individual nuclei are rounded in outline, uniform in size, contain a single prominent nucleolus, and do not overlap. Osteoclasts are strongly acid phosphatase positive. They must be distinguished from the other polyploid giant cells in the marrow, the megakaryocytes. These are usually not multinucleate but contain a single large lobulated nucleus.

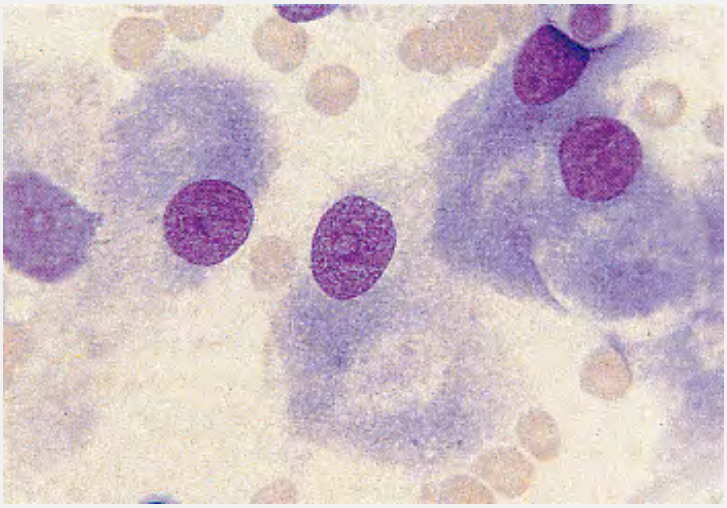

Figure 33.6 Group of osteoblasts from a May-GrÃ¼nwald-Giemsa (MGG)â€“stained smear of normal bone marrow.

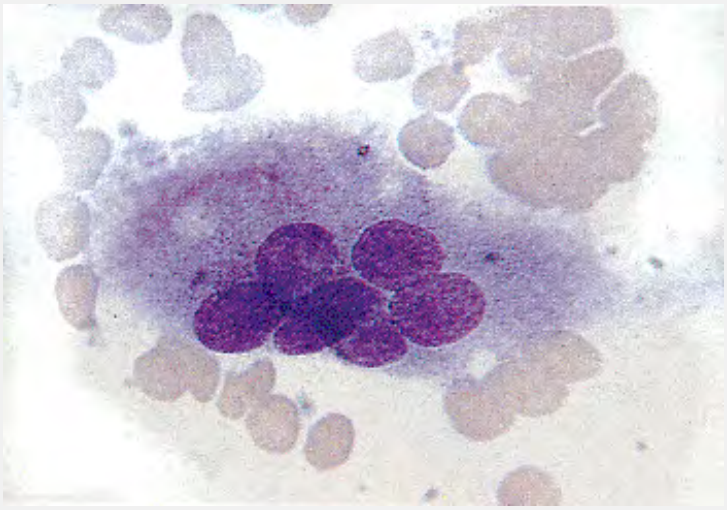

Figure 33.7 A multinucleate osteoclast from an MGG-stained smear of normal bone marrow.

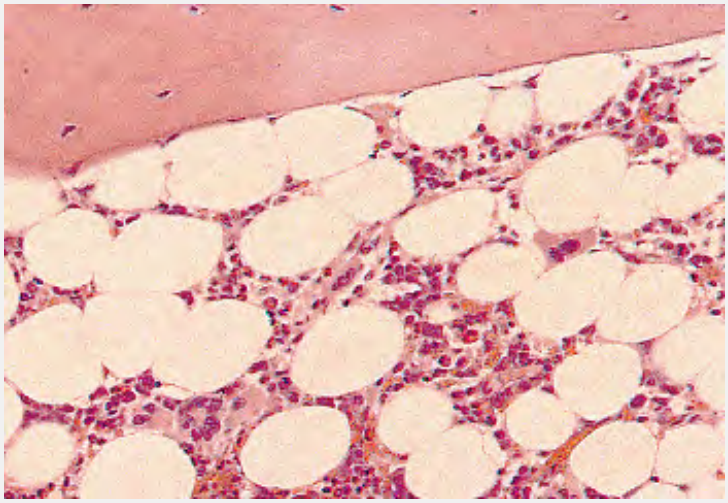

Figure 33.8 Section of a decalcified, paraffin-embedded trephine biopsy core from a hematologically normal adult. About 70% of the area of marrow tissue in this photomicrograph is occupied by fat cells. There may be a substantial variation in cellularity in different parts of the same section. (H&E.)

Fat Cells

The number of fat cells in hematopoietic bone marrow varies markedly with age (53,54). In normal adults, 30 to 70% of the area of a histologic section of hematopoietic marrow consists of fat cells (Figures 33.8,33.9). Fat cells are the largest cells in the marrow, and sections of such cells have average diameters of about 85 Âµm. Ultrastructural studies show that these cells have a single large fat globule at their center and a narrow rim of cytoplasm at their periphery. This cytoplasmic rim contains a flattened nucleus, several small lipid droplets, ribosomes, strands of endoplasmic reticulum, and several mitochondria. The fat cells of the bone marrow only have small quantities of reticulin and collagen fibers around them. They are in intimate contact with vascular channels, macrophages, and all

types of hematopoietic cells. Marrow fat cells seem to be formed by the accumulation of lipid within adventitial cells, other nonphagocytic reticular cells, and, possibly, sinus endothelial cells. Whenever there is an increase or decrease in the number of hematopoietic cells in bone marrow, there is a corresponding decrease or increase, respectively, of the number of fat cells so that the intersinusoidal space within marrow cavities is always fully occupied by cells. The mechanisms underlying this inverse relationship between the mass of fat cells and hematopoietic cells in the marrow are uncertain. In severe anorexia nervosa or cachexia secondary to chronic disorders, such as tuberculosis or carcinoma, there is a marked reduction in fat cells, often together with a reduction in hematopoietic tissue. In these conditions, the space normally occupied by cells is filled with a gelatinous extracellular substance composed of acid mucopolysaccharide (55).

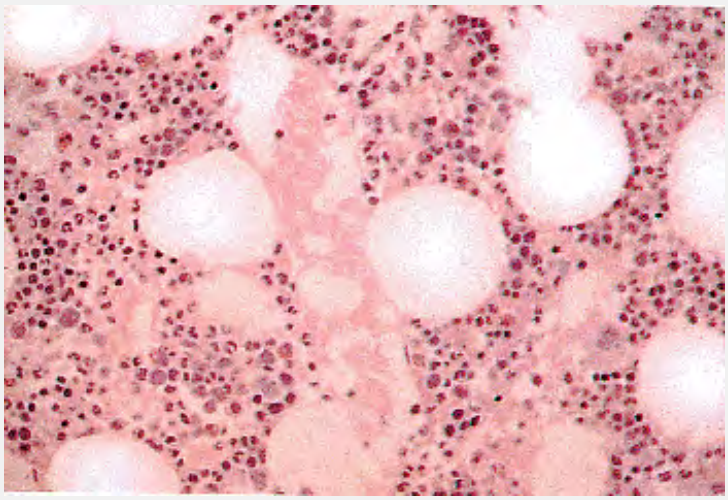

Figure 33.9 Semithin section of an undecalcified, plastic-embedded trephine biopsy core from a hematologically normal adult. A wide sinusoid containing red cells is seen passing vertically between some fat cells. (H&E.)

Macrophages (Phagocytic Reticular Cells)

The bone marrow contains many macrophages. The frequency of this cell type is best appreciated in sections of trephine biopsies stained for an antigen found in macrophages such as CD68 (Figure 33.10) or in electron micrographs of ultrathin sections of marrow fragments rather than in smears of aspirated bone marrow. In H&E-stained sections of trephine biopsies, macrophages appear as moderately large cells with abundant cytoplasm. In Romanowsky-stained marrow smears, they appear as irregularly shaped cells 20 to 30 Âµm in diameter and have a round or oval nucleus with pale, lacelike chromatin and one or more large nucleoli. The cytoplasm is voluminous, stains pale blue, and contains azurophilic granules, vacuoles, and variously sized inclusions consisting of

phagocytosed material (Figure 33.11A). Macrophages are derived from monocytes and, therefore, eventually from the hematopoietic stem cells.

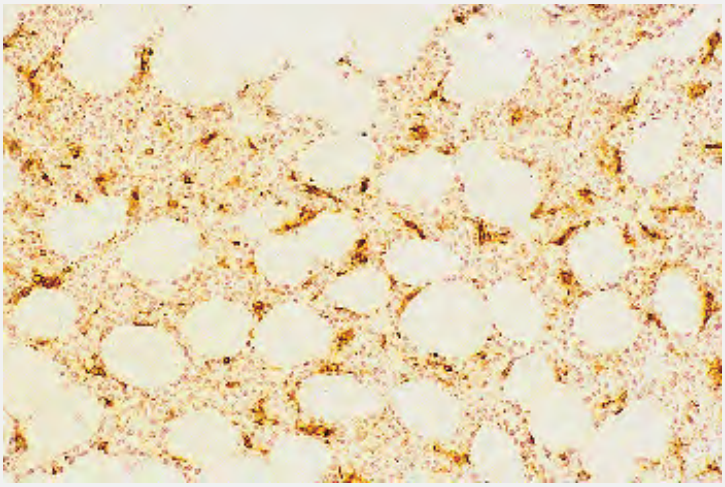

Figure 33.10 Immunohistochemical demonstration of macrophages in a section of a paraffin-embedded trephine biopsy core from a hematologically normal subject. The section was reacted with the monoclonal antibody PG-M1 (against CD68) and

the reaction visualized using an immunoperoxidase technique.

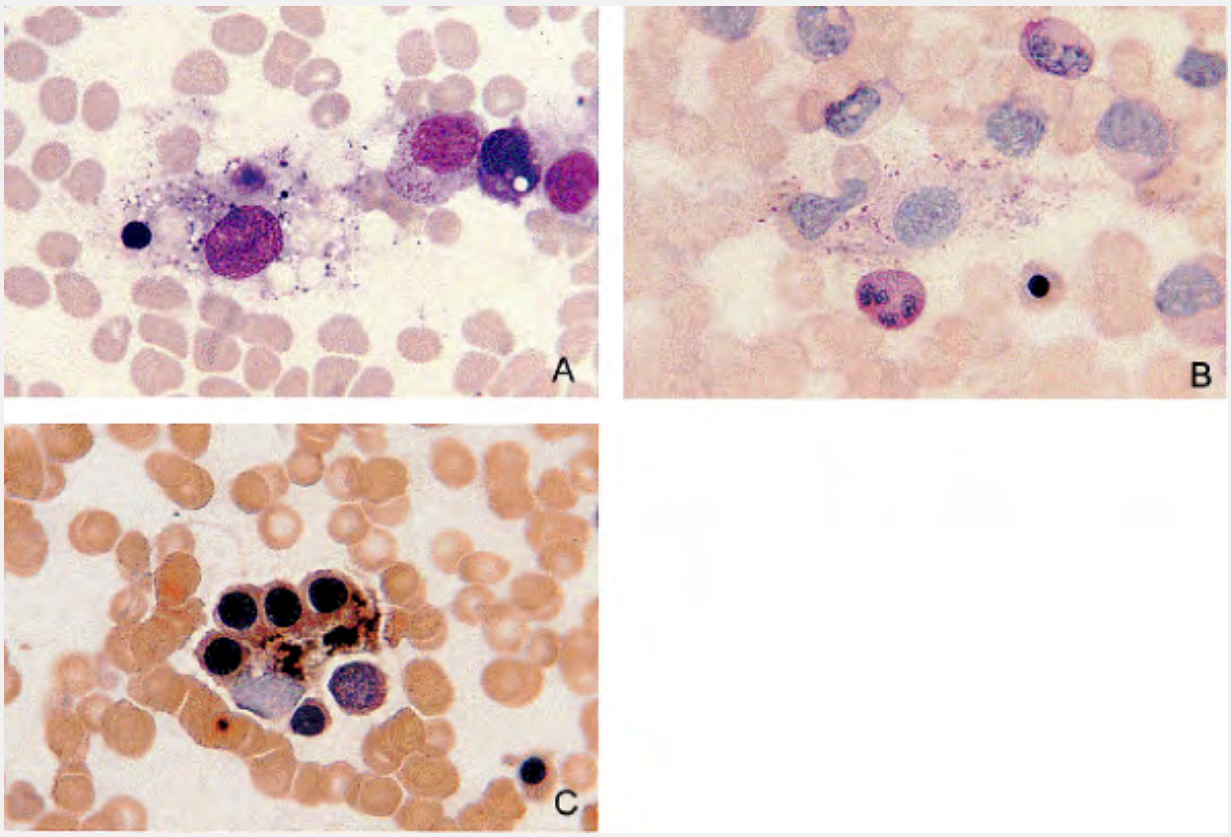

Figure 33.11 Macrophages from normal bone marrow smears. A. Macrophage containing a black extruded erythroblast nucleus and several intracytoplasmic inclusions of various shapes, sizes, and staining characteristics. The large pale rounded inclusions may represent degraded red cells (MGG). B. Macrophage containing several PAS-positive cytoplasmic granules, together with a PAS-negative late erythroblast and several PAS-positive neutrophil myelocytes and granulocytes. C: Macrophage showing strong Î±-naphthyl acetate esterase activity, surrounded by six unreactive erythroblasts. The diazonium salt of fast blue BB was used as the capture agent.

In unstained smears and sections of normal marrow and in Giemsa- or H&E-stained sections, macrophages may show refractile yellow-brown hemosiderin-containing intracytoplasmic inclusions, which vary between 0.5 and 4 Âµm in diameter. These appear as blue or blue-black granules when stained by Perls' acid ferrocyanide method. This stain also may color the entire cytoplasm a diffuse pale blue (Figure 33.12). The amount of iron-positive granules within the marrow fragments on a marrow smear (Figure 33.13) or the amount in a histologic section of a trephine biopsy sample may be assessed semiquantitatively and is a useful guide to the total iron stores in the body (56). Stainable iron is absent or virtually absent in iron deficiency (with or without anemia) and increased in conditions such as hereditary hemochromatosis or transfusion-induced iron overload. Macrophages contain PAS-positive material and are strongly positive for Î±-naphthyl acetate esterase (Figure 33.11Bâ€“C)

and acid phosphatase. They do not stain for Î±-naphthol AS-D chloroacetate esterase activity (57), and most do not stain with Sudan black. Some macrophages appear to stain positively for alkaline phosphatase activity.

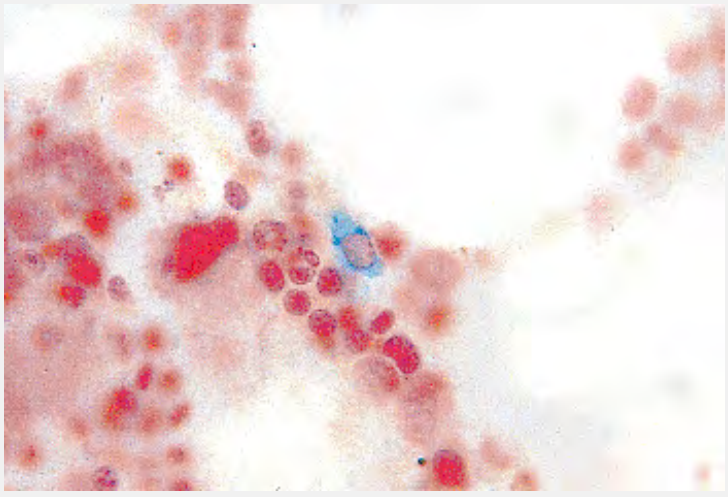

Figure 33.12 Section of a paraffin-embedded normal marrow fragment (*clot section*). The macrophage in the center shows blue hemosiderin-containing intracytoplasmic granules and a diffuse bluish coloration of the cytoplasm (Perls' acid ferrocyanide reaction).

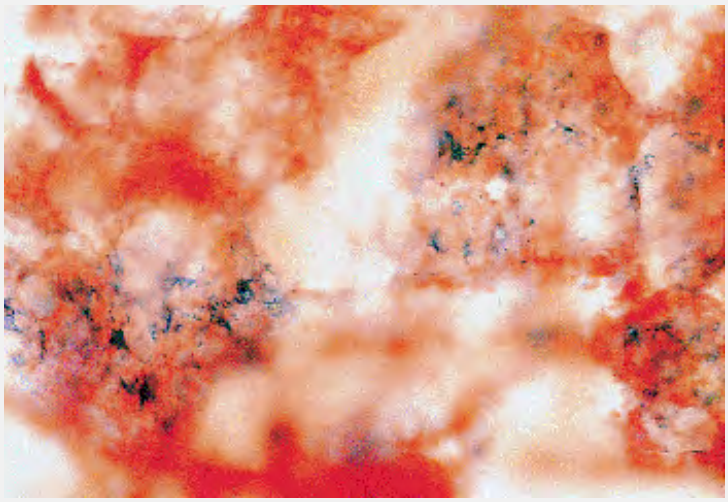

Figure 33.13 Marrow fragment from a normal marrow smear stained by Perls' acid ferrocyanide reaction. The dark blue granular material represents hemosiderin within macrophages.

Ultrastructural studies of marrow fragments show that macrophages form long cytoplasmic processes at their periphery and that such processes extend for considerable distances between various types of hematopoietic cells (Figure 33.14). Some cytoplasmic processes protrude through the endothelial cell layer into the sinusoidal lumen (Figure 33.15) and appear to be involved in recognizing and phagocytosing circulating microorganisms and senescent or damaged erythrocytes and granulocytes. The nucleus often has an irregular outline and contains small to moderate quantities of nuclear

membraneâ€“associated condensed chromatin. The cytoplasm has many strands of RER, scattered ferritin molecules, a well-developed Golgi apparatus, several mitochondria, a number of small or medium-sized homogeneous electron-dense primary lysosomes of variable shape, and a number of large inclusions. Some of the latter have a complex ultrastructure with both electron-dense and electron-lucent areas and myelin figures and may contain numerous ferritin and hemosiderin molecules; these appear to represent secondary lysosomes with residual material from phagocytosed cells (Figure 33.16). Other large inclusions can be recognized readily as granulocytes (Figure 33.17), extruded erythroblast nuclei, and erythrocytes at various stages of degradation. A few reticulin fibers may be found in contact with parts of the cell surface.

Macrophages are present within erythroblastic islands (Figure 33.11C), plasma cell islands, and lymphoid nodules but also may occur elsewhere in the marrow parenchyma. Some are found immediately adjacent to the endothelial cells of sinusoids, forming part of the adventitial cell layer. Bone marrow macrophages not only function as phagocytic cells but also generate various hematopoietic growth factors

(e.g., c-kit ligand or stem cell factor, M-CSF, IL-1, and G-CSF) and are thus involved in short-range regulation of lymphopoiesis and myelopoiesis. They presumably also are involved in antigen processing.

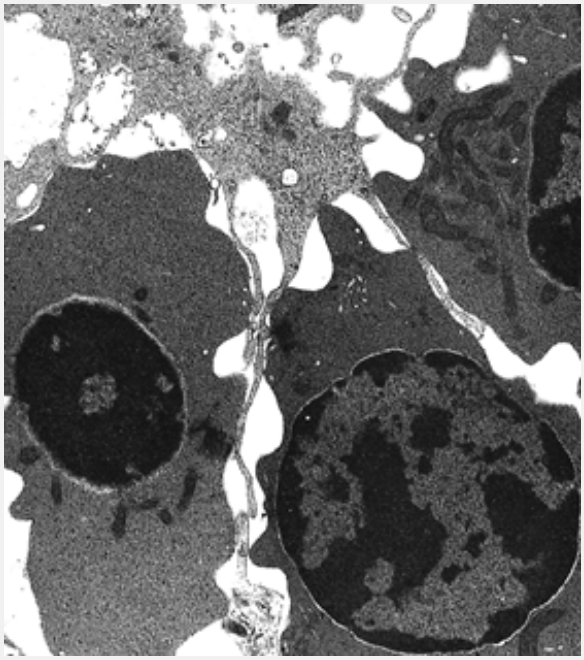

Figure 33.14 Electron micrograph of three erythroblasts from a normal marrow showing fine processes of macrophage cytoplasm extending between the cells.

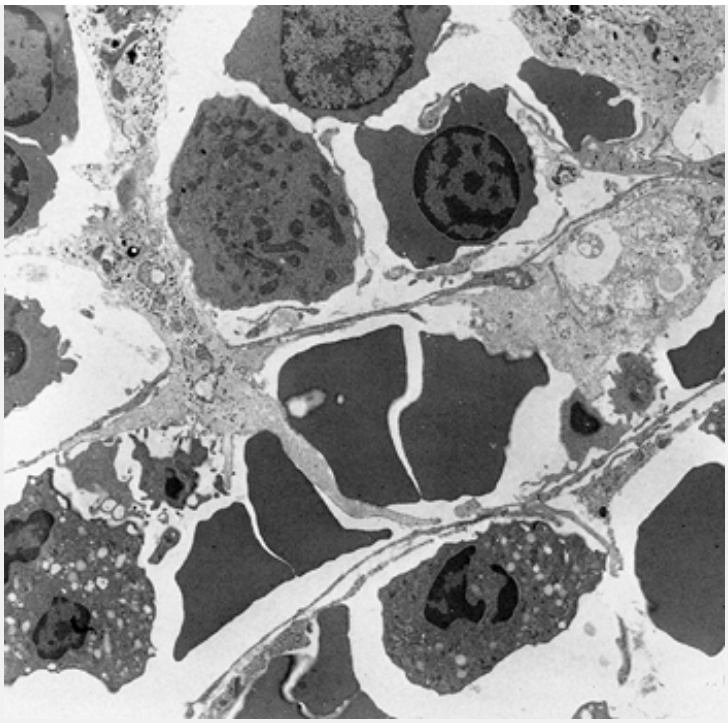

Figure 33.15 Electron micrograph of a sinusoid from a normal bone marrow. A process of macrophage cytoplasm is seen protruding through the lining endothelial cell into the sinusoidal lumen. Serial sectioning of this sinusoid showed that the mass of macrophage cytoplasm occupying the right-hand side of the sinusoidal lumen connected transendothelially with a second extrasinusoidal cytoplasmic process. Both processes arose from the same macrophage.

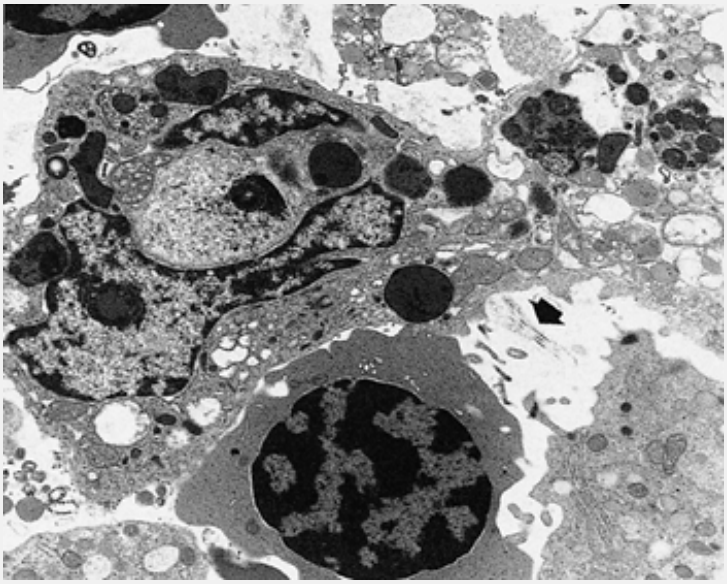

Figure 33.16 Electron micrograph of a macrophage lying next to an early polychromatic erythroblast in a normal bone marrow. The nucleus of the macrophage is irregular in outline, and its cytoplasm contains several inclusions and vacuoles. Some of the inclusions are ultrastructurally complex and probably represent secondary lysosomes. There are some reticulin fibers (*arrow*) near the macrophage.

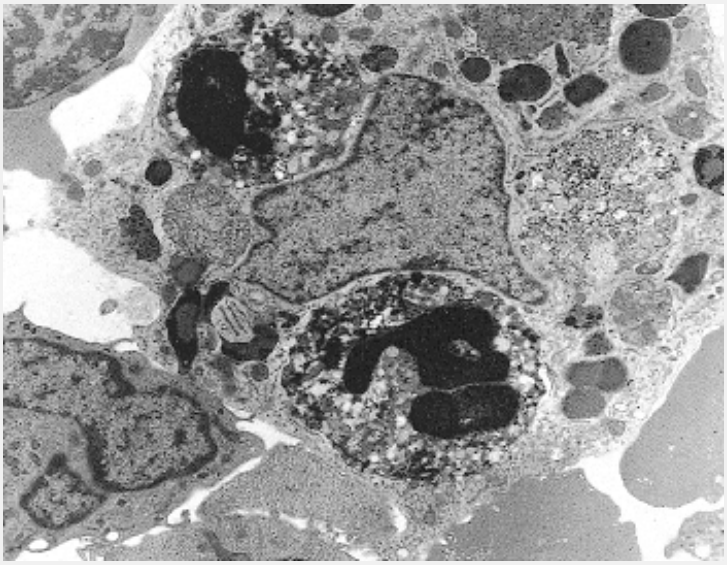

Figure 33.17 Electron micrograph of a macrophage from normal bone marrow. The cytoplasm contains two phagocytosed neutrophils and a large number of other inclusions of varying size, shape, and appearance.

Nonphagocytic Reticular Cells

In Romanowsky-stained marrow smears, nonphagocytic reticular cells have an irregular or spindle shape and resemble macrophages except that they lack large intracytoplasmic inclusions. Light microscope cytochemical and histochemical data indicate that these cells are PAS-negative, strongly positive for alkaline phosphatase, negative for acid phosphatase, negative or only weakly positive for Î±-naphthyl acetate esterase, and negative for stainable iron. Thus, there seems to be some overlap between the cytochemical characteristics of nonphagocytic reticular cells and macrophages (57,58). In the case of mice and rats, however, light and electron microscopic cytochemical data have clearly established the existence of two distinct types of reticular cells in the marrow stroma: (a) fibroblast-

like nonphagocytic reticular cells that have cell membraneâ€“associated alkaline phosphatase and no acid phosphatase and (b) macrophage-like phagocytic reticular cells that are positive for acid phosphatase but not for alkaline phosphatase (59).

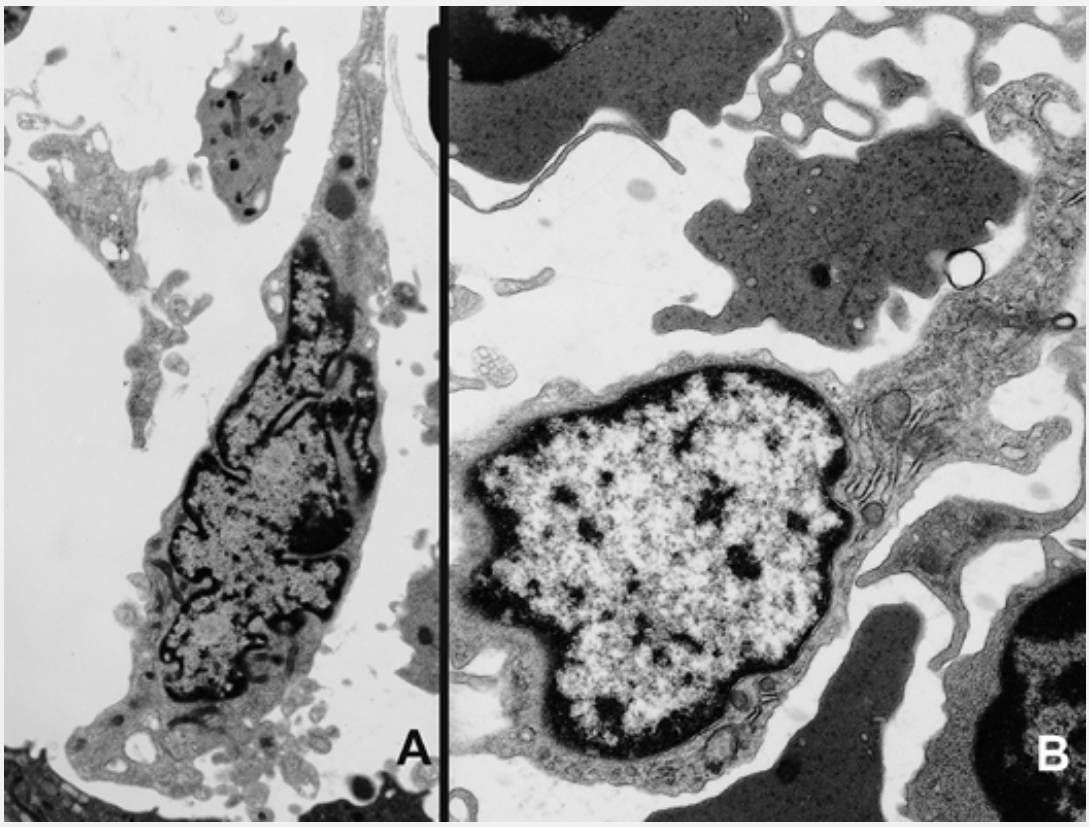

Figure 33.18 Electron micrographs of two nonphagocytic reticular cells from normal bone marrow. The nuclear outline of one of these cells (A) shows several deep clefts and that of the other (B) is less irregular.

Electron microscopic studies of nonphagocytic reticular cells in human bone marrow (48,60,61) have shown that, like macrophages, these cells extend branching cytoplasmic processes between

hematopoietic cells and are in contact with extracellular reticulin fibers (Figure 33.18). However, unlike macrophages, they do not have secondary lysosomes or have only an occasional secondary lysosome. They may contain variable numbers of filaments or a few small fat globules in their cytoplasm. The intracytoplasmic filaments sometime occur in bundles, and the cells are then ultrastructurally indistinguishable from adventitial cells. It is possible that the nonphagocytic reticular cells comprise a number of different cell types including fibroblasts or myofibroblasts, adventitial cells, and cells whose functions have not yet been defined. Myeloid cell and B-lymphoid progenitors are located adjacent to myofibroblasts.

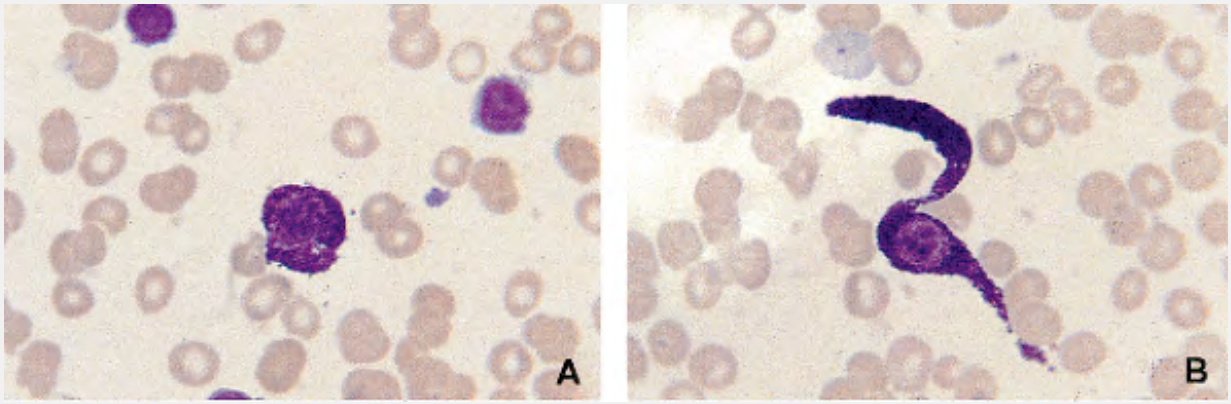

Figure 33.19 Two mast cells, one rounded (A) and one elongated (B) from MGG-stained smears of bone marrow.

At least some of the nonphagocytic reticular cells arise from a mesenchymal stem cell capable of giving rise to colonies of fibroblast-like or myofibroblast-like cells in vitro. As mentioned earlier, nonphagocytic reticular cells appear to play an important role in the microenvironmental regulation of hematopoiesis, both by binding to primitive hematopoietic cells (62) and by producing certain

hematopoietic growth factors both constitutively and in response to stimulation by monokines (63). In mice and presumably also in humans, they synthesize collagen (types I and III) and fibronectin.

Mast Cells

Mast cells tend to be found in association with the periphery of lymphoid follicles and the adventitia of small arteries and adjacent to the endosteal cells of bone trabeculae and the endothelial cells of sinusoids.

It is now known that the hematopoietic stem cells generate morphologically unrecognizable progenitors of mast cells within the bone marrow (64) and that the most mature of these cells enter the blood (65,66). The circulating cells, which still lack mast cell granules, migrate into the tissues, where they proliferate and mature into mast cells. Mast cells and basophils appear not to share a common early progenitor cell (67).

Unlike the granules of basophils, which are very water soluble, those of mast cells are much less so. Nevertheless, mast cells are not easily recognized in sections of marrow stained with H&E. By contrast, they are readily identified in sections stained with the Giemsa stain. In such sections, mast cells have round, oval, or spindle-shaped outlines and many dark purple cytoplasmic granules. The nucleus is often oval and may be situated eccentrically. Immunochemical staining can be performed using the antibody AA1, which reacts with mast cell tryptase (10) and does not cross-react with basophils. In Romanowsky-stained marrow smears, mast cells vary between 5 and 25 Âµm in their long axis and tend to have an ovoid or elongated shape (Figure 33.19Aâ€“B). The cytoplasm is packed with coarse purple-black to red-purple granules; but, unlike in basophil granulocytes, the granules seldom overlie the nucleus. The nucleus is small, round or oval, and either centrally or eccentrically located. It contains less condensed chromatin than that of a basophil granulocyte. The granules of mast cells are rich in

heparin and stain metachromatically with toluidine blue. Mast cells are also peroxidase negative, PAS positive, acid phosphatase positive, and Î±-naphthol AS-D chloroacetate esterase positive. Unlike basophil granulocytes, mast cells are capable of mitosis.

In the electron microscope, the granules of mast cells vary considerably in appearance. They may be homogeneously electron dense, have areas of increased electron density at their centers, or contain parallel arrangements, whorls, or scrolls of a crystalline or fibrillar structure (Figures 33.20Aâ€“B). The nucleus contains moderate quantities of condensed chromatin. In addition to the numerous granules, the cytoplasm contains some mitochondria, a few short strands of endoplasmic reticulum, occasional lipid droplets, and some fibrils.

Hematopoietic Cells

Lymphocytes and Plasma Cells

Histologic sections of normal marrow show nodules of small lymphocytes that are 0.08 to 1.2 mm in diameter and contain occasional reticular cells (68) (Figure 33.21A), as well as much smaller lymphoid aggregates; these nodules and aggregates are usually found in the intertrabecular and perivascular areas and are rarely found immediately adjacent to trabeculae. Paratrabecular nodules and aggregates are characteristic of infiltration by malignant lymphoid cells. In normal marrow, the prevalence of lymphoid nodules increases with age. About 20% of such nodules are irregular in outline, poorly circumscribed, and often contain several fat cells and a few eosinophils between the lymphocytes; they do not contain germinal centers, and their

reticulin content is normal for marrow or only slightly increased. The remaining 80% are rounded or oval, well circumscribed, and compact, and they have a follicular structure with blood vessels at

their center and some plasma cells and mast cells toward their periphery. Well-developed germinal centers are seen in about 5% of the sections. Lymphocytes extend between surrounding fat cells, and the entire nodule may be surrounded by eosinophils. The reticulin content of such a lymphoid nodule is clearly increased (Figure 33.21B). Immunohistochemical studies indicate that the lymphocytes within such nodules are of both T and B phenotypes (mainly T).

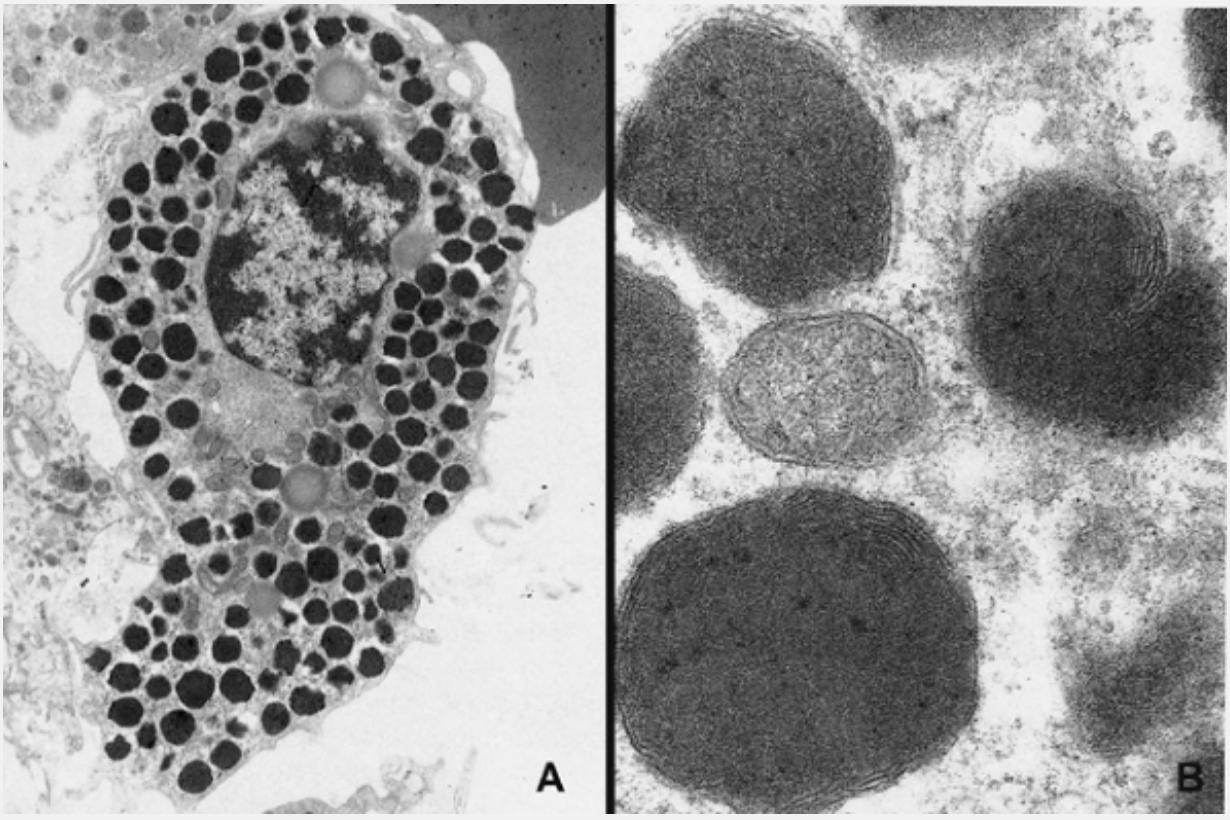

Figure 33.20 Electron micrographs of mast cells from normal bone marrow. A. The cytoplasm is packed with characteristic granules and contains four lipid droplets. B. Granules from a mast cell at high magnification showing parallel lamellae.

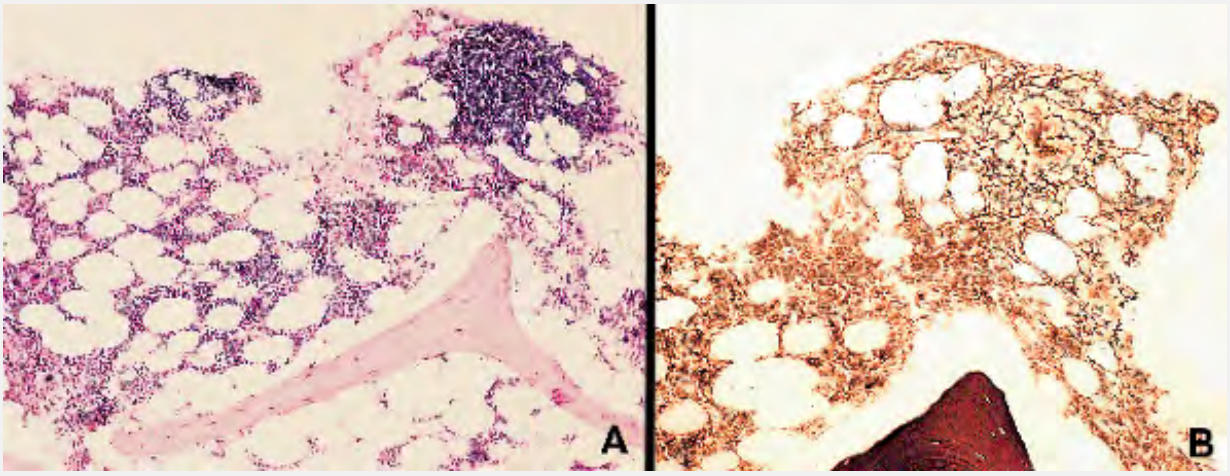

Figure 33.21 Lymphoid nodule in a paraffin-embedded trephine biopsy core from a woman without any evidence of a lymphoproliferative disorder. A. Section stained with hematoxylin and eosin showing a nodule (*top right*) incorporating fat cells at its periphery. B. Parallel section stained by a silver impregnation technique, showing increased reticulin in the nodule (photographed at higher magnification than A).

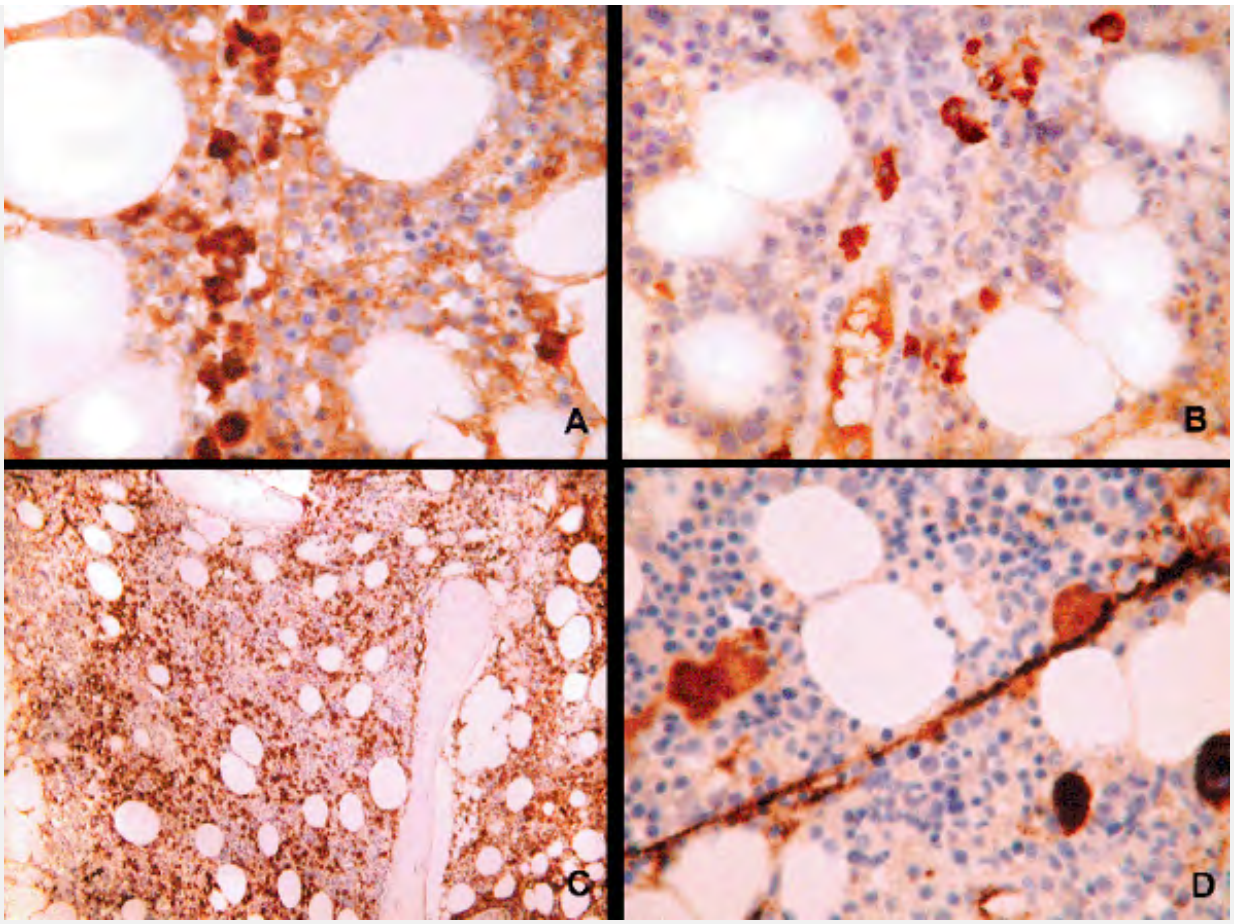

Figure 33.22 Immunohistochemical studies on sections of paraffin-embedded trephine biopsy cores. The reactions were visualized using an immunoalkaline phosphatase method. A. Section reacted with anti-Ig Îº light chains, showing plasma cells aligned along a blood vessel. B. Section reacted with anti-Ig Î» light chains showing a cluster of plasma cells. There are fewer positive plasma cells with anti-Î» chain than anti-Îº chain antibody. C. Section reacted with antimyeloperoxidase antibody showing positively-stained promyelocytes and more mature cells of the neutrophil granulocyte series. Note the presence of stained cells along the endosteal surface of the bone trabeculum. D. Section reacted with antibody against factor VIIIâ€“related antigen showing positively stained megakaryocytes and linearly arranged endothelial cells. One of the megakaryocytes is closely

apposed to the blood vessel. (Courtesy of Dr. Alex Rice, Department of Histopathology, St. Mary's Hospital, London).

T and B lymphocytes (with more T than B cells) and plasma cells also are found unassociated with lymphoid nodules. Lymphocytes are found scattered between hematopoietic cells, and plasma cells are often present in small groups, surrounding a central macrophage or sheathing some small blood vessels.There are more Îº than Î» light chainâ€“positive plasma cells (Figure 33.22Aâ€“B).

Precursors of Red Cells, Granulocytes, Monocytes, and Platelets

The early granulocytopoietic cells (myeloblasts and promyelocytes) mainly are found near the endosteum of bone trabeculae and the adventitial aspects of arterioles (Figure 33.22C). Maturing granulocyte precursors radiate outward from these sites, and the neutrophil granulocytes often are found in the center of intertrabecular areas, adjacent to sinusoids. A few promyelocytes and myeloctyes are present singly or in small clusters at sites away from bone trabeculae and blood vessels. Erythroblasts and megakaryocytes are also found away from the endosteum. The erythroblasts occur in one or two layers surrounding one or two central macrophages; the late erythroblasts and marrow reticulocytes usually are situated next to sinusoids. The megakaryocytes usually lie near sinusoids (Figure 33.22D) and protrude cytoplasmic processes into their lumina; these processes discharge platelets directly into the microcirculation.

Hematopoietic Cells: Characteristics in Marrow Smears and Ultrastructure

Neutrophil Precursors

The earliest morphologically recognizable neutrophil precursor is termed the myeloblast. The successive cytologic

classes through which myeloblasts mature into circulating neutrophil granulocytes are termed neutrophil promyelocytes, neutrophil myelocytes, neutrophil metamyelocytes, juvenile neutrophils, and marrow neutrophil granulocytes (Figures 33.23,33.24). Cell division occurs in myeloblasts, promyelocytes, and myelocytes but not in more mature cells.

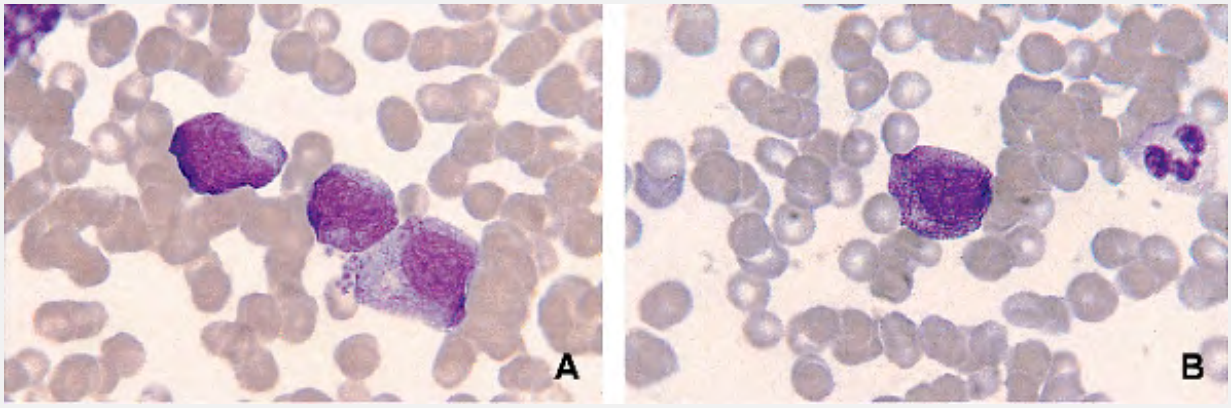

Figure 33.23 Neutrophil precursors from an MGG-stained normal marrow smear. A. A myeloblast, an early promyelocyte, and a late promyelocyte/early myelocyte. B. A promyelocyte and a neutrophil granulocyte.

A myeloblast is 10 to 20 Âµm in diameter. It has a large rounded nucleus with finely dispersed chromatin and two to five nucleoli. The nucleus-to-cytoplasm ratio is moderately high, and the cytoplasm is basophilic and nongranular. It is likely that only some myeloblasts mature into neutrophil promyelocytes and that others mature into eosinophil or basophil promyelocytes.

Neutrophil promyelocytes are larger than myeloblasts and have basophilic cytoplasm containing a few to several purple-red (azurophilic) granules. The nuclear chromatin pattern is slightly coarser than in myeloblasts, and there may be prominent nucleoli. The neutrophil myelocytes are characterized by the presence in their cytoplasm of many fine light pink (neutrophilic) granules in addition to some azurophilic granules; the neutrophilic granules also are termed *specific granules.* The nucleus is often eccentric and is round, oval, or slightly indented. The nuclear chromatin is coarsely granular, and the nucleoli are indistinct. The cytoplasm occupies a larger fraction of the cell volume than in promyelocytes; it initially appears pale blue but subsequently becomes predominantly pink. The progressive reduction of cytoplasmic basophilia during the maturation of a myeloblast to a mature myelocyte results largely from a reduction of blue-staining cytoplasmic RNA. The neutrophil metamyelocyte has a C-shaped nucleus and an acidophilic cytoplasm containing numerous fine neutrophilic granules. Few or no azurophilic granules are seen. Juvenile neutrophils (also called band or stab forms) have U-shaped or long, relatively narrow, bandlike nuclei that are often twisted into various configurations. The nuclei contain large clumps of condensed chromatin and may show one or more partial constrictions along their length. These constrictions become progressively more complete and eventually develop into the fine strands of chromatin that are typical of the segmented nuclei of marrow and blood neutrophil granulocytes. Most neutrophil granulocytes have two to five nuclear segments that are joined together by such strands. Some of the neutrophil granulocytes of females have a drumsticklike nuclear appendage (representing an inactivated X chromosome) attached to one of the nuclear segments.

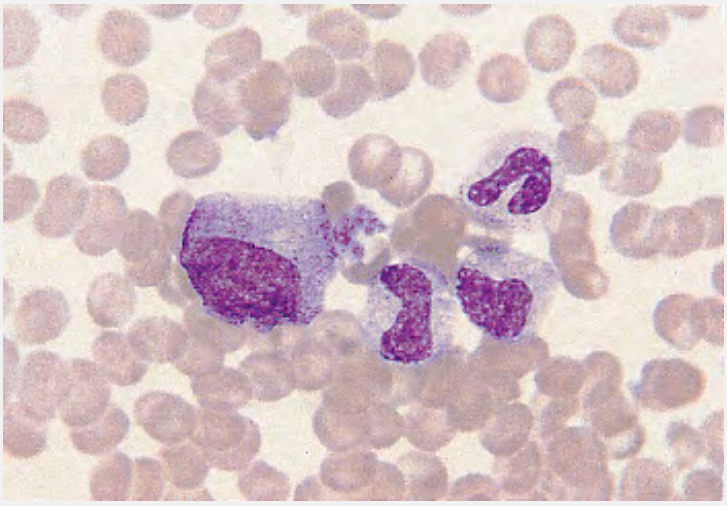

Figure 33.24 Two neutrophil myelocytes (one large and one small), a neutrophil metamyelocyte, and a juvenile neutrophil (stab form) from a normal marrow smear.

Cytochemistry

When stained by the PAS reaction, myeloblast cytoplasm shows a diffuse, pale red-purple tinge, sometimes with fine granules of the same color. Myeloblasts either do not stain with Sudan black or show a few small sudanophilic granules near the nucleus. They are also peroxidase-negative and, usually, Î±-naphthol AS-D chloroacetate esteraseâ€“negative. The cytoplasm of neutrophil promyelocytes and

more mature cells of the neutrophil series stain positively with the PAS reagent, with Sudan black, and with reactions for peroxidase and Î±-naphthol AS-D chloroacetate esterase activity. A granular staining pattern is produced with all these cytochemical reactions (Figure 33.25). The intensity of staining increases in cell classes of increasing maturity with the PAS reaction and, to a lesser extent, with Sudan black. Promyelocytes and neutrophil myelocytes, but not neutrophil granulocytes, stain for Î±-naphthyl acetate esterase

activity and, more weakly, for Î±-naphthyl butyrate esterase activity. Acid phosphatase activity is present in cells at and after the promyelocyte stage; this activity is strongest in the immature cells and weak in neutrophil granulocytes. A few neutrophil metamyelocytes stain weakly for alkaline phosphatase activity, and segmented neutrophil granulocytes stain with a variable intensity (weak to strong) (24,69,70,71). Immunocytochemical studies indicate that both lysozyme (muramidase) and elastase are present in promyelocytes and all of the more mature cells of the neutrophil series and that lactoferrin is present in neutrophil myelocytes, metamyelocytes, and granulocytes.

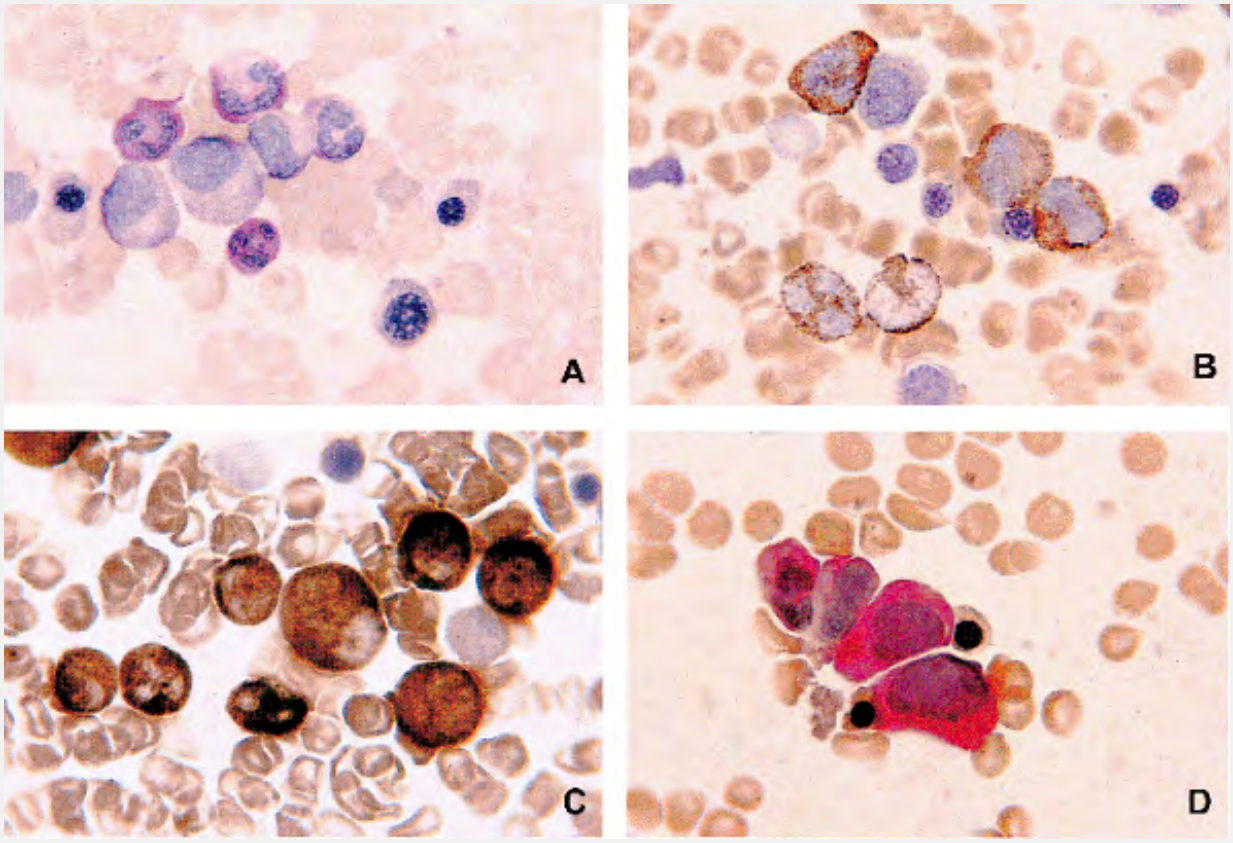

Figure 33.25 Cytochemical reactions of neutrophil precursors and neutrophil granulocytes. A. Faint PAS positivity in neutrophil myelocytes and stronger positivity in neutrophil granulocytes.

The three erythroblasts are PAS negative. B. Sudan black positivity in two neutrophil myelocytes, one eosinophil myelocyte, a neutrophil metamyelocyte, and a neutrophil granulocyte. The lymphocytes and erythroblasts are sudanophobic. C. Strong peroxidase positivity in neutrophil myelocytes and granulocytes; *p*-phenylene diamine and catechol were used as the substrate. D. Alpha-naphthol AS-D chloroacetate esterase positivity in three neutrophil myelocytes and a neutrophil granulocyte. The two erythroblasts have not stained. The diazonium salt of fast violet-red LB was used as the capture agent.

Ultrastructure

Myeloblasts show no special ultrastructural features (72,73,74,75). The nucleus has one or more well-developed nucleoli and shows only slight peripheral chromatin condensation. The cytoplasm contains many ribosomes but only a few strands of endoplasmic reticulum and a poorly developed Golgi apparatus. By contrast, the cytoplasm of a promyelocyte is much more complex, being rich in ribosomes, RER, and mitochondria. It also contains a highly developed Golgi apparatus. During the maturation of a promyelocyte to a neutrophil granulocyte, there is a progressive increase in the degree of condensation of nuclear chromatin; a progressive reduction in the quantity of ribosomes, RER, and mitochondria; a diminution of the Golgi apparatus after the myelocyte stage; and the accumulation of large quantities of glycogen at the metamyelocyte and

granulocyte stages. The cytoplasm of a promyelocyte characteristically contains a variable number of immature and mature primary granules. Mature primary granules are elliptical, measure 0.5 to 1.0 Âµm in their long axis, are electron dense, and contain peroxidase, lysozyme, elastase, Î±1 antitrypsin, and sulphated

mucosubstances. Some have a core with a linear periodic substructure. Ultrastructurally different granules, the secondary granules, are found in addition to primary granules at the neutrophil myelocyte stage (Figures 33.26,33.27). Secondary granules are larger and less electron dense than primary granules, have rounded outlines, tend to undergo a variable degree of extraction, and are only peroxidase positive if a high concentration of diaminobenzidine is used at alkaline pH. They contain lysozyme and vitamin B_{12} binding protein. Another variety of granule, known as tertiary granules, is present at and after the metamyelocyte stage. These granules are small (0.2â€“0.5 Âµm in their long axis), pleomorphic (including rounded, elongated, or dumbbell-shaped forms), and peroxidase negative. Their electron density is usually between that of primary and secondary granules (Figure 33.28). Other electron microscopic cytochemical studies have shown that acid phosphatase is present in primary granules but not in secondary or tertiary granules. The above data on the distribution of peroxidase and acid phosphatase suggest that secondary and tertiary granules do not arise from the modification of primary granules but are synthesized de novo at the myelocyte and metamyelocyte stages, respectively (72). Immunoelectron microscopy has demonstrated that lactoferrin is only found in some of the granules at and after the neutrophil myelocyte stage. The alkaline phosphatase activity in neutrophil granulocytes is present within small membrane-bound intracytoplasmic vesicles called phosphosomes.

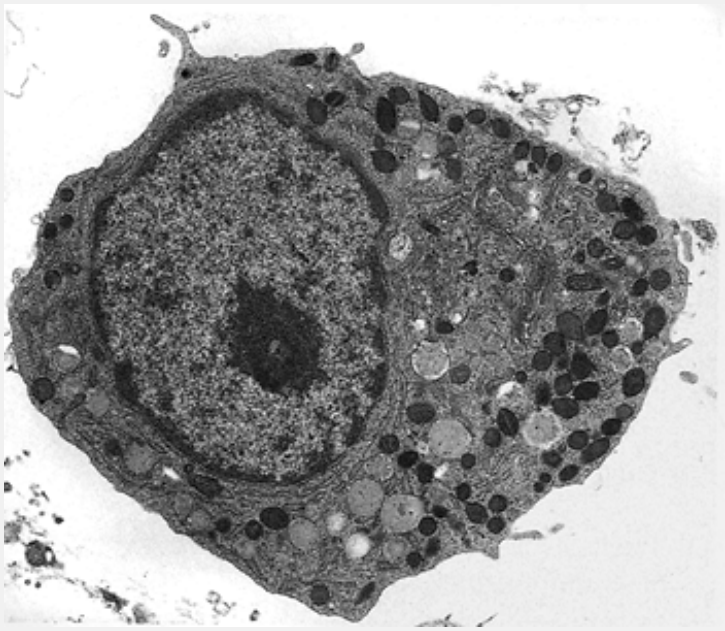

Figure 33.26 Electron micrograph of an immature neutrophil myelocyte from normal bone marrow. The nucleus contains a prominent nucleolus and a small quantity of nuclear membraneâ€“associated condensed chromatin. The cytoplasm contains several strands of endoplasmic reticulum, a prominent paranuclear Golgi apparatus, and two ultrastructurally distinct types of granules.

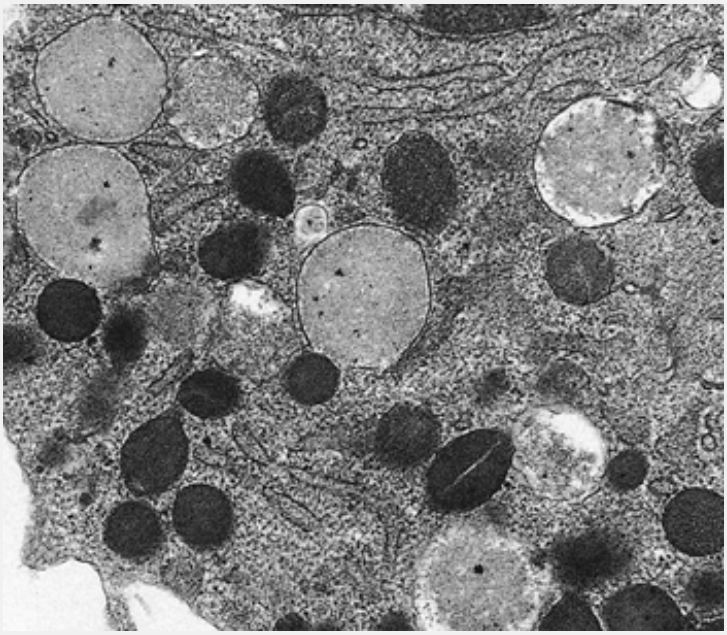

Figure 33.27 Part of the cytoplasm of the cell in Figure 33.26 at higher magnification. Two types of granules can be clearly recognized. These are (a) rounded or elliptical, very electron-dense primary granules (formed at the promyelocyte stage) and (b) larger, rounded, less electron-dense secondary granules (formed at the myelocyte stage).

The primary granules observed with the electron microscope correspond to the azurophilic granules seen in Romanowsky-stained smears, and the secondary and tertiary

granules correspond to the neutrophilic or specific granules. Although primary granules are present in all granule-containing cells of the neutrophil series, they lose their azurophilic property and are therefore not detectable by light microscopy at and after the metamyelocyte stage.

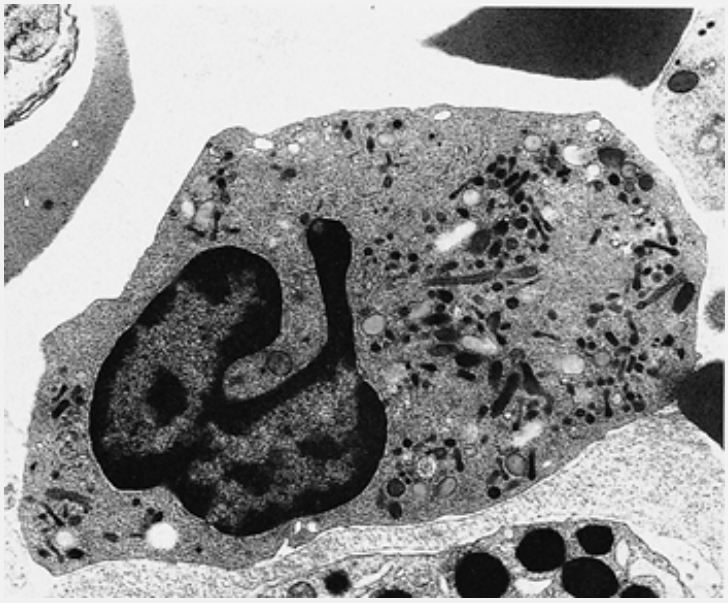

Figure 33.28 Electron micrograph of a neutrophil granulocyte from a normal bone marrow. In addition to some primary and secondary granules, the cytoplasm contains several small pleomorphic tertiary granules.

Eosinophil and Basophil Precursors

The eosinophil and basophil granulocytes develop through stages that are essentially similar to those through which the neutrophil granulocytes develop. The earliest morphologically recognizable precursors are cells in which a few eosinophil or basophil granules have formed, that is, the eosinophil promyelocytes and basophil promyelocytes. Eosinophil promyelocytes have rounded nuclei with dispersed chromatin and nucleoli and contain two types of granules: large red-orange (eosinophilic) granules and large bluish granules. Eosinophil myelocytes (Figure 33.29), metamyelocytes, and granulocytes have only large eosinophilic granules. Basophil myelocytes, metamyelocytes, and granulocytes are characterized by

the presence of large, round, deeply basophilic granules that often overlie the nucleus (Figure 33.30); the more mature granules stain metachromatically with toluidine blue. The majority of circulating eosinophil and basophil granulocytes have two nuclear segments.

Cytochemistry

The granules of eosinophil and basophil granulocytes and their precursors do not stain by the PAS reaction (24,76). However, PAS-positive deposits are found between the specific granules in both cell lineages. The periphery of the eosinophil granules of all cells of the eosinophil series stains strongly with Sudan black, and the core stains weakly or not at all. Basophil granules are strongly sudanophilic in basophil promyelocytes and myelocytes, but the degree of sudanophilia decreases with increasing maturity; in mature basophils, the granules either do not stain or stain metachromatically (reddish). Peroxidase and acid phosphatase but not lysozymes are demonstrable in the eosinophil granules in all eosinophil precursors and eosinophils. Human eosinophil peroxidase is biochemically and immunochemically distinct from myeloperoxidase, the type of peroxidase present in the neutrophil series. In the basophil series, the granules are strongly positive for peroxidase in basophil promyelocytes and myelocytes, weakly positive in basophil metamyelocytes, and almost negative in basophil granulocytes. Basophil granules stain positively for acid phosphatase. Basophil and eosinophil granulocytes are essentially negative for Î±-naphthol AS-D chloroacetate esterase and Î±-naphthyl butyrate esterase.

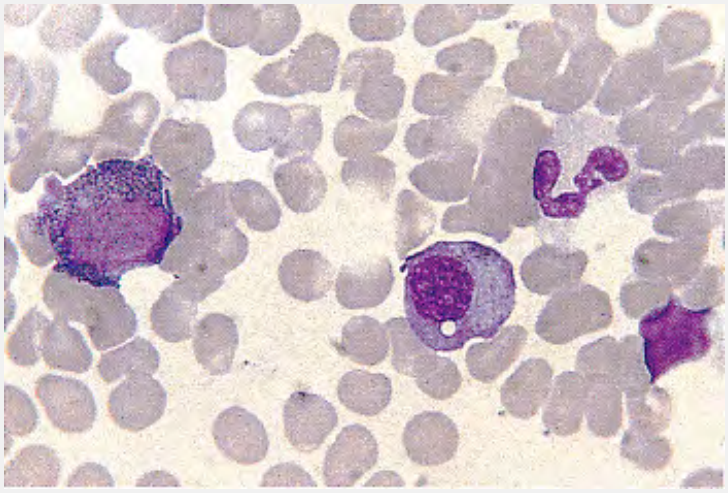

Figure 33.29 Cells from an MGG-stained normal bone marrow smear. The cell types shown are, from left to right, an eosinophil myelocyte, a plasma cell, a neutrophil granulocyte, and a lymphocyte.

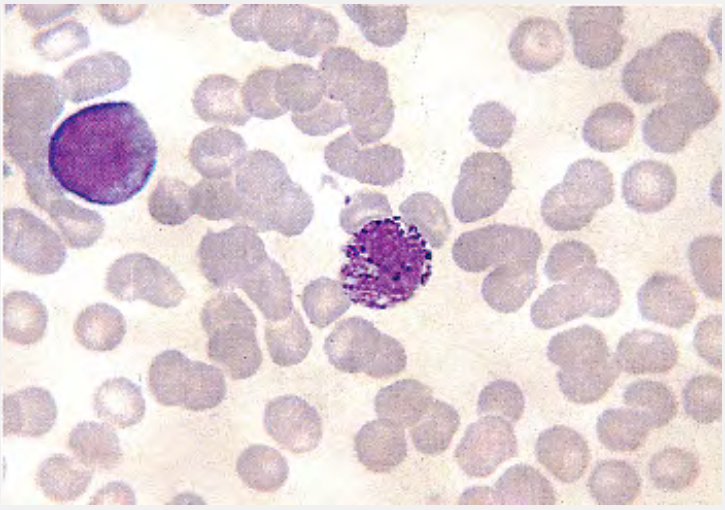

Figure 33.30 Basophil granulocyte from an MGG-stained normal marrow smear.

Eosinophil granules contain eosinophil cationic proteins and an arginine- and zinc-rich major basic protein that are involved in the killing of metazoan parasites. The major basic protein also stimulates basophils and mast cells to release histamine. Other constituents of eosinophil granules include histaminase and arylsulfatase, which are involved in the modulation of immediate-type hypersensitivity reactions. Basophil granules contain chondroitin sulfate and heparin sulfate, which account for their property of staining metachromatically (red-violet) with toluidine blue. They also contain histamine, one of the substances released when immunoglobulin E (IgE)-coated basophils react with specific antigen.

Ultrastructure

On the basis of their electron microscopic features, two types of eosinophil granules, termed primary and secondary granules, are recognized (75,77). Primary granules are large, rounded, homogeneous, and electron dense, and

secondary granules contain a central electron-dense crystalloid inclusion consisting largely of polymerized major basic protein. It is generally held that the primary granules mature into secondary granules. Early eosinophil promyelocytes contain only primary granules, but more mature promyelocytes contain many primary and a few secondary granules. Eosinophil myelocytes contain some primary and several secondary granules (Figure 33.31). By contrast, the majority of the granules in eosinophil metamyelocytes and granulocytes are secondary granules (Figure 33.32). The primary granules of eosinophil promyelocytes are larger and more rounded than the primary granules of neutrophil promyelocytes and

promonocytes.

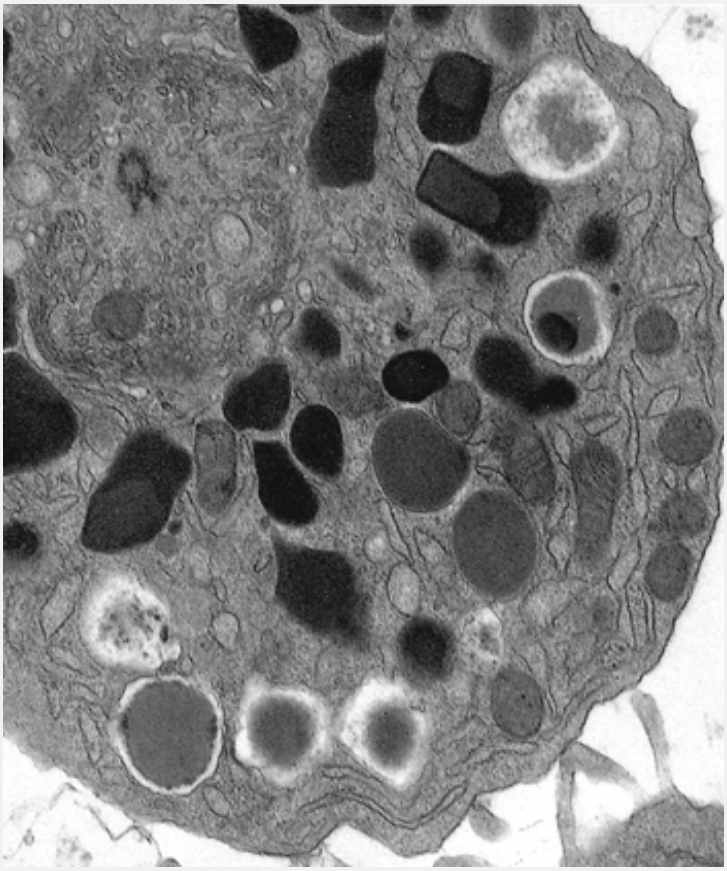

Figure 33.31 Electron micrograph of part of the cytoplasm of an early eosinophil myelocyte. A centriole surrounded by well-developed Golgi saccules, several strands of rough endoplasmic reticulum, and a number of large granules are seen. Some of the granules are homogeneously electron dense (primary granules), but others have a central crystalloid (secondary granules).

Cells of the basophil series contain characteristic basophil granules, which are prone to undergo varying degrees of extraction during processing for electron microscopy (Figure 33.33). Basophil granules are made up of numerous, closely packed, fine rounded particles (Figure 33.34); the particles are about 20 nm in diameter in mature

basophils and slightly smaller in basophil promyelocytes and myelocytes.

Monocyte Precursors

The morphologically recognizable cells belonging to the monocyte series are the monoblasts, promonocytes, marrow monocytes, and blood monocytes. The blood monocytes are not end cells but develop further in the tissues to become macrophages. Certain data suggest that macrophages and osteoclasts have a common progenitor. All these cells are considered to constitute the mononuclear phagocyte system. In this system, cell division occurs mainly in the monoblasts and promonocytes.

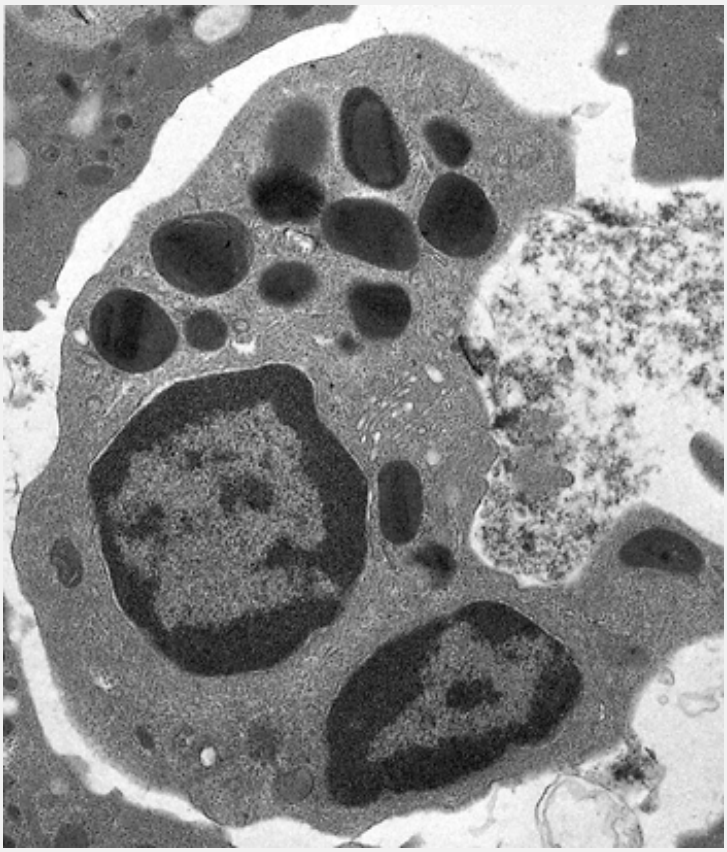

Figure 33.32 Electron micrograph of an eosinophil granulocyte

from normal bone marrow. The majority of the cytoplasmic granules are crystalloid-containing secondary granules. Note that the uppermost granule is unusual in that its crystalloid stains more lightly than the surrounding granule matrix.

Monoblasts are similar in appearance to myeloblasts except that their nuclei may be slightly indented or lobulated.

They have small quantities of agranular deeply basophilic cytoplasm and can only be reliably distinguished from other types of blast cells by cytochemical and other special techniques (Figure 33.35). Promonocytes are larger, have a lower nucleus-to-cytoplasm ratio, and contain less basophilic cytoplasm than monoblasts; their cytoplasm contains a few azurophilic granules. Promonocytes usually have a large, rounded, cleft or lobulated nucleus with the chromatin appearing as a fine network. Nucleoli may or may not be visible.

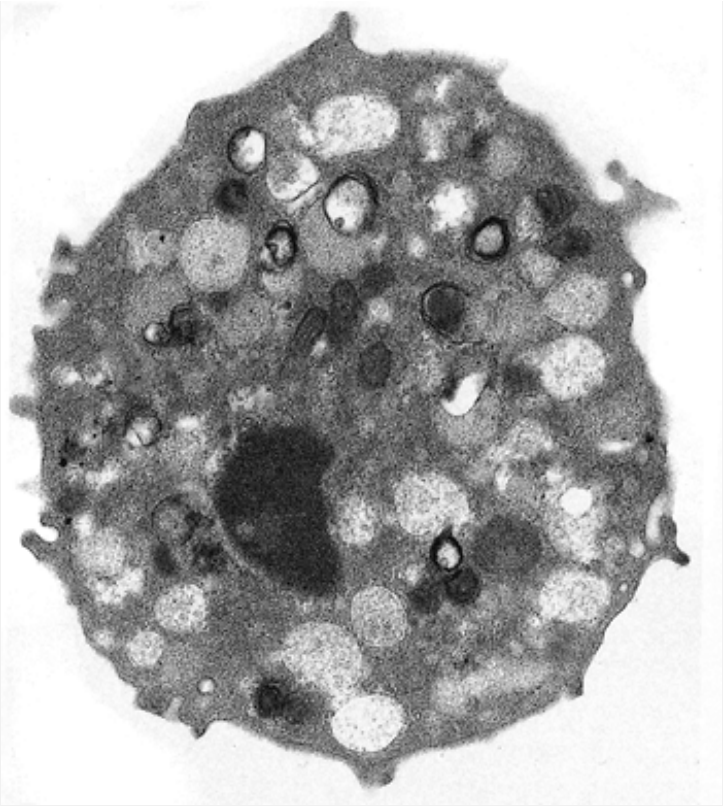

Figure 33.33 Electron micrograph of a basophil granulocyte from a normal bone marrow. The granules have been markedly extracted during processing, but the characteristic closely packed rounded particles can still be recognized in several of the granules.

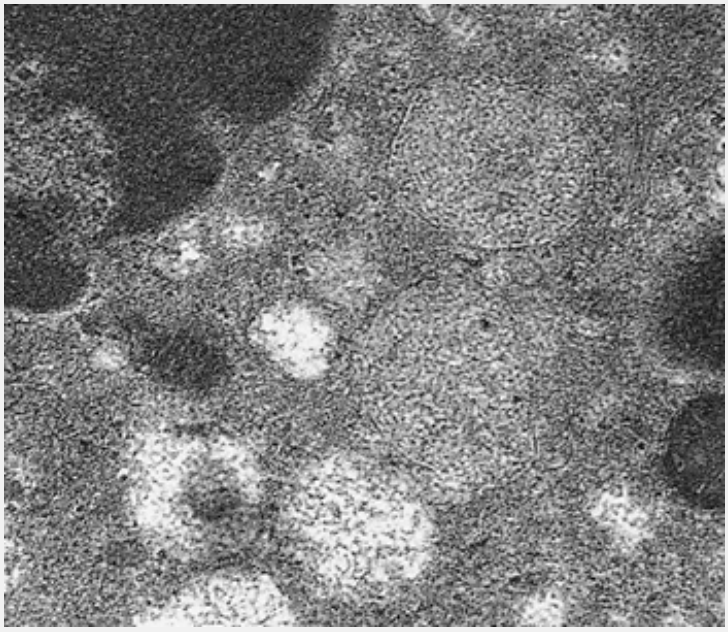

Figure 33.34 Electron micrograph illustrating the particulate ultrastructure of basophil granules at high magnification.

Marrow monocytes and blood monocytes have a lower nucleus-to-cytoplasm ratio (<1), a less basophilic cytoplasm, and a larger number of azurophilic granules than promonocytes. The cytoplasm is pale gray-blue, has a ground glass appearance, and may contain vacuoles. The nucleus is eccentrically placed and may be oval, kidney-shaped, horseshoe-shaped, or lobulated; the chromatin has a skeinlike or lacy appearance.

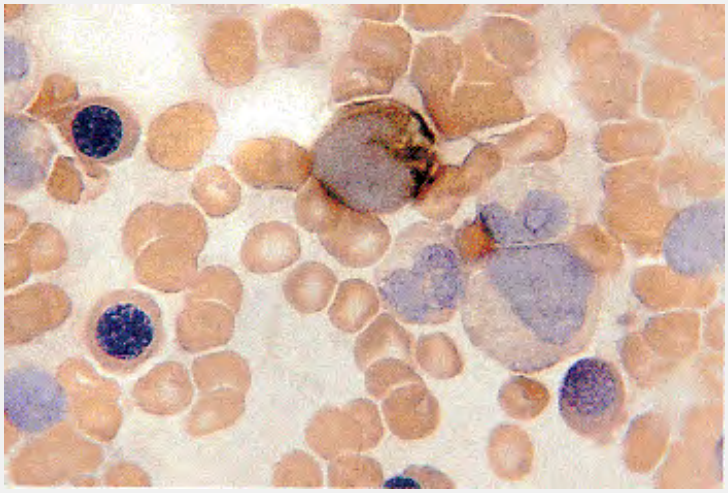

Figure 33.35 A cell with strong Î±-naphthyl acetate esterase activity from a normal marrow smear (the diazonium salt of fast blue BB was used as the capture agent). This cell has a slightly convoluted nucleus and relatively little cytoplasm and is most probably a monoblast or early promonocyte.

Cytochemistry

Some normal monocytes show several fine or moderately coarse PAS-positive granules and sudanophilic granules and a few peroxidase-positive granules scattered in their cytoplasm (24,71,78). Monocytes do not stain for alkaline phosphatase but stain strongly for acid phosphatase. They contain lysozyme.

Monocytes are Î±-naphthol AS-D chloroacetate esterase negative but are Î±-naphthyl acetate esterase (nonspecific esterase) positive. Alpha-naphthyl acetate esterase activity is present not only in monocytes and macrophages, but also in other myeloid cells, including neutrophil promyelocytes and myelocytes, megakaryocytes, and immature red cell precursors. Alpha-naphthyl butyrate esterase activity is stronger than Î±-naphthyl acetate esterase activity in

monocytes and macrophages and is much weaker in the other types of myeloid cells mentioned above. Both the Î±-naphthyl acetate and the Î±-naphthyl butyrate esterase activities of monocytes are inhibited by fluoride; in granulocytes and their precursors, these enzyme activities are fluoride insensitive.

Ultrastructure

The earliest monocyte precursor that can be identified on ultrastructural criteria (72,75) is the promonocyte. The nucleus of this cell has only small quantities of nuclear membraneâ€“associated condensed chromatin and has one or more nucleoli. The cytoplasm contains many ribosomes, a moderate number of mitochondria, several strands of RER, bundles of fibrils, a prominent Golgi apparatus, and a few characteristic cytoplasmic granules. The strands of endoplasmic reticulum are shorter and less abundant than in neutrophil promyelocytes. Two types of cytoplasmic granules are seen in promonocytes: (a) immature granules, which have a central zone of flocculent electron-dense material and a clear peripheral zone, and (b) mature granules, which are smaller than the immature granules, vary considerably in size and shape, and are homogeneously electron dense (Figures 33.36,33.37). The maturation of promonocytes first into marrow monocytes and then into blood monocytes is associated with some increase in the quantity of condensed chromatin in the nucleus, a progressive reduction in the number of ribosomes, RER, and fibrils in the cytoplasm, and an increase in the number of cytoplasmic granules. Most or all of the granules of marrow monocytes and all the granules of blood monocytes are of the mature type. Ultrastructural cytochemical studies have shown that some large round granules have acid phosphatase activity and that such granules are more frequent in promonocytes than

monocytes. All the promonocyte granules and some of the monocyte granules are peroxidase positive.

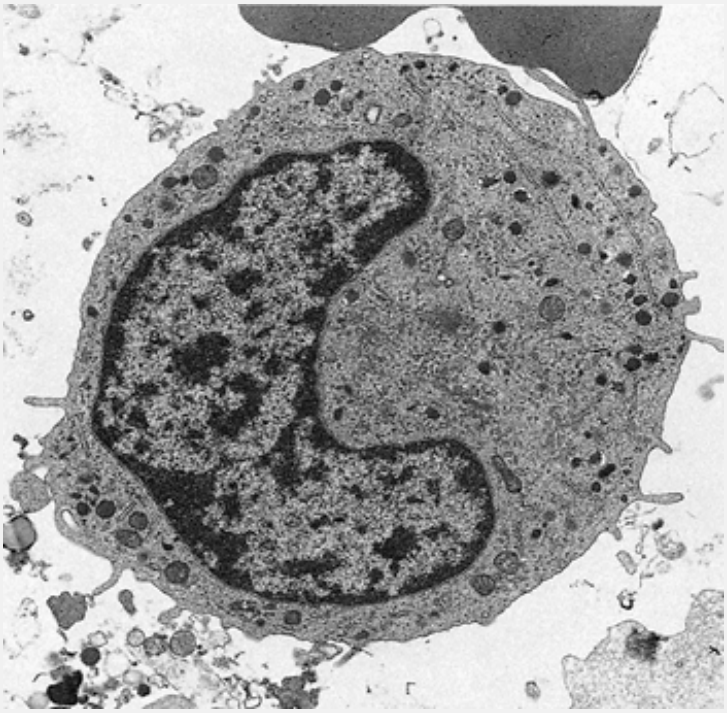

Figure 33.36 Electron micrograph of an immature monocyte from normal bone marrow. The cytoplasm contains many small mature granules and a few immature granules (see Figure 33.37). Several short cytoplasmic processes can be seen at the periphery of the cell.

Red Cell Precursors

In this chapter, the term *erythroblast* is used to describe any nucleated red cell precursor, normal or pathologic, and the term *normoblast* to describe all cells that have the morphologic characteristics of the erythroblasts found in normal bone marrow. The terms used to describe various classes of normal red cell precursor are, in order of increasing maturity, pronormoblast, basophilic normoblast, early polychromatic normoblast, late polychromatic normoblast, marrow reticulocyte, and blood

reticulocyte (Figure 33.38). Cell division occurs only in the first three of these cytologic classes. Marrow samples containing normoblasts are said to show normoblastic erythropoiesis.

Pronormoblasts are large cells with a diameter of 12 to 20 Âµm. They have rounded nuclei and moderate quantities of agranular cytoplasm that stains intensely basophilic except for a pale area (corresponding to the Golgi apparatus) adjacent to the nucleus. The nuclear chromatin has a finely stippled or fine reticular appearance, and there are one or more prominent nucleoli. The basophilic normoblasts resemble pronormoblasts except that their nuclear chromatin is slightly more condensed and consequently has a coarsely granular appearance. The early polychromatic normoblasts are smaller than basophilic normoblasts and have a smaller nucleus and a lower nucleus-to-cytoplasm ratio. The cytoplasm is polychromatic and agranular, and the nucleus contains several medium-sized clumps of condensed chromatin, particularly adjacent to the nuclear membrane. The polychromasia results from the presence of moderate quantities of cytoplasmic RNA (which stains blue), as well as of hemoglobin (which stains red). Late polychromatic normoblasts are even smaller and show a further reduction in the ratio of the area of the nucleus to the area of the cytoplasm. The cytoplasm is predominantly orthochromatic but still has a grayish tinge (i.e., is faintly polychromatic). The nucleus is small and eccentric and contains large clumps of condensed chromatin. The nuclear diameter is less than about 6.5 Âµm. When mature, late polychromatic normoblasts extrude their nuclei and become marrow reticulocytes; the extruded nuclei are rapidly phagocytosed and degraded by adjacent macrophages. The marrow reticulocyte is irregular in outline and has faintly polychromatic cytoplasm. It is motile and soon enters the marrow sinusoids. When marrow and blood reticulocytes are stained supravitally with brilliant cresyl blue, the ribosomal RNA responsible for their polychromasia precipitates into a basophilic reticulum (hence the term *reticulocyte*). Reticulocytes circulate in the blood for one to two days before becoming mature red cells. The average

volume of blood reticulocytes is 20% larger than that of red cells. The latter are circular, biconcave, and acidophilic (i.e., stain red) and, in dried fixed smears, have an average diameter of 7.2 Âµm (range: 6.7â€“7.7 Âµm).

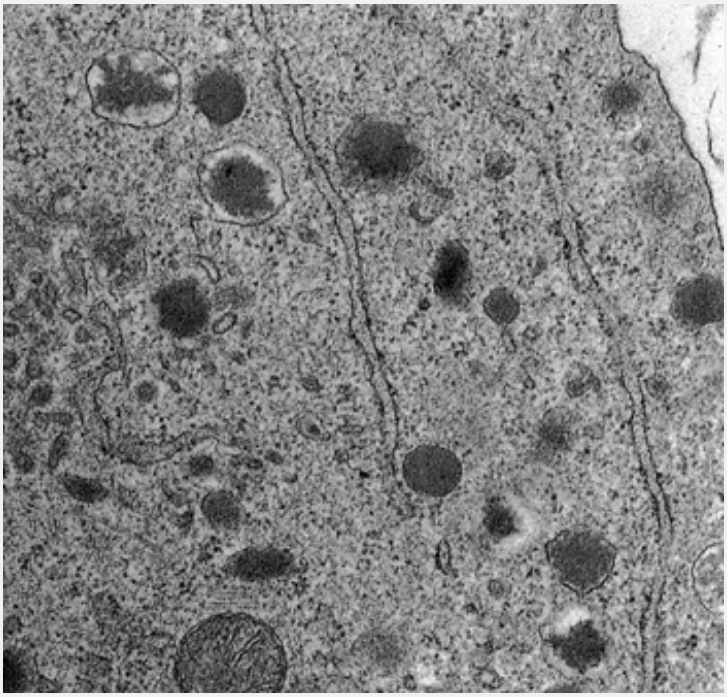

Figure 33.37 A higher-power view of part of the cytoplasm of the cell in Figure 33.36 showing a few immature-looking granules with an electron-dense central zone and an electron-lucent peripheral zone. There are also some small, uniformly electron-dense mature granules.

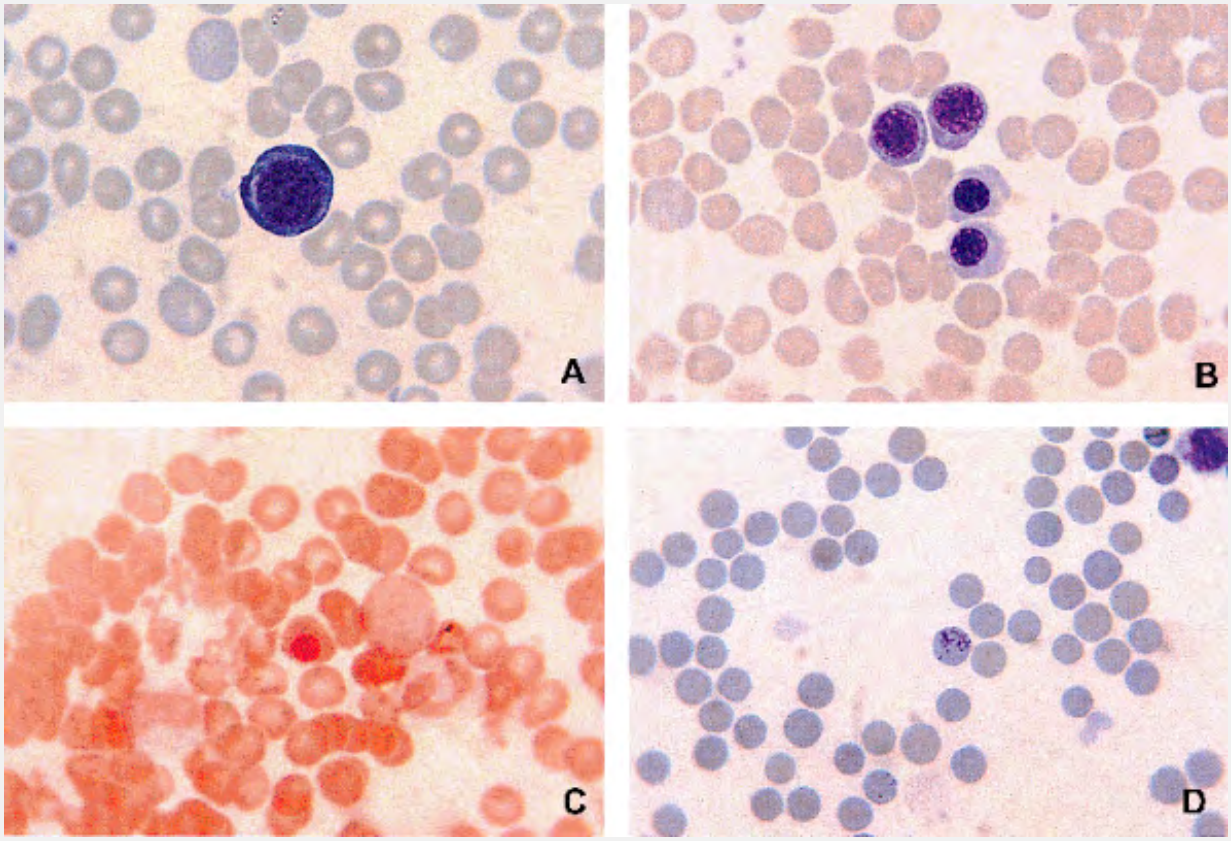

Figure 33.38 Red cell precursors from a normal bone marrow smear (Aâ€“C) and a reticulocyte from normal peripheral blood (D). A. Pronormoblast. B. Two early polychromatic normoblasts and two late polychromatic normoblasts. C. A sideroblast showing a fine, barely visible blue siderotic granule. (A and B, MGG stain; C, Perls' acid ferrocyanide reaction; D, supravital staining with brilliant cresyl blue.)

Cytochemistry

Normal erythroblasts are PAS negative. They also fail to stain with Sudan black and are peroxidase negative. Most nucleated red cells are Î±-naphthol AS-D chloroacetate esterase negative, but occasional

cells show a few positive granules. A few Î±-naphthol butyrate esteraseâ€“positive granules are seen in some nucleated red cells of all degrees of maturity; the positive granules are sometimes seen at the nuclear margin. Coarse acid phosphataseâ€“positive paranuclear granules are frequently present in all types of erythroblasts.

In normal bone marrow smears stained by Perls' acid ferrocyanide method, 20 to 90% of the polychromatic erythroblasts contain one to five small blue-black granules that are usually just visible at high magnification (Figure 33.38C). These iron-containing (siderotic) granules are randomly distributed within the cytoplasm and correspond to the siderosomes seen under the electron microscope. Erythroblasts containing siderotic granules are termed *sideroblasts.* In iron deficiency anemia and, to a lesser extent, in the anemia of chronic disorders, the percentage of sideroblasts is decreased. In conditions associated with an increased percentage saturation of transferrin (e.g., hemolytic anemias), the average number of siderotic granules per cell and the average size of such granules are increased.

Ultrastructure

All nucleated red cell precursors are characterized by the presence of small surface invaginations that develop into intracytoplasmic vesicles (rhopheocytotic vesicles) (75) (Figure 33.39). The nucleus of the pronormoblast has a small quantity of nuclear membraneâ€“associated condensed chromatin (Figure 33.40). The cytoplasm is of low-electron density and contains numerous ribosomes, a moderately well-developed Golgi apparatus, several mitochondria, some strands of endoplasmic reticulum, and small numbers of scattered ferritin molecules. It also contains a few pleomorphic electron-dense acid phosphataseâ€“positive lysosomal granules, which are usually arranged in a group near the Golgi saccules. During the maturation of a pronormoblast into a late polychromatic normoblast (Figure 33.41), the following changes are

seen: (a) a steady increase in the quantity of condensed chromatin, (b) a gradual increase in the electron density of the cytoplasmic matrix due to the synthesis of increasing quantities of hemoglobin, (c) a progressive reduction in the number of ribosomes in the cytoplasm, (d) a reduction in the number and size of the mitochondria, and (e) an increasing tendency for some of the intracytoplasmic ferritin molecules to aggregate and form siderosomes (Figures 33.42,33.43). Small autophagic

vacuoles are found in 22% and slight to substantial degrees of myelinization of the nuclear membrane in 12% of erythroblast profiles (79). Other data shown by electron microscopic studies of the erythron are that (a) part of the cell's cytoplasmic membrane and a narrow rim of hemoglobin-containing cytoplasm completely surrounds the extruded erythroblast nucleus (Figure 33.44); (b) the marrow reticulocytes enter the sinusoids by passing through, rather than between, endothelial cells (Figure 33.45); and (c) whereas reticulocytes contain ribosomes and mitochondria, mature red cells do not.

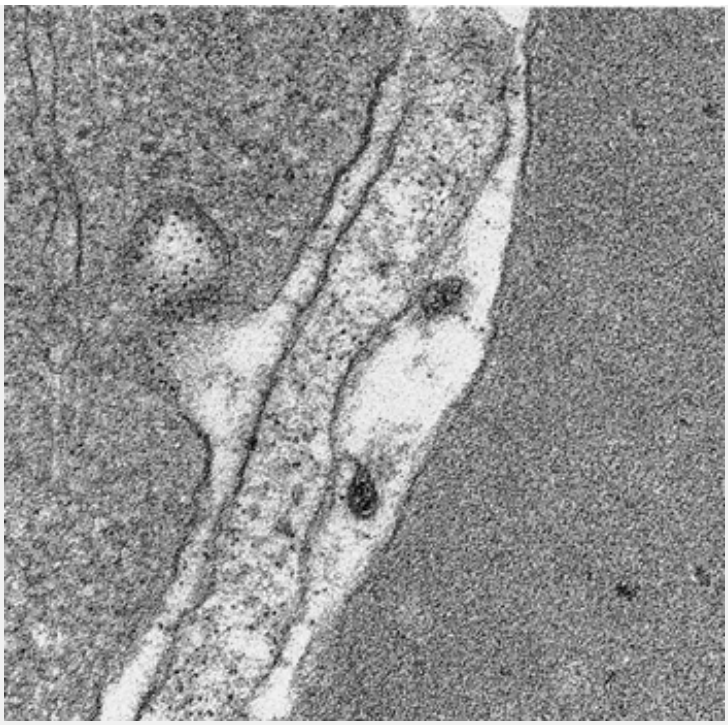

Figure 33.39 Part of an early polychromatic erythroblast showing a rhopheocytotic surface invagination with a few adherent ferritin molecules. A rhopheocytotic vesicle containing several ferritin molecules is closely apposed to the surface invagination. A narrow process of ferritin-containing macrophage cytoplasm is present between the erythroblast displaying rhopheocytosis and the adjacent cell.

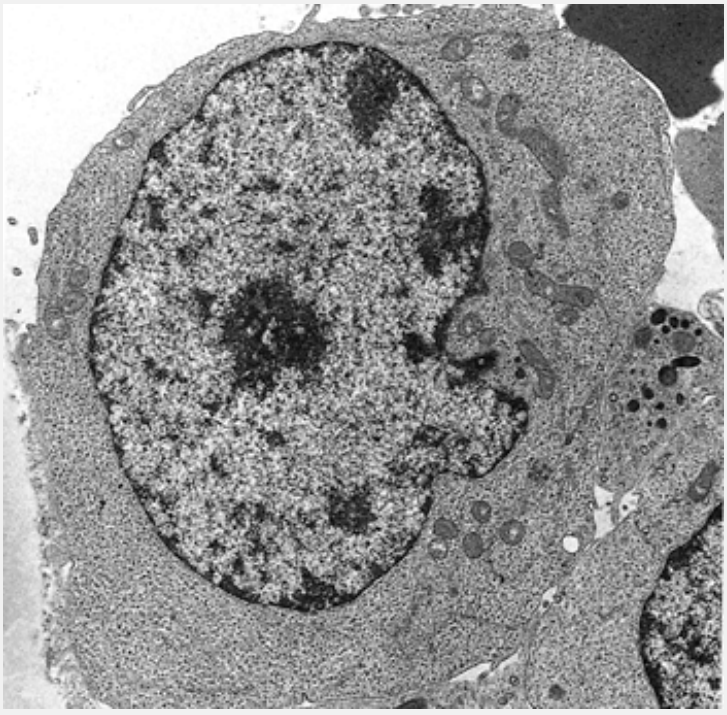

Figure 33.40 Electron micrograph of a pronormoblast from normal bone marrow. The nucleus contains very small quantities of condensed chromatin and has a prominent nucleolus. The cytoplasm is relatively electron lucent and rich in polyribosomes.

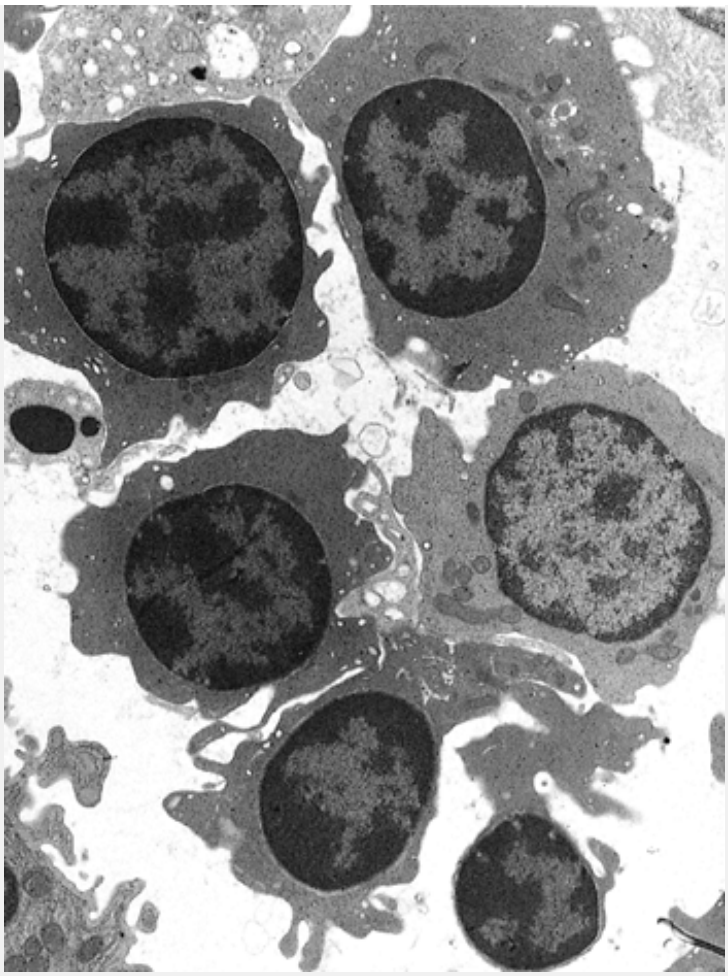

Figure 33.41 Electron micrograph of a group of six erythroblasts at various stages of maturation. Note that maturation is associated with an increase in the electron density of the cytoplasm. The lowermost cell is a late erythroblast about to extrude its nucleus.

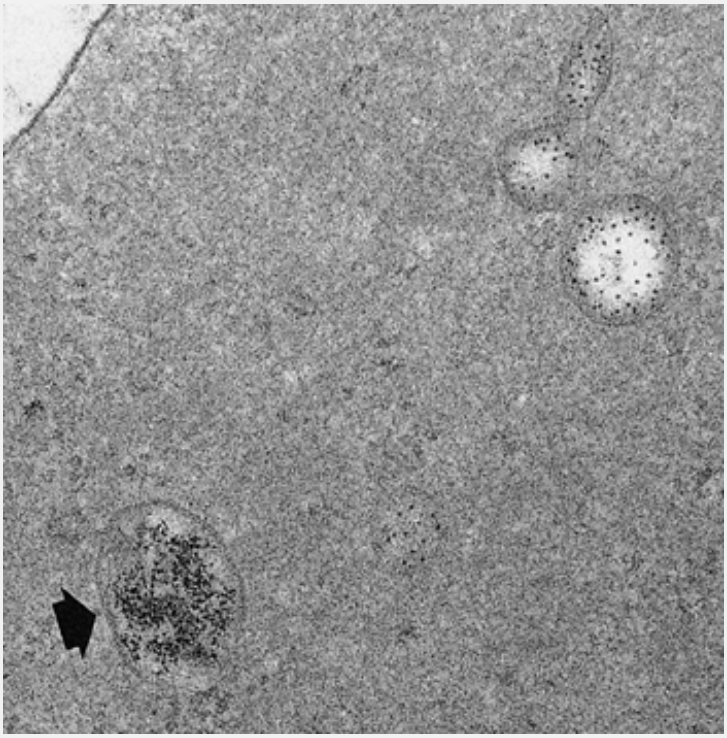

Figure 33.42 Electron micrograph of part of the cytoplasm of a polychromatic erythroblast from normal bone marrow. The cytoplasm shows a membrane-bound accumulation of ferritin and hemosiderin (siderosome) (*arrow*) and a few ferritin-containing rhopheocytotic vesicles.

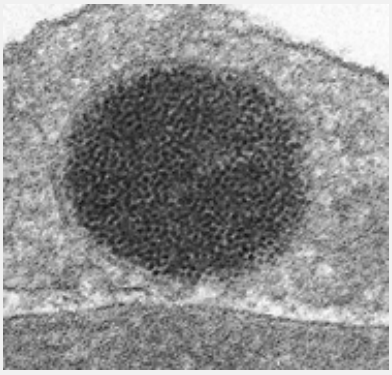

Figure 33.43 Part of a polychromatic erythroblast from a normal marrow showing a membrane-bound siderosome that is much more densely packed with ferritin and hemosiderin molecules than the siderosome in Figure 33.42.

Dyserythropoiesis and Ineffective Erythropoiesis

Most of the erythroblasts in normal bone marrow are uninucleate and do not display any unusual morphologic features. However, when 400 to 1,000 consecutive erythroblasts (excluding mitoses) were studied in bone marrow smears from each of 10 healthy volunteers with stainable iron in the bone marrow, 0 to 0.57% (mean: 0.31%) were found to be binucleate, 0.7 to 4.8% (mean: 2.4%) showed intererythroblastic cytoplasmic bridges, 0 to 0.9% (mean: 0.24%) showed cytoplasmic stippling, and 0 to 0.7% (mean: 0.39%) showed cytoplasmic vacuolation. In addition, 0 to 0.55% (mean: 0.22%) had markedly irregular nuclear outlines or karyorrhectic nuclei, and 0 to 0.39% (mean: 0.18%) contained Howell-Jolly bodies (micronuclei), a marker of chromosome breaks (80) (Figure 33.46). In another study of 15 healthy males in which 5,000 erythroid cells (including mitoses) were assessed per subject, 0.14% Â± 0.04 (SD) were found

to be binucleate or multinucleate cells or to be pluripolar mitoses (81). A number of other unusual morphologic features are seen in some erythroblast profiles when the marrow is examined with the electron microscope. These include short stretches (250â€“910 nm) of duplication of the nuclear membrane in 2% of the profiles, short (260â€“520 nm) intranuclear clefts in 1.7%, and iron-laden mitochondria in less than 0.2% (79). The above-mentioned light and electron microscopic features are sometimes described as dyserythropoietic changes, with the implication that they are morphologic manifestations of a minor disturbance of

proliferation or maturation in the affected cells. In many congenital or acquired disorders characterized by grossly disordered erythropoiesis, the proportion of erythroblasts showing these dyserythropoietic changes is increased, and some erythroblasts show various dyserythropoietic changes not seen in normal marrow (43). The latter include nonspecific abnormalities, such as large autophagic vacuoles and extensive intranuclear clefts, as well as abnormalities that are specific for certain diseases or groups of diseases.

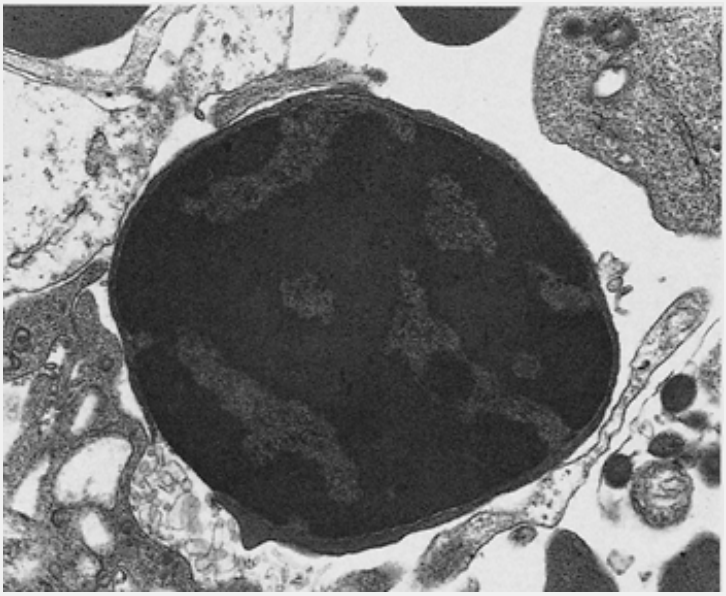

Figure 33.44 Electron micrograph of an extruded erythroblast nucleus. Note that the nucleus is surrounded by a rim of hemoglobin-containing cytoplasm and lies in close contact with processes of macrophage cytoplasm.

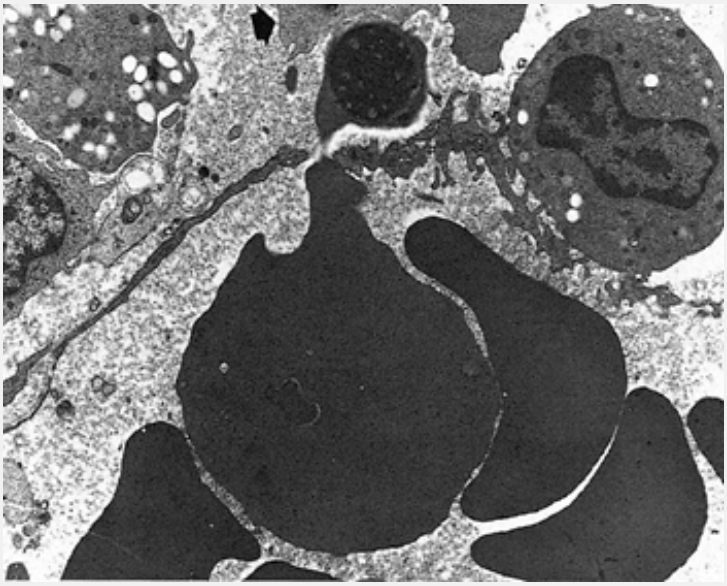

Figure 33.45 Electron micrograph illustrating an uncommon mechanism of formation of a reticulocyte. Whereas nuclear expulsion often occurs extravascularly and the resulting reticulocytes then enter a sinusoid, the cytoplasm of the late erythroblast shown has passed through the endothelial cell of the sinusoid before nuclear expulsion. The nucleus of this erythroblast has not passed through the narrow passage in the endothelial cell and presumably will be severed from the rest of the cell and phagocytosed by the macrophage (*arrow*) lying in contact with it. Thus, in this erythroblast, nuclear expulsion appears to occur during entry of the future reticulocyte into the sinusoid.

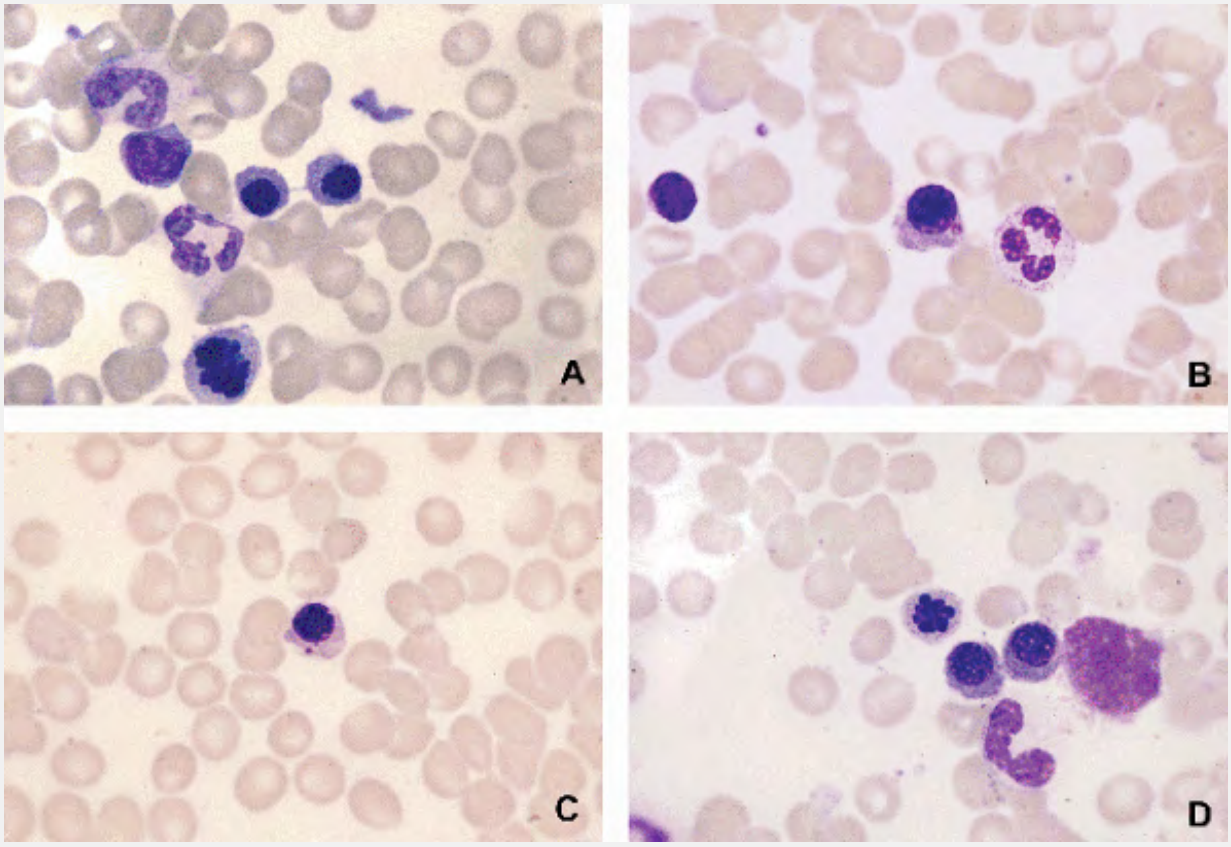

Figure 33.46 Morphologic evidence of dyserythropoiesis in bone marrow smears from healthy volunteers. A. Intererythroblastic cytoplasmic bridge. B. Large Howell-Jolly body in an early polychromatic erythroblast. C. Two smaller Howell-Jolly bodies in a late polychromatic erythroblast. D. Karyorrhexis in a late polychromatic erythroblast.

The phrase *ineffective erythropoiesis* is used to describe the loss of potential erythrocytes due to the phagocytosis and destruction of developing erythroblasts within the bone marrow. The extent of ineffective erythropoiesis in normal bone marrow is small (25). In a number of conditions such as homozygous Î²-thalassemia and the megaloblastic anemias, there is a gross increase in the ineffectiveness of erythropoiesis; some of the abnormal erythroblasts

undergo apoptosis prior to phagocytosis. In such conditions, erythroblasts at various stages of degradation may be recognized within marrow macrophages, both by light and electron microscopy. Apoptosis at the late BFU-E and CFU-E stages is thought to be a major factor controlling the rate of erythropoiesis.

Megakaryocytes

The majority of the cells of the megakaryocyte series are larger than other hematopoietic cells and have polyploid DNA contents. The earliest morphologically recognizable cells in this series are called megakaryoblasts. These are 20 to 30 Âµm in diameter and have a single large, oval, kidney-shaped, or lobed nucleus that is surrounded by a narrow rim of intensely basophilic agranular cytoplasm. The nucleus contains several nucleoli. Megakaryoblasts (group I megakaryocytes) mature into promegakaryocytes (group II megakaryocytes), which in turn develop into granular megakaryocytes (group III megakaryocytes). Promegakaryocytes are larger than megakaryoblasts and have a larger volume of cytoplasm relative to that of the nucleus. They possess a single large multilobed nucleus with the overlapping lobes arranged in a C-shaped formation. The cytoplasm is less basophilic than that of megakaryoblasts and contains a few azurophilic granules that are usually grouped within the concavity formed by the overlapping nuclear lobes. The granular megakaryocytes (Figure 33.47) are up to 100 Âµm in diameter and have abundant pale-staining cytoplasm containing many azurophilic granules. The nucleus has multiple lobes, and these become

fairly tightly packed together before the shedding of platelets. The nuclear chromatin has a coarse-grained appearance. Platelets are formed by the fragmentation of cytoplasmic processes of the mature granular megakaryocytes. When platelet formation is completed, a bare nucleus remains.

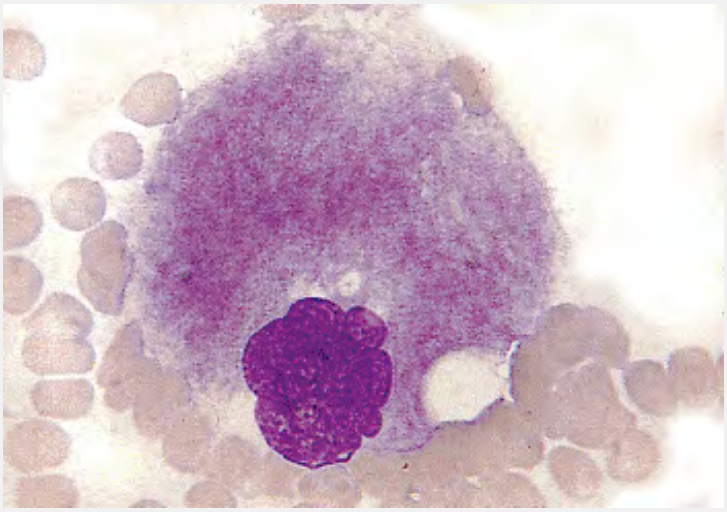

Figure 33.47 Granular megakaryocyte from an MGG-stained normal bone marrow smear.

Mature platelets are usually 2 to 3 Âµm in diameter and are irregular in outline. The cytoplasm stains pale blue and has a number of azurophilic granules at its center. Newly formed platelets are slightly larger than mature ones.

About 40% of megakaryoblasts, 20% of promegakaryocytes, and 2% of granular megakaryocytes synthesize DNA (82). However, cell division is probably uncommon in megakaryoblasts and is not seen in the other two cell types. The occurrence of cycles of DNA replication without cytokinesis results in the characteristic polyploidy of these cells. The total DNA contents of megakaryoblasts range between 4c and 32c and of promegakaryocytes and granular megakaryocytes between 8c and 64c (1c = the haploid DNA content). There is a positive correlation between the nuclear area and DNA content of megakaryocytes.

Cytochemistry

When stained by the PAS reaction, megakaryocytes show a diffuse

and finely granular positivity over both the nucleus and the perinuclear and intermediate zones of the cytoplasm (24,69,70,71). These positive areas also contain varying numbers of densely positive blocks (Figure 33.48). A narrow peripheral zone of the cytoplasm is often PAS negative, and this may be surrounded by clumps of positive granules within attached platelets. Within platelets, PAS-positive material appears as scattered, lightly staining fine granules at the periphery and as clumps of darkly staining coarse granules at the center. Megakaryocytes and platelets are usually unstained by Sudan black, but occasional megakaryocytes may show a diffuse positivity with fine positive granules scattered both in the cytoplasm and over the nucleus. Megakaryocytes and platelets display strong acid phosphatase activity.

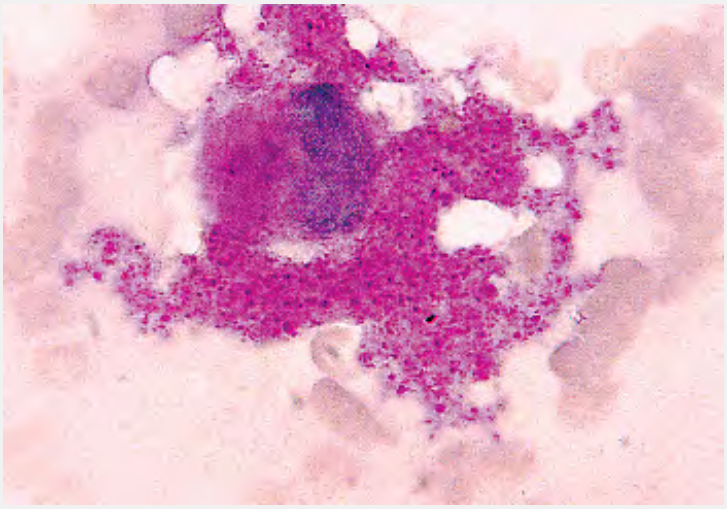

Figure 33.48 Megakaryocyte from a normal bone marrow smear showing large quantities of PAS-positive material.

Peroxidase activity cannot be demonstrated in megakaryocytes by light microscopy but can be demonstrated in a characteristic distribution using the electron microscope.

Megakaryocytes show no Î±-naphthol AS-D chloroacetate esterase activity. However, they have substantial Î±-naphthyl acetate esterase activity (Figure 33.49) and weaker Î±-naphthyl butyrate esterase activity; the latter generates many coarse or fine positive granules in the cytoplasm and over the nucleus.

Ultrastructure

The nucleus of a megakaryoblast has two or more lobes, very little condensed chromatin, and prominent nucleoli (75,83,84). The cytoplasm contains large numbers of ribosomes, scattered RER, several mitochondria, and a few

membrane-lined vesicles representing the beginning of the demarcation membrane system (DMS). The cytoplasm also contains a well-developed Golgi apparatus within a deep nuclear indentation. A few immature Î± granules and a few lysosomal vesicles containing acid phosphatase and arylsulfatase are present near the Golgi apparatus. The maturation of megakaryoblasts into promegakaryocytes and granular megakaryocytes (Figure 33.50) is accompanied by a progressive increase in the quantity of nuclear membraneâ€“associated condensed chromatin, an increase in the number of a granules, a progressive development of the DMS, and a reduction in the number of ribosomes, RER, and mitochondria. Megakaryocyte maturation also is accompanied by the formation of increasing quantities of glycogen in the cytoplasm; the glycogen particles often are found in large clumps. The DMS is an extensive system of membrane-lined cytoplasmic sacs, which arises as invaginations of the surface membrane; it demarcates areas of cytoplasm that eventually become platelets (Figure 33.51).

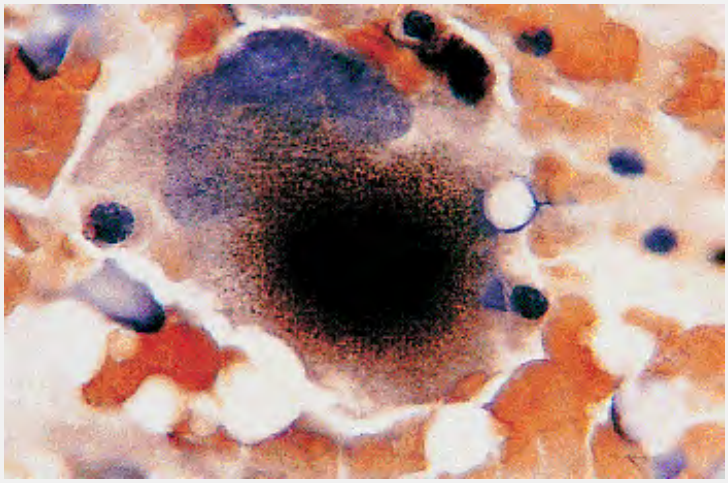

Figure 33.49 Strong Î±-naphthyl acetate esterase activity in a normal megakaryocyte.

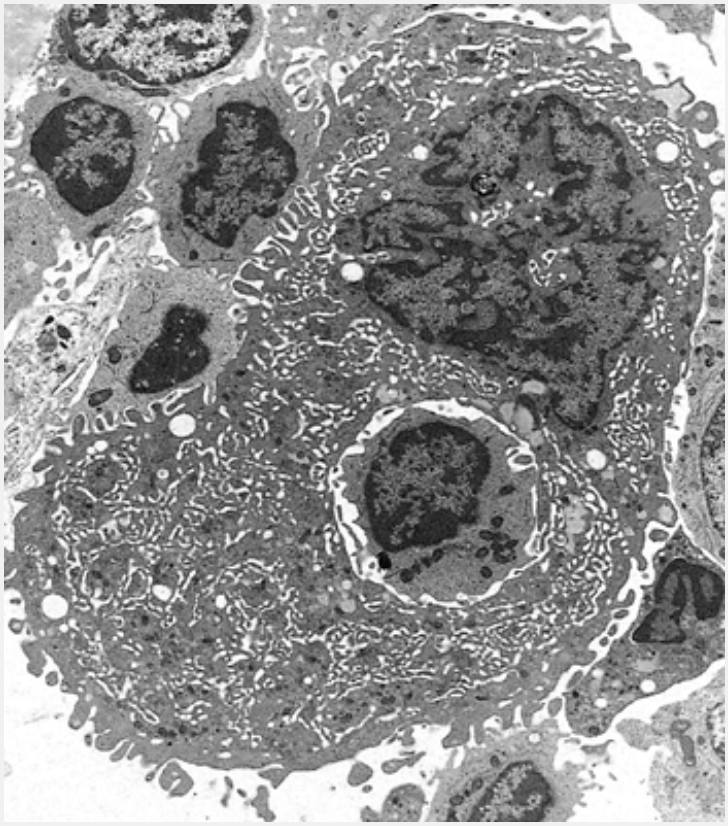

Figure 33.50 Electron micrograph of a granular megakaryocyte from normal bone marrow. The cytoplasm contains a lymphocyte that appears to be traveling through the megakaryocyte (emperipolesis).

Three zones can be recognized in the extensive cytoplasm of a granular megakaryocyte (Figure 33.50): (a) a narrow perinuclear zone containing the Golgi apparatus and some of the ribosomes, RER, and mitochondria, (b) a wide intermediate zone containing many ovoid, electron-dense a granules, numerous sacs of the DMS, lysosomal vesicles, ribosomes, RER, and mitochondria, and (c) a narrow outer zone that is devoid of organelles. Mature granular megakaryocytes protrude cytoplasmic processes that lie near to or within marrow sinusoids. Platelets are formed by the fragmentation of these processes, the platelet membranes being made up of membranes of the DMS.

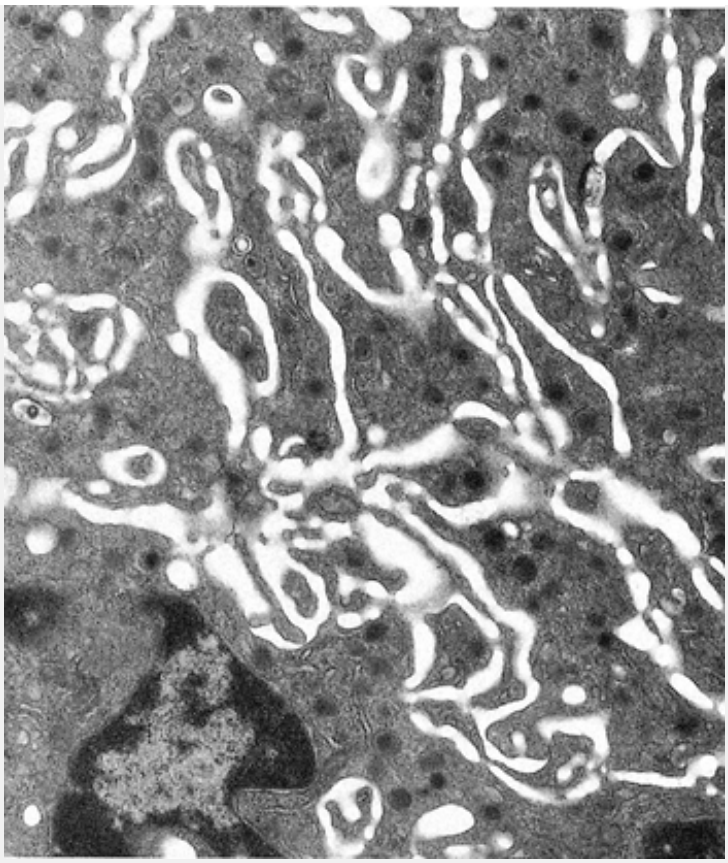

Figure 33.51 Electron micrograph of a part of the intermediate zone of the cytoplasm of a granular megakaryocyte, showing the extensive demarcation membrane system, demarcating granule-containing future platelet areas.

Ultrastructural cytochemical studies of the oxidation of 3,3â€²-diaminobenzidine have demonstrated a platelet peroxidase (PPO) in the endoplasmic reticulum and perinuclear space but not in the Golgi apparatus of megakaryoblasts and megakaryocytes and in the dense bodies and dense tubular system of platelets (85). A few small rounded cells present in normal marrow also have PPO activity in the endoplasmic reticulum and perinuclear space and have been identified as promegakaryoblasts (86). Platelet peroxidase appears to be distinct from myeloperoxidase.

Some normal megakaryocytes display the phenomenon of emperipolesis (87,88). This term is used to describe the movement of one cell type within the cytoplasm of another. The cytoplasm of an affected megakaryocyte may contain one or more cells of a number of types, including neutrophil and eosinophil granulocytes and their precursors, lymphocytes, erythroblasts, and red cells (Figure 33.50). The physiologic relevance of megakaryocyte emperipolesis is uncertain; one suggestion has been that certain marrow cells may enter the circulation via the processes of megakaryocyte cytoplasm that protrude into marrow sinusoids.

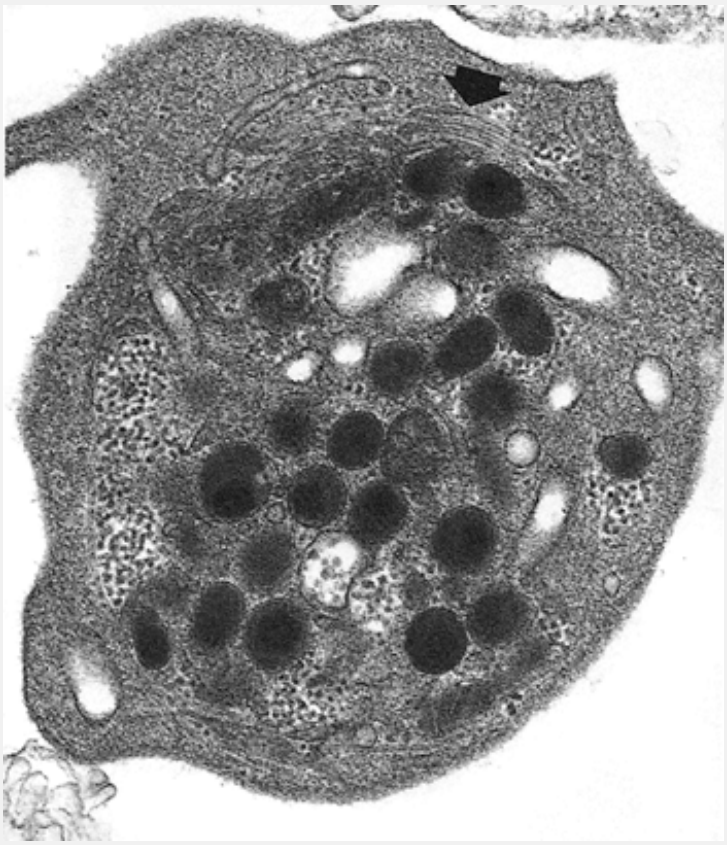

Figure 33.52 Electron micrograph of a platelet from normal blood. The platelet has been sectioned near, rather than at, the equatorial plane and, consequently, shows only part of the circumferential band of microtubules (*arrow*). The section also

shows the electron-lucent vesicles of the surface-connected canalicular system, several platelet granules, a few mitochondria, and numerous clumps of glycogen molecules.

Nonactivated platelets are biconvex and have a smooth surface. Their shape is maintained by an equatorial bundle of microtubules situated below the cell membrane, as well as by microfilaments found between various organelles. Other structures found in the cytoplasm include various types of granules, mitochondria, a surface-connected canalicular system, the dense tubular system, and many glycogen particles, which may occur singly or in clumps (Figure 33.52).

Four types of cytoplasmic granule are recognized, namely, the Î± granules, Î» granules (lysosomal granules), Î´ granules, and peroxisomes (75,89,90). The Î± and Î» granules are moderately electron dense and can be distinguished from each other only by ultrastructural cytochemistry; for example, Î» granules have acid phosphatase activity and Î± granules do not. Substances present in Î± granules include Î²-thromboglobulin, platelet factor 4, platelet-derived growth factor, fibrinogen, fibronectin, von Willebrand factor, and thrombospondin. In addition to acid phosphatase, the Î» granules contain Î²-glucuronidase and arylsulfatase. The Î´ granules (dense granules) are smaller and much more electron dense than Î± granules and often have a peripheral electron-lucent zone, which gives them a bull's-eye appearance. They contain serotonin, calcium, and the storage pool of ADP and ATP. The peroxisomes are smaller than the Î± and Î» granules; they are moderately electron dense and contain catalase.

The surface-connected canalicular system is an extensive system of electron-lucent intracytoplasmic canaliculi and saccules that open to the exterior at multiple sites on the cell membrane. This canalicular system provides a large surface through which various substances, including granule contents, could be discharged extracellularly. The

channels of the dense tubular system are shorter and narrower than those of the surface-connected canalicular system and contain material with an electron density similar to that of the cytoplasm. The dense tubular system contains platelet peroxidase and seems to be derived from the endoplasmic reticulum of megakaryocytes. It is an important site of synthesis of thromboxane A_2, which is involved in the release of granule contents. It is also rich in calcium and may regulate various calcium-dependent reversible reactions such as the activation of actomyosin and the polymerization of tubulin.

Lymphocytes and Plasma Cells

All lymphocytes are eventually derived from the lymphoid stem cells present in the marrow, which are in turn derived from the pluripotent hematopoietic stem cells. The lymphoid stem cells generate both B-cell progenitors and T-cell progenitors. The former mature through a number of antigen-independent intermediate stages into B cells; this maturation occurs within the microenvironment of the marrow. The newly formed B cells travel via the blood into the B-cell zones of peripheral lymphoid tissue. Either the lymphoid stem cells or early T-cell progenitors migrate from the marrow through the blood into the thymus. Here, these cells undergo antigen-independent maturation into T cells, and those T cells that recognize self are deleted. The mature T cells then travel through the blood into the T-cell zones of the peripheral lymphoid organs. The mature B and T lymphocytes that enter the peripheral lymphoid tissue are triggered into division when they react with specific antigen in the presence of appropriate accessory cells. Their progeny develop into effector cells or memory cells. In the case of B cells, the effector cell is an antibody-secreting plasma cell. Antigen-dependent proliferation of B cells occurs in normal marrow and results in the presence of plasma cells in this tissue.

Immunohistochemical studies show that the ratio of T cells to B cells in normal adult marrow is around 3:1. The light and electron

microscopic appearances of bone marrow lymphocytes are indistinguishable from those of other lymphocytes in the body. Some T and B lymphocytes have fine or coarse PAS-positive granules arranged in one to four (usually one or two) rings around the nucleus, and occasional cells have large clumps of PAS-positive material. Lymphocytes are peroxidase negative and Î±-naphthol AS-D chloroacetate esterase negative, and over 99% of cells are alkaline phosphatase negative. Some lymphocytes

show a positive paranuclear dot when stained for Î±-naphthyl butyrate esterase; this staining is unaffected by fluoride. A substantial proportion of normal lymphocytes show either a paranuclear dot or diffuse granular positivity when stained for acid phosphatase. A paranuclear dot is found in both T cells and B cells but more frequently in T cells.

Plasma Cells

Plasma cells seen in smears of normal bone marrow vary considerably in size and appearance. Most are 14 to 20 Âµm in diameter and have deep blue cytoplasm. The cytoplasm has a pale paranuclear area corresponding to the Golgi apparatus and may contain one or more vacuoles (Figure 33.53Aâ€“B). The nucleus is small relative to the volume of cytoplasm, contains moderate quantities of condensed chromatin, and is eccentrically located. Although most plasma cells are uninucleate, a few are binucleate or multinucleate. Some normal plasma cells have other features. For example, occasional cells may contain one or a few large rounded acidophilic, PAS-positive cytoplasmic inclusions (Russell bodies) or several smaller slightly basophilic rounded inclusions (Mott cells, grape cells, or morular cells). Some plasma cells have many pleomorphic cytoplasmic inclusions and, consequently, appear reticulated (Figure 33.53C). Others have eosinophilic cytoplasm, usually at the periphery, but sometimes in the entire cell (flaming cell); when the eosinophilia is confined to the periphery, it contrasts

markedly with the intense basophilia of the rest of the cytoplasm. Occasional plasma cells have azurophilic rods that resemble Auer rods present in acute myeloid leukemia but that are PAS, Sudan black, and peroxidase negative. Plasma cells show strong acid phosphatase activity, particularly around the nucleus and over the Golgi zone. They do not stain for Î±-naphthol AS-D chloroacetate esterase.

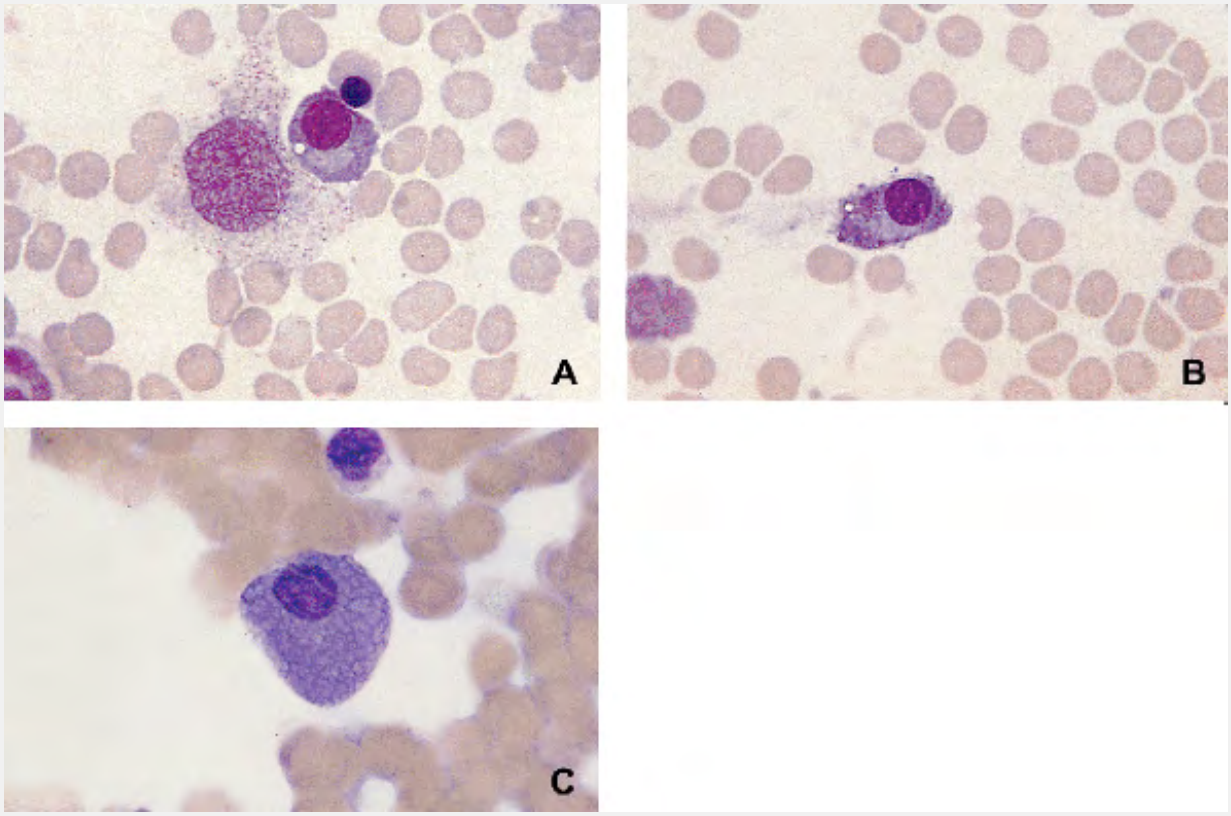

Figure 33.53 Various appearances of plasma cells in a smear of normal bone marrow. A prominent pale paranuclear zone and cytoplasmic vacuoles are seen in (A) and (B). The cytoplasm in (C) has a reticular appearance. The other cells in (A) are a nonphagocytic reticular cell and a late polychromatic erythroblast.

The electron microscope shows that the eccentric rounded nucleus of a plasma cell contains a variable quantity of condensed chromatin (Figures 33.54,33.55A) and a well-developed nucleolus (Figure 33.55A). The presence of moderately large clumps of nuclear membraneâ€“associated condensed chromatin gives the nuclei of mature plasma cells a cartwheel or clock face appearance in histologic sections (but not in marrow smears). The cytoplasm contains numerous long flattened sacs of RER that are arranged either parallel to each other (Figure 33.56), concentrically, or spirally; the sacs are distended to varying extents with a granular, moderately electron-dense material, consisting mostly of immunoglobulin. The cytoplasm also contains mitochondria, a large Golgi apparatus situated immediately adjacent to the nuclear membrane (Figure 33.54), and a few small or medium-sized membrane-bound electron-dense granules. The latter are often found near the Golgi complex, contain acid phosphatase, and appear to be primary lysosomes. Occasional cells contain larger cytoplasmic inclusions that vary markedly in size, electron density, and shape

and are often lined by RER. Many of these inclusions are rounded, elliptical, or irregular in outline, but a few are rhomboidal or needlelike and have a crystalline structure (Figure 33.55Bâ€“D). Thus, the various types of cytoplasmic inclusion seen under the light microscope appear to be formed by the accumulation of unusually large quantities of immunoglobulin within regions of the RER.

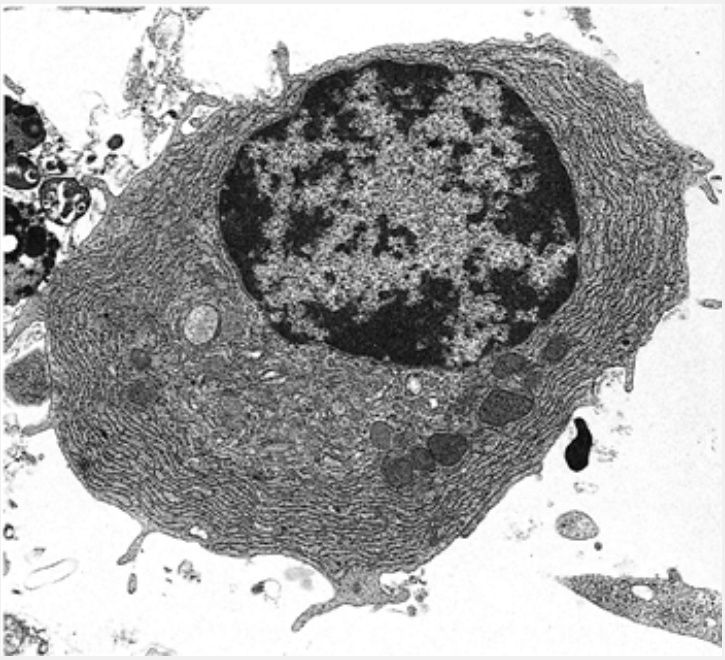

Figure 33.54 Electron micrograph of a plasma cell from a normal bone marrow showing numerous parallel sacs of rough endoplasmic reticulum and a very prominent Golgi apparatus immediately adjacent to the nucleus. The nucleus has moderate quantities of condensed chromatin.

Hematopoietic Cells: Characteristics in Histologic Sections

In H&E-stained sections of formalin-fixed paraffin-embedded trephine biopsies, insufficient cytoplasmic basophilia and nuclear detail is seen to enable reliable distinction between myeloblasts, neutrophil promyelocytes, neutrophil myelocytes, and early erythroblasts. However, neutrophil metamyelocytes and band cells can be recognized by their C- or U-shaped nuclei and neutrophil granulocytes by the presence of two or more darkly staining nuclear lobes or segments lying close together (Figure 33.57). In histologic

sections, the fine chromatin strands that join the nuclear lobes of granulocytes usually are not seen. The cytoplasm of neutrophil myelocytes and metamyelocytes stains pale pink and that of neutrophil granulocytes a very pale pink. The granules contained within cells of the neutrophil series stain poorly and are usually difficult to see. Neutrophil promyelocytes and myelocytes can be reliably distinguished from immature cells belonging to other cell lineages by immunohistochemical staining of neutrophil seriesâ€“specific antigens such as neutrophil elastase (Table 33.1). In sections of paraffin-embedded marrow fragments, the neutrophil promyelocytes/myelocytes, metamyelocytes, and granulocytes are stained by Leder's stain for chloroacetate esterase (Figure 33.58A). These cells are also stained, both in sections of marrow fragments and trephine biopsy cores, by the PAS reaction (Figure 33.58B). Eosinophil myelocytes, metamyelocytes, and myelocytes can be readily recognized by their red-orange cytoplasm, resulting from the presence of large eosinophilic granules (Figure 33.57). Because basophil granules are water soluble, their contents become extracted during routine fixation for histologic studies. Consequently, basophil granulocytes cannot be seen in histologic sections processed in the usual way.

Erythroblasts of varying degrees of maturity are found in distinctive clumps. Pronormoblasts and basophilic normoblasts are large cells with rounded nuclei containing nucleoli. They only show slight cytoplasmic basophilia when stained by H&E and thus resemble early granulocyte precursors; their identification is therefore based largely on their association with groups of more mature erythroblasts. The late erythroblasts contain rounded heavily stained nuclei showing little structural detail and have moderate quantities of poorly staining cytoplasm, usually with a distinct cytoplasmic membrane. They may show clear halos around the nucleus as a consequence of the shrinkage of the cytoplasm (Figure 33.59). Lymphocytes do not show this artifact. Erythroblasts can be reliably identified by immunohistochemical staining of glycophorins A and C and of

hemoglobin A (Table 33.1, Figure 33.60).

The Giemsa stain is superior to H&E for identifying myeloblasts and promyelocytes as well as pronormoblasts and basophilic normoblasts, staining their cytoplasm blue. However, it is still not possible to reliably distinguish myeloblasts from promyelocytes. In Giemsa-stained sections, pronormoblasts have more basophilic cytoplasm than do other blasts and promyelocytes (Figure 33.61).

Lymphocytes may be difficult to distinguish from late erythroblasts in histologic sections of paraffin-embedded trephine biopsy cores except when present in lymphoid nodules. They have a narrow rim of slightly basophilic (Giemsa) or poorly staining (H&E) cytoplasm, indistinct cytoplasmic margins, and a clumped nuclear chromatin pattern. The nuclei of lymphocytes are less perfectly rounded and more variable in size and shape and show more structural detail than those of late erythroblasts. In H&E-stained sections, plasma cells can be identified by the presence of slightly or moderately basophilic cytoplasm, an eccentric nucleus with a cartwheel or clock face chromatin pattern, and a pale paranuclear zone corresponding to the Golgi apparatus. In Giemsa-stained sections, the cytoplasm of many plasma cells stains a deep blue and, consequently, the pale Golgi zone is especially prominent.

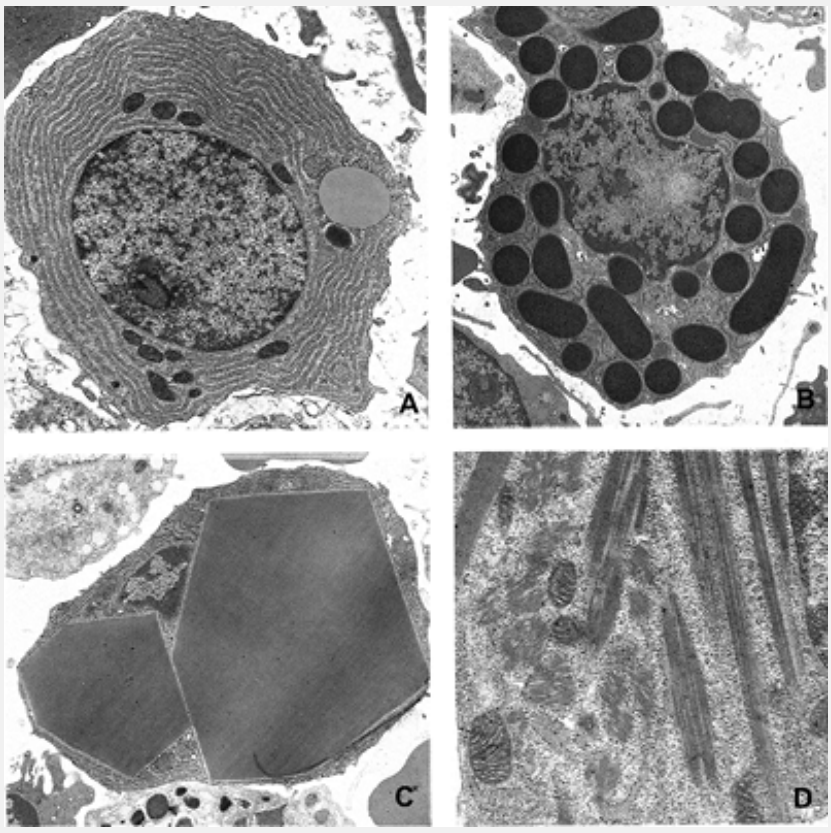

Figure 33.55 Different ultrastructural appearances of plasma cells from normal bone marrow. A. Cell with a prominent nucleolus, small quantities of condensed chromatin, several perinuclear mitochondria, some electron-dense material within all the sacs of rough endoplasmic reticulum (RER), and a single large, round, relatively electron-lucent intracytoplasmic inclusion lined by RER. B. Cell with multiple rounded or elliptical electron-dense intracytoplasmic inclusions lined by RER. C. Cell with two polygonal inclusions lined by RER. D. Cell with needlelike crystalline inclusions. The inclusions in (Aâ€“C) probably result from the accumulation of large quantities of altered immunoglobulin within sacs of RER.

Megakaryocytes are readily recognized by their large size, light or

dark pink cytoplasm, and lobulated nucleus in sections stained either with hematoxylin and eosin or Giemsa (Figure 33.62). In sections of normal bone marrow they are present in clusters of two to five cells and are usually not found in a paratrabecular position. Small numbers of bare megakaryocyte nuclei, with convolutions and a considerable quantity of condensed chromatin, also are seen.

B and T lymphocytes, plasma cells (Figure 33.22Aâ€“B), and megakaryoctyes (Figure 33.22D) can be identified immunohistochemically, and megakaryoblasts can be reliably identified only in this way (Table 33.1). Using the monoclonal antibody Y2/51 which is directed against Gp IIIa, the mean value for the total number of megakaryocytes and megakaryoblasts in 15 normal subjects was 24/mm^2 (range: 14â€“38) and for megakaryoblasts alone it was 2.8/mm^2 (range: 1.2â€“4.9) (91).

As has already been mentioned, much more cytologic detail and especially nuclear detail can be seen in semithin sections of undecalcified plastic-embedded trephine cores (Figure 33.63) than in convention sections of decalcified paraffin-embedded cores (Figure 33.62A).

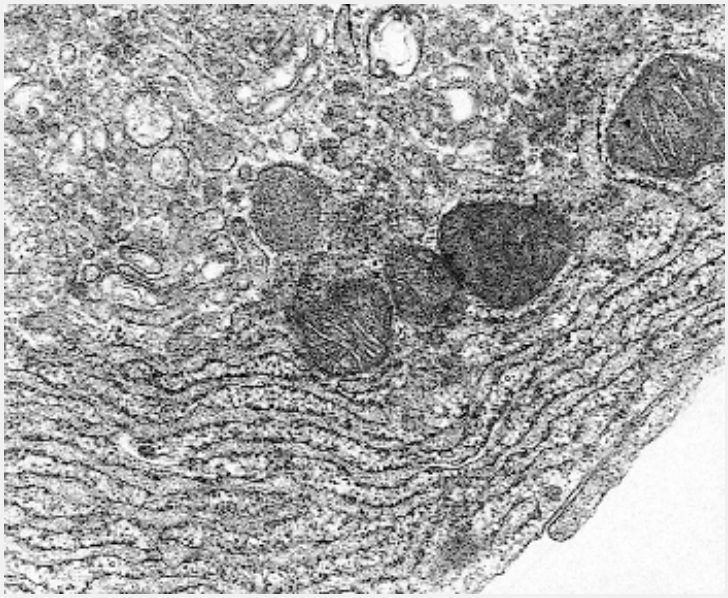

Figure 33.56 Electron micrograph showing part of the Golgi apparatus and some of the sacs of RER from the plasma cell in Figure 33.54, at higher magnification. Four mitochondria are also present.

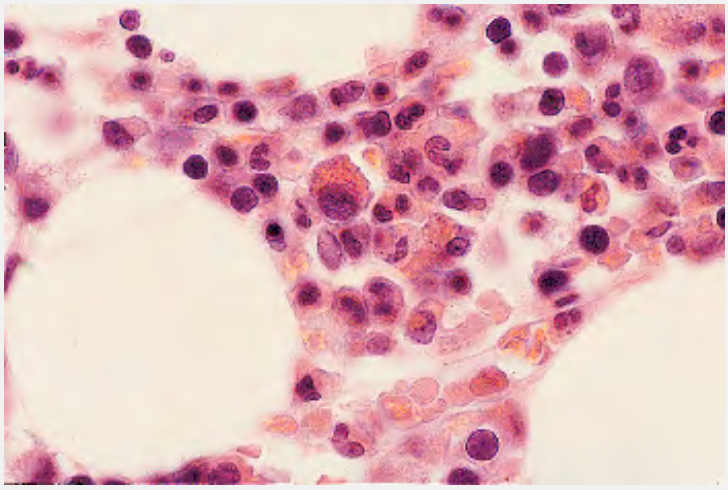

Figure 33.57 Neutrophil promyelocytes/myelocytes, metamyelocytes, stab cells, and granulocytes in a section of a paraffin-embedded trephine biopsy core from a hematologically normal subject. The two cells with large orange granules belong to the eosinophil granulocyte series. (H&E.)

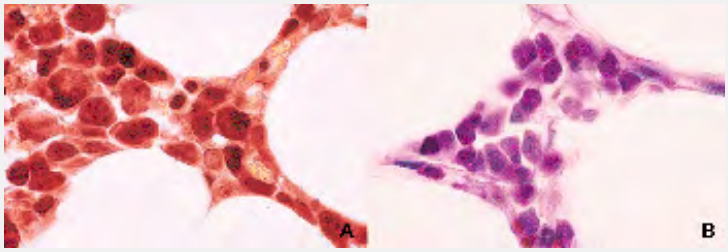

Figure 33.58 Histochemistry of neutrophil series. A. Section of a paraffin-embedded marrow fragment from a hematologically normal subject showing cytoplasmic chloroacetate esterase activity in neutrophil promyelocytes/myelocytes and metamyelocytes but not in two erythroblasts (Leder's stain). Figure 33.61 Giemsa-stained section of a paraffin-embedded marrow fragment from a patient with erythroid hyperplasia due to a congenital dyserythropoietic state. The cell in the center with deep blue cytoplasm and prominent nucleoli is a proerythroblast. The photomicrograph also shows a few other proerythroblasts, several basophilic erythroblasts, and some early and late polychromatic erythroblasts.

Cellularity of the Marrow

The term *marrow cellularity* usually is defined as the proportion of the area of a histologic section excluding bone occupied by hematopoietic cells (by cells other than fat cells). Cellularity is usually assessed by point counting using an eyepiece with a graticule (histomorphometry) or, more accurately, by computerized image analysis (92). The shrinkage of tissue subjected to decalcification and paraffin embedding results in the cellularity of paraffin-embedded sections being about 5% lower than in plastic-embedded sections (93).

In healthy subjects, cellularity varies with age (53,54). In neonates,

there are very few fat cells in the marrow, and the cellularity approaches 100%. Cellularity decreases steadily in the first three decades and stabilizes at 30 to 70% between the ages of 30 and 70 years. During the eighth decade of life, cellularity decreases further and may be less than 20%; this reduction is largely caused by a reduction in bone volume and a consequent increase in the volume of the marrow cavities.

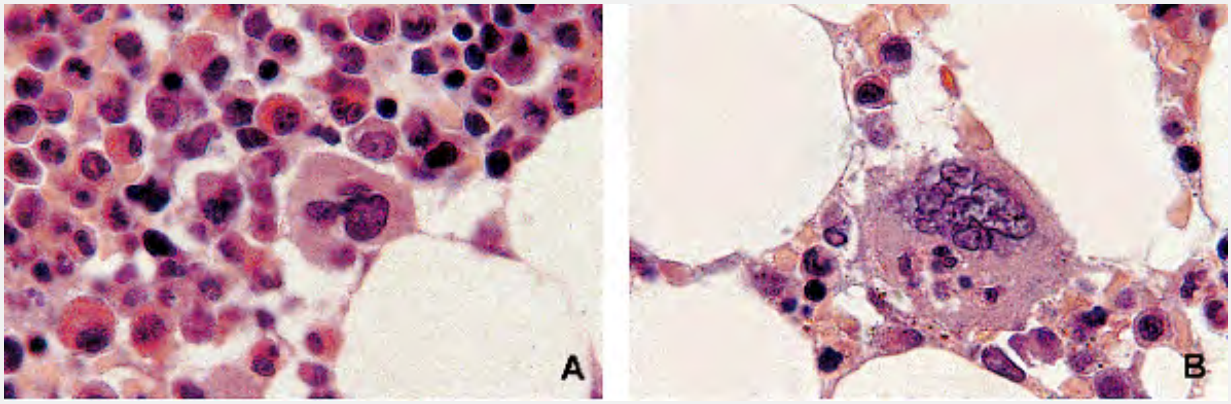

Figure 33.62 Two megakaryocytes from a section of a paraffin-embedded sample of clotted normal marrow (*clot section*). The cells in (A) showing a slight orange tinge are eosinophils and their precursors. The megakaryocyte in (B) displays emperipolesis. (H&E.)

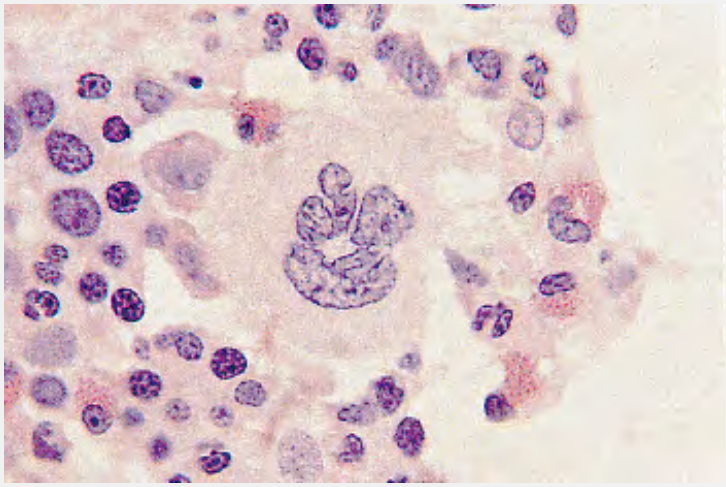

Figure 33.63 Semithin section of an undecalcified, plastic-embedded trephine biopsy core showing a megakaryocyte and adjacent marrow cells. When compared with Figure 33.62A, this semithin section shows considerably more cellular detail, especially nuclear detail. The cytoplasmic granules of cells of the eosinophil series are clearly seen; these are stained red-orange. (H&E.)

In assessing cellularity, it should be noted that cellularity varies markedly from one intertrabecular space to the next in a single biopsy specimen so that a reliable estimate requires the examination of at least five such spaces (i.e., a biopsy core of greater than 2 cm). Furthermore, the immediate subcortical marrow of the ilium is frequently less cellular than deeper marrow. A study of postmortem biopsy samples from 100 normal subjects who died suddenly without evidence of bone or marrow disease showed only slight differences in the cellularity at different hematopoietic sites. The percentage cellularity (Â± SD) in biopsies from the anterior iliac crest, posterior iliac crest, lumbar vertebrae, and sternum were, 60 Â± 6, 62 Â± 7, 64 Â± 7, and 61 Â± 8, respectively (94).

Table 33.2 Differential Counts[a] on Marrow Smears from 28 Healthy Adults aged between 20 and 29 years

	Percentages		
Cell Type	Mean	95% Confidence Limits	Observed Range
Myeloblasts	1.21	0.75â€“1.67	0.75â€“1.80
Promyelocytes	2.49	0.99â€“3.99	1.00â€“3.75
Myelocytes			
Neutrophil	17.36	11.54â€“23.18	12.25â€“22.65
Eosinophil	1.37	0â€“2.85	0.25â€“3.45
Basophil	0.08	0â€“0.21	0.00â€“0.25
Metamyelocytes			
Neutrophil	16.92	11.40â€“22.44	11.45â€“23.60
Eosinophil	0.63	0.07â€“1.19	0.25â€“1.30
Juvenile neutrophil	8.70	3.58â€“13.82	4.85â€“13.95

granulocytes (stab forms)			
Granulocytes			
Neutrophil	13.42	4.32â€“22.52	8.70â€“8.95
Eosinophil	0.93	0.21â€“1.65	0.45â€“1.55
Basophil	0.20	0â€“0.48	0.05â€“0.50
Monocytes	1.04	0.36â€“1.72	0.65â€“2.10
Plasma cells	0.46	0â€“0.96	0.10â€“0.95[b]
Lymphocytes	14.60	6.66â€“22.54	9.35â€“25.05
Basophilic erythropoietic cells	0.92	0.40â€“1.44	0.50â€“1.60
Early polychromatic normoblasts	6.76	2.56â€“10.96	3.30â€“12.20
Late polychromatic normoblasts	11.58	6.16â€“17.0	7.85â€“19.55
Reticular cells	0.24	0â€“0.54	0.05â€“0.65

[a]Two thousand cells were studied in each individual.
[b]The observed range in 63 cases, aged 20â€“93 years, was 0.10â€“2.00%.

Marrow Differential Count

During the first day of life, the erythroblasts account for 18.5 to 65% (mean: 40%) of the nucleated cells in a marrow smear. Over the next 8 to 10 days, this figure decreases progressively to 0 to 20.5% (mean: 8%). After a period of erythroblastopenia lasting about three weeks, the percentage of erythroblasts increases again, reaching values of 6.5 to 31.5% (mean: 16%) at the age of 3 months (95). These changes are caused by an increase in arterial oxygen saturation soon after birth and the consequent suppression of erythropoietin production. Erythropoietin production increases again 6 to 13 weeks later when the hemoglobin concentration in the blood decreases to about 11 g/dL. The proportion of granulocytes and their precursors ranges between 20 and 73% (mean: 46%) of the nucleated marrow cells on the first day of life (95), increases during the next three weeks, and then decreases again to reach a stable value of about 55% after the second month. The average value for the proportion of lymphocytes in the marrow increases from 12% during the first two days of life, to 33% at seven to ten days, and 47% at one month. The lymphocyte percentage then remains stable until the end of the first year, after which it decreases slowly to 19% at 4 to 4.5 years, which is only slightly higher than the adult value of 15% (95,96,97,98). Plasma cells are infrequent in the neonate, accounting for up to 0.4% (mean: 0.016%) of nucleated marrow cells (99). They gradually increase in number to reach a mean value of 0.386% at the age of 12 to 15 years (5000 cell differential count).

When 300 to 500 consecutive marrow cells are assessed in each case, the prevalence of plasma cells in healthy adults is 0.4 to 4.0%.

The differential count on 2000 consecutive nucleated cells in bone marrow smears from normal adults is given in Table 33.2 (100). The mean and range for the myeloid/erythroid ratio in healthy adults are 3.1 and 2.0:8.3, respectively (101).

Kidney

William L. Clapp

Byron P. Croker

Introduction

The kidney has an intricate structure that underlies its diverse roles of excreting waste products, regulating body fluid and solute balance, regulating blood pressure, and secreting hormones. A familiarity with the basic structure of the kidney facilitates the evaluation and comprehension of diseases and functional disorders that can affect the kidney. The structure of the normal human kidney is considered in this chapter. Although the focus is on the human kidney, analogous renal structures in other mammalian species are discussed or illustrated when pertinent.

Pediatric Kidney

Renal enthusiasts, especially developmental biologists and pathologists, have long been fascinated with how a kidney develops from primitive mesoderm into such a wondrously complex organ. A basic understanding of nephrogenesis provides a framework to enhance our knowledge of congenital kidney disease. The human kidney is structurally immature at the time of birth, and important morphologic changes occur during infancy and childhood. Pathologists not familiar

with the histologic peculiarities of the pediatric kidney may mistake normal findings for abnormalities or fail to observe significant abnormalities of renal maturation. The following section covers the pediatric kidney, focusing first on kidney development prior to birth, and second, on the kidney after birth.

Kidney Development

During development, cells proliferate, migrate, differentiate, die, and interact with other cells to form tissues and organs. These different aspects of cell behavior are controlled by genes in a temporal and spatial manner. The kidney has long been considered an excellent model system for the study of organogenesis. However, when one considers the elaborate architecture and heterogenous cellular elements of the organ, it is not surprising that understanding the mechanisms of kidney development remains a considerable challenge. Detailed reviews of kidney development are available for more information (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12).

Embryonic Kidneys

Organogenesis begins during the third week of human embryogenesis with the initial formation of the central nervous and cardiovascular systems. The urogenital system represents the last organ system to develop. Kidney development goes through three successive stages: pronephros, mesonephros and metanephros. All three systems develop from the intermediate mesoderm, located between the dorsal somites and lateral plate mesoderm and extending from the cervical to the caudal regions of the embryo. The

pronephros and mesonephros are transient structures in mammals. However, all three systems are essential for the formation of each subsequent organ and are dependent on the presence of the preceeding structure. The mesonephros forms before the pronephros regresses, and the metanephros develops before the mesonephros

disappears (Figure 34.1). This developmental scheme may be likened to a wave of nephrogenesis moving in a cervical to caudal direction through the intermediate mesoderm. Some genes that regulate metanephric kidney development are also believed to be involved in forming the earlier embryonic kidneys.

Figure 34.1 Mesonephros amd metanephros. The mesonephros (*arrowhead*) contributes somatic cell lineages to the gonadal ridge (*single arrow*), which will develop into the gonad. Early nephron formation is present in the metanephros (*double arrows*), whose development is dependent on the presence of the mesonephros. Reprinted with permission from:
Murphy WM, Grignon DJ, Perlman EJ. Tumors of the kidney, bladder, and related urinary structures. In: *Atlas of Tumor Pathology* . 4th series, fascicle 1. Washington, DC: Armed Forces Institute of Pathology; 2004.

Pronephros

The pronephros develops in the cervical region at the end of the third week of human gestation. However, most of our knowledge of the pronephros has come from the study of lower vertebrates (13 ,14). The pronephros consists of a glomus (glomerulus-like structure), tubules, and a duct. The glomus, not physically connected to the

tubules, projects into the coelomic cavity and filters blood.

Ciliated tubules, called nephrostomes, open into the coelom and collect the filtrate. The nephrostomes connect to proximal tubules, which empty into a distal tubule that joins the pronephric duct. In humans, the pronephros is a rudimentary organ and does not function. As the pronephric duct extends caudally, the glomus and tubules regress. However, the pronephric duct persists and becomes the mesonephric duct.

Mesonephros

The human mesonephros develops in the middle of the fourth week of gestation as a thoracic organ. Considerable variation in structure and function of the mesonephros exists, even among mammalian species (15). The human mesonephros contains 20 to 40 nephrons, consisting of glomeruli directly connected to tubules, with proximal and distal segments, some of which directly connect to the mesonephric duct (wolffian duct). The distal mesonephric duct fuses with the cloaca, a precursor of the urinary bladder. In some mammals, two sets of mesonephric tubules exist. The caudal tubules, representing the majority of the mesonephric nephrons, never fuse with the mesonephric duct, whereas the more cephalad tubules are connected to the duct. Moreover, mice deficient for the Wilms' tumor suppressor gene, *WT1,* lack the caudal set of mesonephric tubules but develop the cephalad ones (16). Thus, *WT1* appears to regulate only caudal mesonephric development, which may have some molecular events similar to metanephric development since both require *WT1* for formation. The excretory function of the human mesonephros is believed to be limited. As observed with the pronephros, the mesonephros undergoes apoptosis and degenerates (17).

In the male, some mesonephric tubules form the efferent ducts of the epididymis, whereas the mesonephric duct gives rise to the duct of the epididymis, the seminal vesicle, and the ejaculatory duct. In females, the mesonephros undergoes dissolution, with the epoÃ¶phoron,

paroÃ¶phoron, and Gartner's duct remaining as vestigial structures. Evidence has emerged indicating the mesonephros contributes cell lineages for other organ systems. A region including the dorsal aorta, gonad, and mesonephros (AGM) is the first site in which adult-type hematopoietic stem cells are generated (18 ,19).

Metanephros

Overview

The metanephros, the definitive and permanent kidney, develops from an inductive interaction between the ureteric bud and the mesenchyme of the caudal intermediate mesoderm, called the metanephric mesenchyme, or blastema. During the fifth week of gestation, the first step in metanephric development occurs. Factors expressed by the metanephric mesenchyme induce the ureteric bud, a branch of the caudal mesonephric duct, to grow dorsally until it encounters the mesenchyme. The ureteric bud undergoes iterative branching to form the renal pelvis, calyces, and collecting ducts. Induced by the ureteric bud, the metanephric mesenchyme differentiates into the glomeruli, proximal and distal tubules, and Henle's loops. Thus, cells of the metanephric kidney originate from two different lineages to form the collecting ducts and nephrons. The reciprocal inductive interaction between the ureteric bud and the metanephric mesenchyme is the central process of metanephrogenesis. For detailed information, the reader is directed to the classic light

microscopic (1 ,2 ,3), microdissection (4 ,5 ,6), and experimental (7 ,8) studies.

Formation of the Renal Pelvis and Calyces

The complex three-dimensional branching pattern of the ureteric bud and its derivatives creates an elaborate renal architecture. The ureteric bud and its branches consist of a tubule portion, which elongates, and

an actively growing ampullary tip. Various types of branching have been observed, including bifid and trifid branching from the ampullary tip and different modes of lateral branching (Oliver's â€œclosed and open dividedâ€• models) from the tubule portion of the ureteric bud. The complexity of branching morphogenesis varies according to the period of nephrogenesis and also among mammalian species (4 ,5 ,6 ,20 ,21 ,22).

The first three to five generations of ureteric bud branches form the renal pelvis, with more divisions occuring in the poles than in the midpolar region (Figure 34.2). Urine production is accompanied by progressive dilatation and coalescence of the earlier branches to form the early pelvic-calyceal system by 11 to 12 weeks. Subsequent generations of branches form the calyces. Extensive tissue remodeling of the calyceal system occurs. By 11 to 14 weeks, the calyces become compressed between the expanding renal pelvis and the aggregation of nephrons induced by collecting ducts in the developing papillae. The minor calyces convert from a bulbous configuration to their definitive cuplike shape, and the papillae become conical (Figure 34.3). The fate of the very first nephrons formed, presumably induced by and attached to the first generations of the ureteric bud that form the pelvis and calyces, remains a question. They are believed to either degenerate or attach to a later generation branch that elongates eventually to reach the juxtamedullary cortex.

Formation of the Collecting System

At eight weeks, the first nephrons can be observed attached to ureteric bud branches. The organogenetic processes of collecting duct branching/elongation and nephron differentiation occur simultaneously. Collecting duct morphogenesis has been divided into four periods (5). In the first period, from the fifth to the fourteenth week of gestation, branching occurs from the ampullary tips, and individual nephrons remain attached to their ampullae. In an iterative bifurcation model of branching, one of the two new ampullae retains the old nephron

whereas the other induces the formation of a new one. The second period, weeks 14 through 22, is characterized by the formation of arcades. Ampullae rarely branch, but single elongating tips repeatedly induce new nephrons while carrying attached older nephrons. As new nephrons are formed, the connecting tubule of the older nephron merges its point of attachment away from the ampulla to the connecting tubule of the newer nephron. Repetition of this process results in three to seven nephrons forming around a single ampulla, joined to one another in an arcade by their connecting tubules. Arcades are associated with juxtamedullary nephrons in the inner cortex of the fully developed kidney.

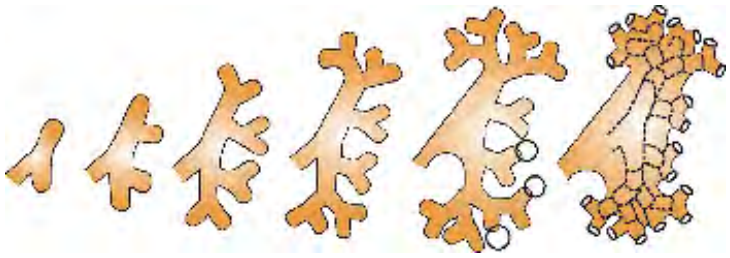

Figure 34.2 Diagram depicting early branches of ureteric bud that dilate and coalesce to form the renal pelvis. Examples of third, fourth, and fifth generation branches are *circled* . Modified with permission from:

Potter EL. *Normal and Abnormal Development of the Kidney* . Chicago: Year Book; 1972.

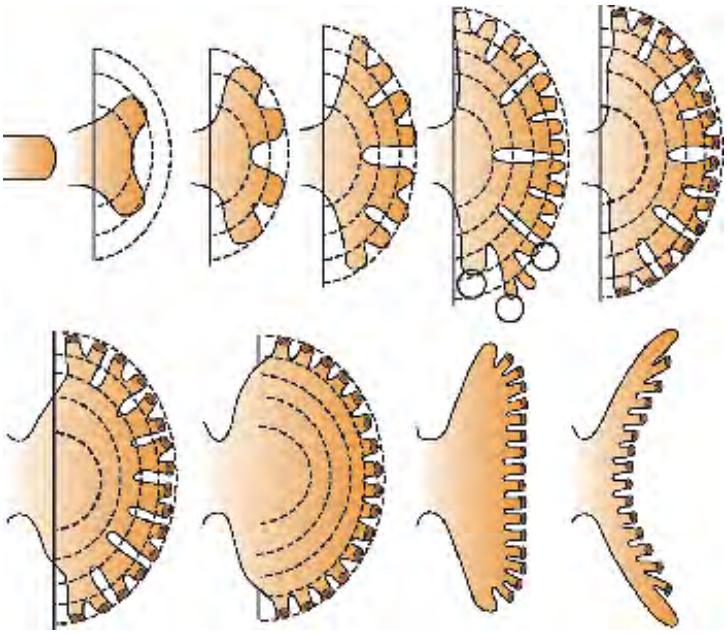

Figure 34.3 Diagram illustrating later branches of ureteric bud forming a minor calyx and papilla. *Circles* indicate generation branches that may expand to form part of the calyx or, if not expanding, form papillary ducts. The expanding pelvis and the peripheral zone of differentiating nephrons compress the original saccular cavity, producing the cuplike shape of the calyx and the conical configuration of the papilla. Modified with permission from:
Potter EL. *Normal and Abnormal Development of the Kidney* . Chicago: Year Book; 1972.

In the third period, weeks 20 through 36, the ampullae advance beyond the attachment point of the arcade, toward the outer surface. The ampullae do not branch but induce five to seven nephrons, each of which will have a direct connection to the developing collecting tubule. This type of nephron attachment predominates in the outer cortex of the mature kidney (Figure 34.4). Since nephrons retain contact with their ampullae of origin, either through arcades or directly, the longitudinal growth of the collecting tubules positions the attached glomeruli in the cortex. In the fourth period, beginning at 32 to 36 weeks, the ampullae disappear, and no new nephrons form. Normally, nephrogenesis does not occur beyond 36 weeks of gestation. The last

nephrons formed are in the outer cortex with their glomeruli near the renal capsule.

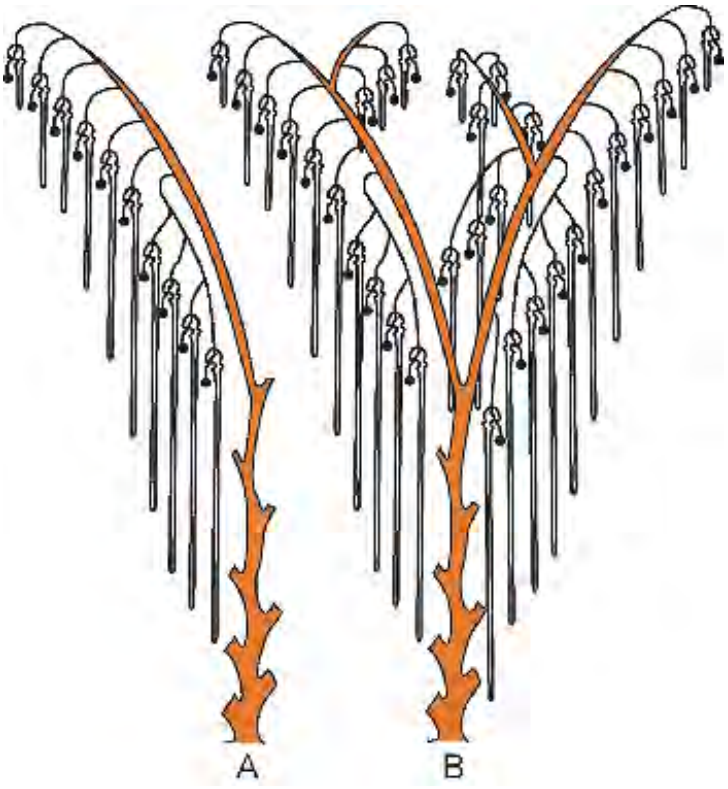

Figure 34.4 Diagram demonstrating the pattern of nephrons and collecting tubules at birth. A. The most common arrangement is for each collecting tubule to have a single arcade composed of three to five nephrons and five to seven nephrons individually attached. B. Depending on the division of the ampullary tips, other variations are possible. Modified with permission from:
Potter EL. *Normal and Abnormal Development of the Kidney* . Chicago: Year Book; 1972.

Nephron Formation

Over 100 years ago, investigations by Herring and Huber provided a fairly accurate morphologic view of human nephron development (Figure 34.5) (1 ,2). They were also prescient in regard to some

mechanisms of nephrogenesis; for example, the development of glomerular capillaries. From eight weeks of gestation, the nephrons and collecting duct system develop together. The stages in individual nephron development do not vary and occur continously throughout the periods of collecting duct formation. The formation of nephrons can be divided into two phases: the induction stage and the morphogenetic stage (7 ,8 ,23). In the induction stage, the mesenchyme condenses around the ampullary tips in response to inducing signals from the ureteric bud. Two types of mesenchymal condensates form in this induction stage prior to epithelial differentiation of the mesenchyme (24). The first condensate, called the *cap* , closely surrounds each ampullary tip. A short time later, another condensate, termed the *pretubular aggregate* , forms at the lateral edges of the ampullary tip, below the cap. At the stage of ureteric bud division, forming a T-shaped structure, two pretubular aggregates may be observed, one on each side of the T bud. The caps and pretubular aggregates can be distinguished by histology. The cap is believed to regulate ureteric bud branching, whereas the pretubular aggregate is destined to form the nephron.

The morphogenetic stage of nephron formation involves several complex phases (Figure 34.5). First, the cells of the pretubular aggregate undergo a mesenchyme-to-epithelium transition, characterized by expression of epithelial markers and synthesis of basement membrane matrix glycoproteins. The cells develop intercellular junctions and become polarized and surrounded by a basal lamina, forming a structure termed the *vesicle.* A central cavity may be observed in the vesicle. Soon after formation, the vesicle fuses to the ureteric duct epithelium, and a continuous basal lamina surrounds both the vesicle and the duct. Opposite the area of fusion between the vesicle and the ureteric duct, a vascular cleft develops representing the site where the glomerular capillaries will emerge. The vesicle becomes a comma-shaped tubular structure. Another crevice forms near the fusion between the comma structure and the ureteric duct. After elongation and folding, an S-shaped figure (representing an early

nephron) forms (Figure 34.6). At this stage, the S-shaped body is already compartmentalized into distinct cell types that are arranged into three areas. The vascular cleft lies below the upper and middle limbs of the S-shaped body and above the lower limb. The upper limb (connected to the ureteric duct) and the middle limb (also known as *Stoerk's complex*) generate the proximal and distal convoluted tubules and the loops of Henle. The lower limb, most distant from the ureteric bud, differentiates into the parietal and visceral epithelium of the glomerulus.

Active nephron formation occurs across the developing renal cortex in a band, known as the *nephrogenic zone* (termed the *neogenic zone* in early studies) (Figures 34.7 ,34.8 ,34.9). After nephron formation ceases, generally by 36 weeks of gestation, the nephrogenic zone disappears (Figure 34.10). The growth of the collecting ducts and the incremental formation of nephrons result in a centrifugal developmental pattern extending through the renal cortex. The earliest nephrons to form are found in the juxtamedullary zone of cortex, whereas the last nephrons to develop are in the outer cortex. This principle is fundamental to understanding postnatal structural changes in the kidney and is sometimes useful in the timing of developmental disturbances in the cortex. For example, a disturbance during the early months of development may result in an abnormality of the entire cortical thickness, whereas one that occurs in the last half of gestation may involve only the outermost layers of cortical nephrons. In summary, the coincident processes of ureteral-derived epithelial branching and nephron formation largely establish the basic architectural organization of the kidney.

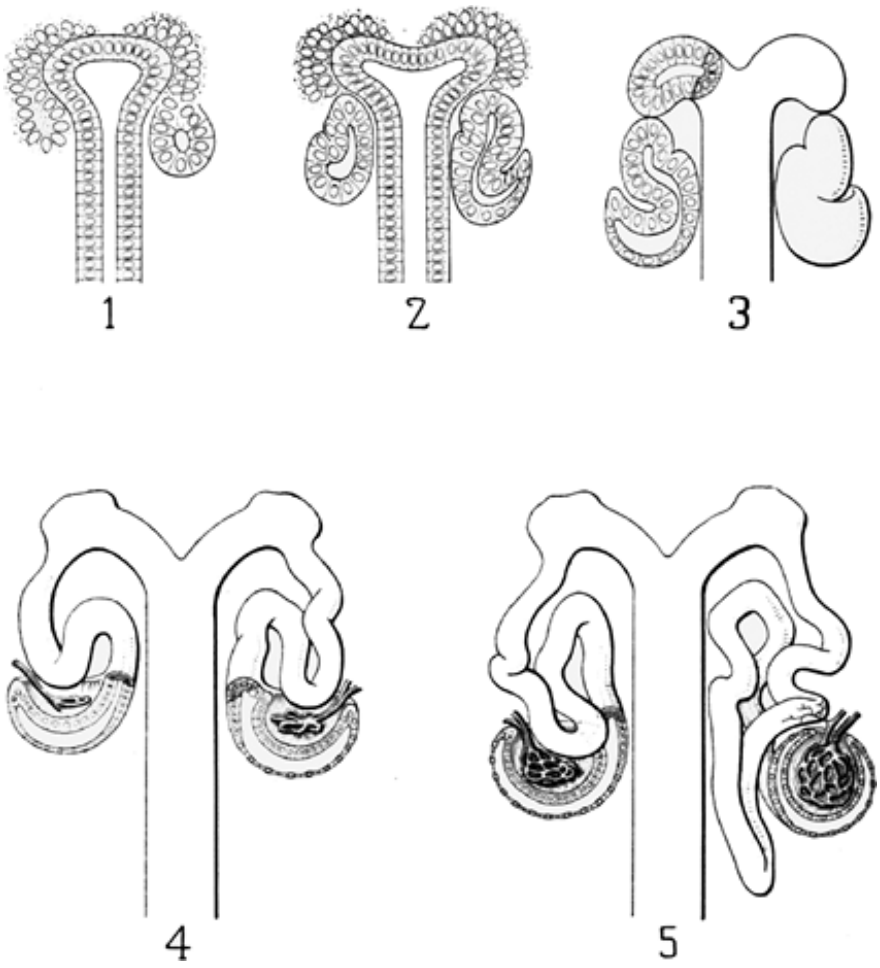

Figure 34.5 Huber's schematic drawings of nephron development. 1. Condensation stage with the cap and the pretubular aggregate. A renal vesicle (*right*) is present. 2. Comma-shaped body. 3. S-shaped body. 4. Early glomerular capillary development, Bowman's capsule formation and tubule elongation. 5. Glomerular and tubule maturation (*right*). Reprinted from:

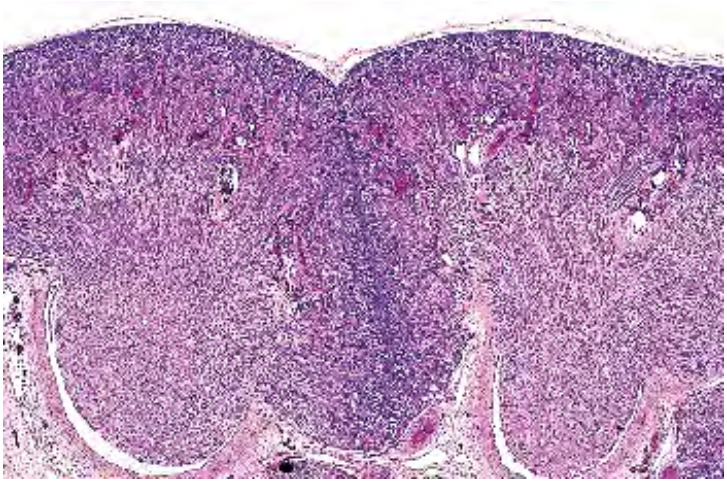

Figure 34.7 Developing kidney at 21 weeks of gestation showing two medullary pyramids with surrounding cortex. The nephrogenic zone represents a thin layer outlining the peripheral aspects of the lobes, both at the surface and in the midplane of the septa (column) of Bertin, between the two renal lobes.

Glomerulogenesis

To appreciate how some glomerular diseases arise or how the glomerulus responds to injury, an understanding of glomerular development is indispensable. Glomerular development proceeds through a sequence of structures described as vesicle, comma-shaped, S-shaped, capillary loop, and maturing glomerulus stages (9 ,25 ,26). The vesicle and comma-shaped stages were discussed previously. At the S-shaped stage, the lower limb beneath the vascular cleft separates into two layers (lips) divided by a narrow developing Bowman's space (Figure 34.6). Lining the upper, internal lip are the visceral epithelial cells, which will differentiate into podocytes. On the opposite side of Bowman's space, the cells of the lower, outer lip will become the parietal epithelial cells lining Bowman's capsule.

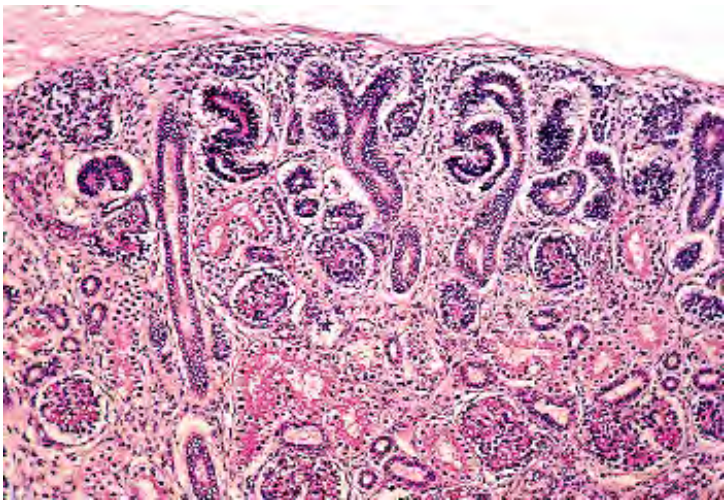

Figure 34.8 Nephrogenic zone from developing kidney at 26 weeks of gestation illustrating several stages of nephron formation.

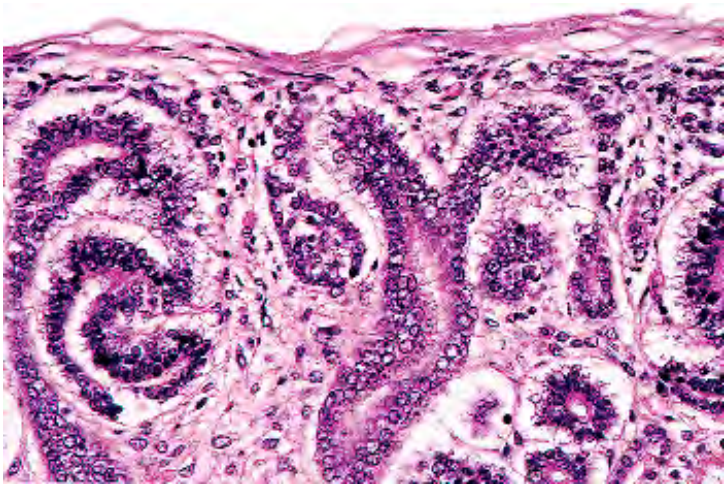

Figure 34.9 Higher magnification of same field as in Figure 34.7 . In the center, pretubular aggregates (early renal vesicles) are present on either side of the ureteric duct. An early S-shaped body is present (*left*).

During the S-shaped stage, microvessels can often be identified within the vascular cleft of the S-figure. Because this vascular cleft is the site where the glomerular capillaries emerge, the origin of the microvessels has generated considerable study. A long-standing question has been

whether the glomerular endothelial cells have an *angiogenic* or a *vasculogenic* origin. Earlier evidence favored the process of angiogenesis, whereby endothelial cells sprout from external vessels that grow into the kidney. More recent studies

provide compelling evidence for a vasculogenic mechanism, whereby endothelial cells of the early glomerular capillaries originate from intrinsic angioblasts, likely derived from the metanephric mesenchyme (27 ,28). Release of growth factors, such as vascular endothelial growth factor (VEGF), from the immature podocytes may attract the angioblasts, expressing VEGF receptors (as Flk1) into the vascular clefts. Other signaling systems such as the angiopoietin (ligand)-Tie (receptor) axis also play a role in endothelial cell and vascular development (29). At this stage, the endothelial cells contain few fenestrae. The early podocytes are cuboidal or columnar, whereas the parietal epithelial cells are already flattening. Situated between the endothelial and podocyte layers are two basement membranes. The basement membrane beneath the podocytes is usually thicker and more continuous than the one underneath the endothelial cells.

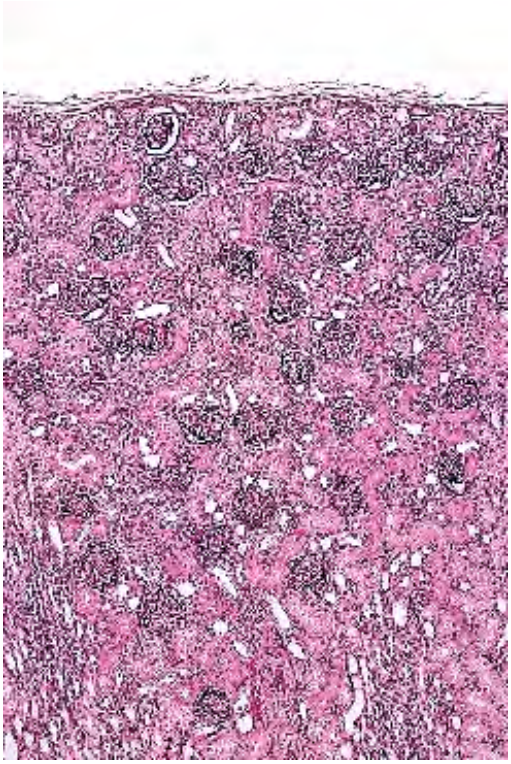

Figure 34.10 Newborn kidney (40 weeks of gestation). Note the absence of a nephrogenic zone. Some glomeruli are near the renal capsule.

During the capillary loop stage, the capillaries start to fill out into an expanding Bowman's space. The endothelial cells flatten and develop numerous fenestrae. The podocytes develop a complex cellular architecture as they become terminally differentiated and cease to undergo mitosis. They flatten and form cytoplasmic primary processes, which in turn, extend foot processes that interdigitate with those from adjacent podocytes and adhere to the developing glomerular basement membrane (GBM). Intercellular junctional complexes are present at the apical membranes between podocytes. With foot process development, these junctions migrate down the lateral surfaces of the emerging foot processes and disappear, when they are either replaced by or converted into the slit diaphragms (26). Slit diaphragms, specialized intercellular junctions, bridge the space between adjacent foot processes. The slit diaphragm is connected to the podocyte

cytoskeleton as part of a multifunctional protein complex that includes nephrin, CD2-associated protein (CD2AP), and podocin (30 ,31). Nephrin is the protein encoded by the *NPHS1* gene that is mutated in congenital nephrotic syndrome of the Finnish type, which is associated with loss of the slit diaphragm, abnormal foot processes, and massive proteinuria (32). Thus, the slit diaphragm is critical for maintaining podocyte architecture and the glomerular filtration barrier. The dual GBM, synthesized by both the endothelium and podocytes, is still present, but areas of fusion between the two membranes are found. Beginning during the capillary loop stage, a complex series of transitions in the GBM protein composition occurs. There is developmental switching of both type IV collagen and laminin isoforms in the GBM, events which are essential for forming normal glomerular capillaries (26 ,33).

Glomeruli in the maturing stage resemble adult glomeruli by histology but are smaller in diameter. The podocytes of the maturing glomeruli may have a cuboidal appearance. A single fused GBM predominates, and areas of dual unfused basement membranes are rarely seen. At this time, the synthesis of components for the GBM is largely by the podocytes. In areas where foot process interdigitation is continuing, irregular outpocketings of basement membrane are found beneath the podocytes. These outpocketings, or loops, reflect newly synthesized GBM that will be deposited into the existing GBM.

The development of the mesangium occurs relatively later in glomerulogenesis. Although the mesangial cells likely derive from the metanephric mesenchyme, their origin is not entirely clear. The mesangial cell precursors are distinct from the VEGF receptor expressing angioblasts that differentiate into the glomerular endothelial cells. However, the emergence of mesangial cells in the glomerulus is dependent on platelet-derived growth factor-B (PDGF-B), produced by podocytes and endothelial cells, and its receptor, PDGF receptor-B (PDGF-RB), expressed on mesangial cells (34).

Development of the Juxtaglomerular Apparatus

In the human mesonephros, a complete juxtaglomerular apparatus has not been observed, although renin-expressing cells have been noted (35). Renin expression in the metanephric kidney has been detected as early as eight weeks of gestation, and renin mRNA levels are significantly higher in the developing kidney than in the adult organ (35 ,36). In the developing kidney, renin-expressing cells are found in intrarenal arteries, including the arcuate and interlobular arteries. As development progresses, the distribution of renin-expressing cells shifts from the larger vessels to the juxtaglomerular apparatusâ€”primarily to the terminal afferent arterioleâ€”in the mature kidney (37 ,8). However, within the afferent arterioles themselves, heterogeneous patterns of renin expression exist (39). The juxtaglomerular (JG) cell, as a cellular component of the mature juxtaglomerular apparatus, is located in the wall of the terminal afferent arteriole close to the glomerulus. Studies of the embryonic origin and lineage of JG cells have demonstrated that JG cells originate from renin-expressing precursor cells of the metanephric blastema rather than an extrarenal source (40). Furthermore, studies have provided in vivo genetic evidence that renin precursor cells, in addition to differentiation into JG cells, can also differentiate into nonâ€“renin-expressing cells, such as vascular smooth muscle cells and glomerular mesangial cells (41).

Development of the Interstitium

Compared to other parenchymal components, there is far less known about the interstitium (stroma) in kidney development. In addition to providing a structural framework around the other components, an emerging view is that the developing interstitium plays an essential role in nephron and collecting duct differentiation (42 ,43 ,44). A traditional view is that cells of the metanephric mesenchyme not induced by the ureteric bud will become interstitial (stroma) cells.

from different cell lineages within the metanephric mesenchyme and also separate from the mesenchyme. A loose stroma containing spindle-shaped cells surrounds the early ureteric bud branches and early nephrons and is known as the primary interstitium (or clear-cell type stroma). As nephrogenesis proceeds, a cortical interstitium and a medullary interstitium, each with distinct cellular phenotypes, forms. Although the interstitial cells resemble fibroblasts, dendritic cells, macrophages, or lymphocytes according to morphologic and immunophenotypical findings, their origins and functions are mysterious (45 ,46 ,47). There is accumulated evidence to indicate that signals emanating from cells in the interstitium as well as the renal capsule are essential for normal nephron and collecting duct development (42 ,43 ,44). These important stromal cellâ€“expressed molecules include Foxd1, RARÎ±, RARÎ²2, FGF-7, BMP4, Pod1 and Pbx1 (Table 34.1).

Structural fibers extending between the ureteric bud ampulla and the renal capsule may represent a morphologic correlate that in part mediates the signals between the developing collecting duct and the capsule (48).

Apoptosis

In addition to prominent cell proliferation in the nephrogenic zone of the cortex, cell proliferation also contributes to the differentiation of the medullary tubules (49 ,50). Considering the widespread nature of apoptosis during embryologic development, it is not surprising that it occurs in kidney organogenesis. However, unlike the well-known function of apoptosis in the formation of nonwebbed digits, the biologic role of apoptosis in kidney development is not as apparent. During normal nephrogenesis, apoptosis has been observed within uninduced metanephric mesenchyme (51 ,52), comma-shaped bodies (53), developing tubules (52 ,54 ,55), stromal cells surrounding the tubules

(51), and immature glomeruli (56). As shown by several genetic defects in signaling between the mesenchyme and ureteric bud (Table 34.1), the metanephric mesenchyme is programmed to undergo massive apoptosis if it fails to be induced by the ureteric bud. At later stages of kidney development, apoptosis plays a role in remodeling the cell composition of medullary collecting ducts (54) and in the differentiation of the loops of Henle (55). Intercalated cells, involved in urine acidification, are removed from the developing medullary collecting duct by apoptosis or simple extrusion from the epithelium (Figures 34.11 ,34.12) (54). Also, in developing glomeruli, endothelial cells are removed by apoptosis during capillary lumen formation (55), and apoptosis can be observed in the parietal epithelium during glomerular development (Figure 34.13).

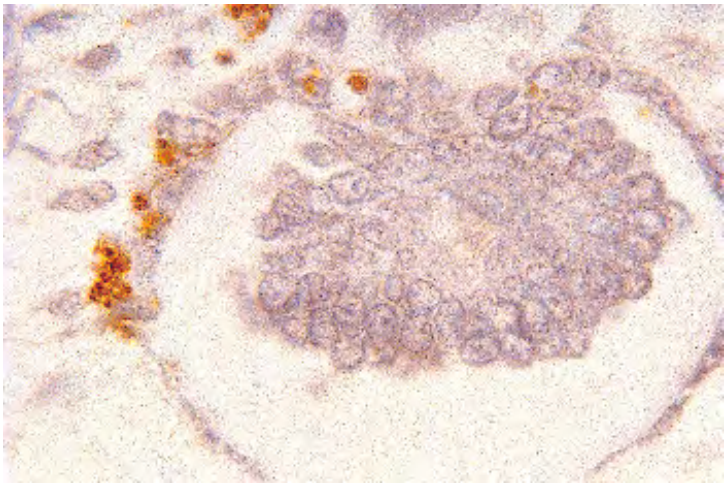

Figure 34.13 Micrograph from cortical nephrogenic zone of a fetal kidney demonstrating labeling for apoptosis in parietal epithelium of a developing glomerulus. Cells with fragmented DNA are identified by a Tdt-mediated dUTP-biotin nick end-labeling (TUNEL) immunoperoxidase method. (Courtesy of Dr. Jin Kim.)

There are disparate findings considering the quantitative scale of apoptosis during nephrogenesis (52 ,57). However, a role for apoptosis during nephrogenesis is further evidenced by the fact that mice deficient for *Bcl-2* , the major antiapoptotic regulator, have fulminant apoptosis of the metanephric mesenchyme, develop multiple cysts, and die of renal failure (58). Considering the above findings and the complex morphogenetic processes occurring during nephrogenesis, it seems likely that apoptosis plays a role in sculpting the kidney.

Molecular Regulation of Kidney Development

To make a kidney requires an orchestration of numerous complex cellular and molecular events. Several experimental approaches and model systems have enhanced our understanding of kidney development. A variety of in vitro studies have been valuable, including organic culture of metanephric rudiments, pioneered by Grobstein (7), and cell cultures of individual nephrogenic lineages. Gene targeting studies such as gene ablation in mice (â€œknockoutâ€• mice) have provided powerful in vivo evidence for the role of certain genes in nephrogenesis. A detailed review of the molecular aspects of nephrogenesis is beyond the scope of this chapter, but several reviews are available (9 ,10 ,11 ,12 ,59 ,60 ,61). Table 34.1 outlines some of the genes involved in mammalian kidney development, their encoded protein functions, their normal expression in the developing kidney, and the mutant kidney phenotypes that result from their ablation in mice. In addition, the known human syndromes caused by naturally occurring mutations in these genes are noted. The genes are listed under the cellular process (specification of nephrogenic mesenchyme, cell survival, cell proliferation, ureteric bud branching, mesenchymal-to-epithelial transition, glomerulogenesis and nephron differentiation) in which they are believed to have an important function (60). Where some of the genes are temporally positioned (upstream or downstream to one another) in the functional cascade of kidney organogenesis remains to be determined.

Compelling evidence exists to indicate that some genes, for example *WT1* , *Pax 2,* and *Pod1* , play multiple roles during nephrogenesis. Note that these particular genes are placed under more than one nephrogenic cellular process in Table 34.1 . The listing of the genes in Table 34.1 is based predominantly on in vivo genetic evidence. The generation of knockout mice using homologous recombination in embryonic stem cells has been very informative. However, embryonic lethality and pleiotropic phenotypes may occur, preventing an analysis of the significance of the targeted gene in nephrogenesis. Creating â€œconditionalâ€• knockout mice by disrupting genes only in specific renal cell types using site-specific DNA recombinase systems (e.g., Cre-lox P system) will provide important insights into kidney development (62). Moreover, some of the mutant kidney phenotypes will serve as valuable models for human disease.

In the near future, a list similar to Table 34.1 will be significantly lengthened. There will be a greater appreciation for the multiple roles that some genes have during nephrogenesis. However, our understanding of the cellular and molecular events that underlie the dynamics of kidney formation will be enhanced. In addition to a morphogenetic role during kidney organogenesis, some genes have an important physiologic function in the adult kidney. Also, the tabulated genes and their encoded proteins will no doubt be useful as lineage- or cell-specific markers to study renal diseases, including tumors.

Gross Anatomy

Kidney Position and Blood Supply

Upon formation, the metanephric kidneys are situated close to each other in the pelvis at the level of the upper sacrum. Between the sixth and ninth weeks of gestation, the kidneys are found further apart and at higher levels in the abdomen until they reach their final upper lumbar position (178). This â€œascentâ€• of the kidneys is believed to result largely from differential growth of the caudal part of the

embryo away from the kidneys (179 ,180). However, others have argued that the cephalad movement of the kidneys is active and not caused by differential growth of the vertebral column (181). With this migration, the renal hilum, where the main vessels enter and exit, rotates from a ventral orientation to face anteriomedially. Initially, the kidneys receive their blood supply from branches of the common iliac arteries. With their ascension, the kidneys are supplied by arteries originating from progressively higher levels of the distal aorta (178). The question of whether some of these vessels anastomose in a periaortic plexus is not well studied (182). As the ascending kidneys receive new branches from the aorta, the older, caudal branches undergo involution. Persistence of these inferior vessels may result in accessory renal arteries. The most cephalad branches arising from the abdominal aorta become the permanent main renal arteries.

Kidney Weight and Configuration

The various reference values reported for fetal and neonatal kidney weights correspond relatively closely, despite potential variability due to factors such as the social and economic status and the level of health care in a given population (183 ,184 ,185 ,186 ,187 ,188). Separate values from nonmacerated and macerated cases are available (188), as well as values using prefixation (187 ,188) and postfixation weighing (183 ,186) of the kidneys. Data for the combined weight (right and left) of the kidneys during the second

and third trimesters are shown in Figure 34.14 . Different reference values published for combined kidney weights during infancy and

childhood also favorably compare (183 ,189). The data of Emery and Mithal (183) are illustrated (Figure 34.15).

Specification of the Nephrogenic Mesenchyme

Lim 1

Transcription factor

Intermediate mesoderm, nephric duct, mesonephros, ureteric bud, collecting ducts, pretubular aggregates, S-shaped bodies, podocytes

Absent pro-, meso-, and metanephros (*Lim 1* required at multiple steps of kidney development)

(63 ,64 ,65)

Eya1

(Mutations in branchiooto-renal [BOR] syndrome)

Transcription coactivator (interacts with *Six1*)

Intermediate mesoderm, uninduced and induced metanephric mesenchyme

Intact pro- and mesonephros, but absent metanephric blastema, renal agenesis

(66 ,67 ,68)

Six1

(Mutations in branchiooto-renal [BOR] syndrome)

Transcription factor (interacts with *Eya1*)

Uninduced and induced metanephric mesenchyme and collecting tubules

Ureteric bud forms but does not fully invade metanephric mesenchyme, which undergoes apoptosis, renal agenesis

(69 â€“70)

Sall 1

(Mutations in Townes-Brocks syndrome)

Transcription factor

Mesonephros, induced metanephric mesenchyme

Ureteric bud forms but does not fully invade metanephric mesenchyme, which undergoes apoptosis, renal hypoplasia, or agenesis

(71)

Hoxa11 , *Hoxd11*

Transcription factors
Intermediate mesoderm, metanephric mesenchyme
Impaired ureteric bud branching, renal hypoplasia in *Hoxa11 /Hoxd11* double mutants
(72 ,73)
Pax 2
Transcription factor
Intermediate mesoderm, nephric duct, mesonephros, ureteric bud, induced metanephric mesenchyme
Intact nephric duct but mesonephric tubules and ureteric bud fail to form, renal agenesis
(74 ,75 ,76)
WT1
Transcription factor
Intermediate mesoderm, mesonephros, uninduced and induced metanephric mesenchyme, comma- and S-shaped bodies, podocytes
Absent caudal mesonephros, ureteric bud fails to form, metanephric mesenchyme undergoes apoptosis, renal agenesis
(77 ,78)
Foxc1/2
Transcription factor
Intermediate mesoderm, mesonephros, uninduced and induced metanephric mesenchyme
Double ureters with one a hydroureter, duplex kidneys (*Foxc1 /Foxc2* compound heterozygous mutants similar to *Foxc1* homozygous mutants)
(79 ,80)
Slit2
Secreted protein
Mesonephric duct, anterior intermediate mesoderm, ureteric bud tips
Supernumerary ureteric buds, hydroureter, fused multiple kidneys
(81)
Robo2
Transmembrane (receptor for *Slit2*)

Intermediate mesoderm, induced metanephric mesenchyme
Supernumerary ureteric buds, hydroureter, fused multiple kidneys
(81)
Cell Survival
BMP7
Growth factor
Mesonephric duct, ureteric bud, induced metanephric mesenchyme, distal tubules, comma-and S-shaped bodies, podocytes
Increased apoptosis in metanephric mesenchyme, decreased ureter bud branching, hydroureter, severe renal hypoplasia
(82 ,83 ,84)
FGF-8
Growth factor
Pretubular aggregates, vesicles, tubule progenitors in S body
Increased apoptosis in S body precursors, truncated nephrons, severe renal hypoplasia
(85 ,86)
Bcl-2
Antiapoptotic factor
Ureteric bud, induced metanephric mesenchyme, parietal epithelium of Bowman's capsule, tubules and collecting ducts
Increased apoptosis especially in metanephric mesenchyme, cysts in tubules and collecting ducts, severe renal hypoplasia.
(87 ,88)
AP-2 Î²
Transcription factor
Distal tubules and collecting ducts
Increased apoptosis and cyst formation in distal tubules and collecting ducts
(89 ,90)
Pax-2
(Heterozygous mutations in renal-coloboma syndrome)
Transcription factor
Intermediate mesoderm, nephric duct, mesonephros, ureteric bud,

induced metanephric mesenchyme
Heterozygous *Pax-2* mutations result in increased apoptosis in collecting ducts, reduced ureteric branching, hypoplastic kidneys
(91 ,92 ,93)
Cell Proliferation
FGF-7
Growth factor
Interstitial fibroblasts or stroma surrounding ureteric bud and developing collecting ducts
Decreased growth of ureteric bud and collecting ducts, decreased number of nephrons, renal hypoplasia
(94)
N-Myc
Transcription factor
Induced metanephric mesenchyme
Decreased cell proliferation, decreased ureteric bud tips and nephrons, renal hypoplasia
(95)
Glypican-3
(Mutations in Simpson-Golabi-Behmel syndrome)
Heparan sulfate proteoglycan
All metanephric mesenchyme and ureteric bud derivatives
Increased cell proliferation in cortical collecting ducts, increased apoptosis in medullary collecting ducts, renal medullary cystic dysplasia
(96 ,97)
Branching of the Ureteric Bud
GDNF
Growth factor
Intermediate mesoderm, mesonephros, induced metanephric mesenchyme, pretubular aggregates
Ureteric bud fails to form or has abnormal branching, renal hypoplasia or agenesis
(98 ,99 ,100)

c-ret
GF receptor (TK) (receptor for *GDNF*)
Mesonephric duct, ureteric bud and tips of ureteric bud
Similar to GDNF-deficient mice
(101 ,102)
GFR Î±1
GF coreceptor (forms signaling complex with *GDNF* and *c-ret*)
Induced metanephric mesenchyme, pretubular aggregates, mesonephric duct, ureteric bud and tips of ureteric bud
Similar to GDNF-deficient mice
(103)
GDF11
Growth factor
Mesonephric duct, uninduced and induced metanephric mesenchyme, ureteric bud and branches
No ureteric bud formation, metanephric mesenchyme undergoes apoptosis, renal hypoplasia or agenesis
(104)
Sprouty1
Receptor (TK) antagonist
Mesonephric duct, ureteric bud and tips of ureteric bud
Supernumerary ureteric buds, multiple ureters, multiplex kidneys
(105)
Emx2
Transcription factor
Intermediate mesoderm, mesonephric duct, mesonephros, ureteric bud, comma- and S-shaped bodies
Ureteric bud invades metanephric mesenchyme but fails to dilate or branch, no induction of mesenchyme, renal agenesis
(106)
RAR Î±, *RAR Î²2*
Transcription factors
RARÎ±â€”ureteric bud, metanephric mesenchyme, stroma
RARÎ²2â€”stroma only

Decreased ureteric bud branching (defective stroma signaling) in *RAR* Î±/ Î²*2* double mutants, renal hypoplasia
(107 ,108)
BMP4
Bone morphogenetic protein
Stromal mesenchymal cells around ureteric bud branches
Reduced and ectopic ureteral branching, ectopic ureterovesical junction, hydoureter, double collecting ducts, hypo/dysplastic kidneys (heterozygous *BMP4* null mice)
(109)
Pod1
Transcription factor
Induced metanephric mesenchyme, stromal cells and podocytes
Decreased ureteric branching, arrest in tubular and glomerular differentiation, renal hypoplasia
(110)
Heparan sulfate 2-sulfotransferase
Enzyme (synthesis of heparan sulfate, a component of HS proteoglycan)
Mesonephric duct, transient in ureteric bud, metanephric mesenchyme
Ureteric bud outgrowth but no branching, no condensation of metanephric mesenchyme, renal agenesis
(111)
Integrin Î±*8*
Transmembrane adhesion receptor
Intermediate mesoderm, induced metanephric mesenchyme, pretubular aggregates
Limited ureteric bud invasion of metanephric mesenchyme, decreased ureteric branching, renal hypoplasia or agenesis
(112)
Integrin Î±*3* Î²*1*
Transmembrane adhesion receptor
Ureteric bud, collecting ducts, podocytes
Decreased branching of medullary collecting ducts, microcystic

proximal tubules, defective glomerulogenesis
(113)
Pbxl
Transcription factor
Induced metanephric mesenchyme and stromal cells
Decreased and irregular ureteric bud branching, large mesenchymal condensates, renal hypoplasia or unilateral agenesis
(114)
Grem1
Bone morphogenetic protein (BMP) antagonist
Intermediate mesoderm, mesonephric duct, metanephric mesenchyme
Ureteric bud forms but fails to invade metanephric mesenchyme, which undergoes apoptosis, renal agenesis
(115)
Wnt11
Secreted glycoprotein
Ureteric bud tips
Loss of ureteric tips, reduced ureteric branching, renal hypoplasia
(116)
Formin
(Mutations in mice cause the limb deformity syndrome)
Protein that regulates cytoskeleton function
Mesonephric duct, mesonephros, ureteric bud, metanephric mesenchyme
Decreased ureteric bud outgrowth, renal hypoplasia, unilateral or bilateral renal agenesis
(117)
Angiotensinogen (*Agt*)
Renin substrate
Ureteric bud, stroma, S-shaped bodies, glomeruli, proximal tubules
Hypoplastic papillae, hydronephrosis, thickened blood vessels, reduced blood pressure
(118 ,119)
Renin

Enzyme (cleaves Agt to form angiotensin I)
Developing arcuate and interlobular arteries and afferent arterioles, restricted to juxtaglomerular apparatus with maturity
Hypoplasic papillae, hydronephrosis, thickened blood vessels, reduced blood pressure
(120 ,121)
Angiotensin converting enzyme (*ACE*)
Enzyme (converts angiotensin I to angiotensin II)
Glomeruli, proximal tubules and collecting ducts, small arteries
Hypoplastic papillae, hydronephrosis, thickened blood vessels, reduced blood pressure
(122)
Angiotensin II receptor, type 1 (AT_1)
Angiotensin II receptor
Ureteric bud, stroma, S-shaped bodies, proximal tubules, collecting ducts
Hypoplastic papillae, hydronephrosis, thickened blood vessels, reduced blood pressure
(123 ,124)
Angiotensin II receptor, type 2 (AT_2)
Angiotensin II receptor
Stroma adjacent to ureteric bud stalk
3% have abnormalities, duplicated collecting system, and hydronephrotic upper pole
(125 ,126)
Mesenchymal-to-Epithelial Transition
Wnt4
Secreted glycoprotein
Pretubular aggregates, comma-shaped body, distal S-shaped body
Ureteric bud branching occurs, no mesenchymal-epithelial transition, renal agenesis
(127)
Wnt9b
Secreted glycoprotein

Mesonephric duct, ureteric bud and collecting ducts but not branching tips
No mesenchymal-epithelial transition, renal agenesis
(128)
Foxd1(BF2)
Transcription factor
Interstitial stroma cells
Decreased ureteric bud branching, large mesenchymal condensates, abnormal renal capsule, small fused pelvic kidneys
(129 ,130)
Pod1
Transcription factor
Induced metanephric mesenchyme, stromal cells and podocytes
Increased size of induced mesenchymal condensates, arrest in tubular and glomerular differentiation, renal hypoplasia
(131)
Fras1
(Mutations in Fraser syndrome)
Extracellular matrix (ECM) protein
Basal side of ureteric ducts
Ureteric bud invades metanephric mesenchyme but decreased induction, apoptosis of mesenchyme, renal hypoplasia or agenesis
(132 ,133)
Grip1
Cytoplasmic protein (interacts with *Fras1*)
Basal side of ureteric ducts
Similar abnormal phenotype as in *Fras1* -deficient mice
(134)
Cadherin-6 (*K-cadherin*)
Transmembrane adhesion protein
Renal vesicle, proximal end of comma-and S-shaped bodies, developing proximal tubules and Henle's loops
Delayed fusion of some comma-shaped bodies to ureteric bud leading to loss of nephrons

(135)
Glomerulogenesis
WT1
(Mutations in WAGR, Denys-Drash, and Frasier syndromes)
Transcription factor
Intermediate mesoderm, mesonephros, uninduced and induced metanephric mesenchyme, S-shaped body, podocytes
Disturbed podocyte differentiation, glomerulosclerosis
(136 ,137 ,138)
PDGF-B
Growth factor
Glomerular endothelial cells and podocytes
Dilated glomerular capillaries with no mesangial cells
(139)
PDGFR- Î²
Growth factor receptor (receptor for *PDGF-B*)
Glomerular mesangial cells
Dilated glomerular capillaries with no mesangial cells
(140)
Notch2
Transmembrane receptor
Developing collecting ducts, comma- and S-shaped bodies, podocytes
Abnormal glomeruli arrested at capillary loop stage, with disorganized podocytes and no mesangial cells
(141)
VEGF-A
Growth factor
S-shaped bodies, podocytes, collecting ducts
Small glomeruli, lack capillary loops, few endothelial cells
(142)
Laminin Î±*5*
Basement membrane protein
Basement membranes of ureteric bud, developing tubules and glomerular basement membrane (GBM)

Abnormal glomeruli with displaced endothelial and mesangial cells, and clustered podocytes
(143)
Laminin Î²2
Basement membrane protein
Glomerular basement membranes beginning at capillary loop stage
Absence of podocyte foot processes, proteinuria
(144)
Laminin Î±3 Î²1
Transmembrane adhesion receptor
Ureteric bud, collecting ducts, podocytes
Glomerular capillary loops dilated and fewer in number, loss of podocyte foot processes, dual GBMs (failure of fusion)
(113)
Collagen IV Î±3
(Mutations in Alport syndrome)
Basement membrane protein
Forms heterodimer with Î±4 (IV) and Î±5 (IV) chains in GBM from capillary stage onward
Thinning and â€œbasket-weaveâ€• thickening of GBMs
(145 ,146 ,147)
Nephrin
(Mutations in Congenital nephrotic syndrome of Finnish type)
Transmembrane protein
Podocyte filtration slit diaphragm
Foot process effacement, absent filtration slit diaphragms, proteinuria
(148)
CD2AP
Adapter protein (interacts with nephrin)
Podocyte filtration slit diaphragm domain
Irregular foot processes, absent filtration slit diaphragms, proteinuria
(149)
Podocin
(Mutations in autosomal recessive steroid resistant nephrotic

syndrome)
Membrane protein (interacts with nephrin)
Podocyte filtration slit diaphragm domain
Irregular foot processes, absent filtration slit diaphragms, proteinuria (150)
Î±-*Actinin*
(Mutations in autosomal dominant focal segmental glomerulosclerosis [FSGS])
Cross-links actin filaments
Podocyte filtration slit diaphragm domain
Foot process effacement, GBM duplication, proteinuria, and FSGS (151 ,152)
TRPC6
(Mutations in autosomal dominant FSGS)
Cation-channel
Podocyte filtration slit diaphragm domain
Foot process effacement and FSGS (humans) (153 ,154)
Neph1
Transmembrane protein (interacts with nephrin)
Podocyte filtration slit diaphragm
Foot process effacement, proteinuria (155)
FAT1
Protocadherin
Podocyte filtration slit diaphragm
Foot process effacement (156)
Lmx1b
(Mutations in nail patella syndrome)
Transcription factor
Podocytes
Abnormal foot processes, absent filtration slit diaphragms (157 ,158)

Podocalyxin
CD34-related transmembrane protein
Podocyte apical membrane domain
Abnormal podocytes, foot process effacement, absent filtration slit diaphragms, anuria
(159)
GLEPP1 (*Ptpro*)
Receptor tyrosine phosphatase
Podocyte apical membrane domain
Shortened and widened podocyte foot processes, reduced glomerular filtration rate
(160)
Kreisler (*Krml1/MafB*)
Transcription factor
Podocytes, initially at capillary loop stage
Abnormal podocyte differentiation with no foot processes
(161)
Tubular Differentation
PKD1 (*polycystin-1*)
(Mutations in autosomal dominant polycystic kidney disease [ADPKD])
Transmembrane protein (adhesion receptor, in cilia, interacts with polycystin-2)
Developing nephron segments and collecting ducts
Renal cysts arising from developing nephron segments and collecting ducts
(162 ,163 ,164 ,165)
PKD2 (*polycystin-2*) (Mutations in autosomal dominant polycystic kidney disease [ADPKD])
Transmembrane protein (calcium channel, in cilia, interacts with polycystin-1)
Developing nephron segments and collecting ducts
Renal cysts arising from developing nephron segments and collecting ducts
(166 ,167)

Frem2 (Mutations in Fraser syndrome)
Extracellular matrix (ECM) protein
Mesonephros, ureteric bud especially at tips, tubule derivatives
Cysts of collecting ducts and thick ascending limbs
(168)
Cox-2 (Cyclooxygenase-2)
Enzyme (prostaglandin synthesis)
Developing collecting ducts, S-shaped bodies, macula densa, cortical thick ascending limb, medullary interstitial cells
Progressive postnatal outer cortical dysplasia, tubular cysts, and glomerular hypoplasia
(169 ,170)
EGFR
Growth factor receptor (TK)
Mesonephric duct, ureteric bud, collecting ducts
Dilatation of collecting ducts, uremia
(171 ,172)
Brnl
Transcription factor
Renal vesicle, comma- and S-shaped bodies, developing Henle's loop (HL), distal convoluted tubule (DCT), macula densa (MD)
Disrupted differentiation of HLs, MD, and DCT
(173)
Psen1/Psen2
Presinilins-(transmembrane protein with Î³-secretase activity)
Developing early nephron structures
Renal vesicles and pretubular aggregates form, but no comma- or S-shaped bodies; proximal tubules and glomeruli fail to form
(*Psen1/Psen2* double null mutant mice with human *PSEN1* transgene)
(174 ,175)
Tensin
Adhesion protein (phosphoprotein, binds actin)
Proximal and distal tubules (adult kidney)
Hydronephrosis, cystic dilatation of proximal tubules

(176)

R-cadherin

Transmembrane adhesion protein

Induced metanephric mesenchyme, renal vesicle, comma- and S-shaped bodies

Dilatation and cytoplasmic vacuolization of proximal tubules

(177)

(*FSGS,* focal segmental glomerulosclerosis; *GBM,* glomerular basement membrane

values for second trimester fetal and neonatal organ weights and measurements. *Pediatr Dev Pathol* 2003;6:160â€“167.

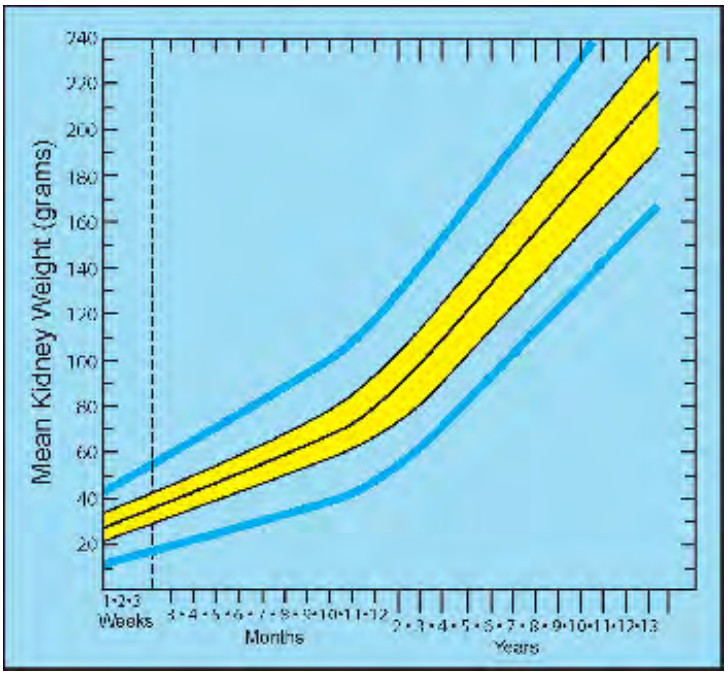

Figure 34.15 Mean combined (right and left) weight of kidneys at various postnatal ages. The middle black line represents the means. The 50th percentile (yellow band) and 95th percentile (blue lines) ranges are shown. Modified with permission from:
Emery JL, Mithal A. The weights of kidneys in late intra-uterine life and childhood. *J Clin Pathol* 1960;13:490â€“493.

Figure 34.16 Gross appearance of newborn kidneys. The rounded configuration with a relatively deeper sinus, characteristic of the infantile kidney, is seen on the sectioned surface. Fetal lobations are prominent on the external surface.

The newborn kidney has a shorter, more rounded configuration than that of the adult. The upper and lower poles project further medially, so the renal sinus is relatively deeper in the infant (Figures 34.16 ,34.17) (190). The renal sinus of infants contains much less fat and connective tissue than in the adult, and the cortical septa (columns) of Bertin approach much closer to the pelvic-calyceal system. Figure 34.17 illustrates the process of â€œunrollingâ€• of the renal poles during childhood, as the kidney assumes the more elongated configuration observed in adults. This change in configuration produces a shallower renal sinus with partial exteriorization of the pelvis. As the pelvic-calyceal system assumes a more exterior position, it also becomes displaced further from the parenchyma lining the sinus. The additional space created between the pelvic-calyceal system and the cortical columns of Bertin is normally filled with fat, which increases in quantity as the kidney approaches maturity.

Fetal Lobations

A renal lobe consists of a medullary pyramid and its surrounding

cortical parenchyma (Figures 34.7 , 34.16). The centrilobar cortex covers the base of a pyramid, whereas the septal cortex surrounds the sides of a pyramid. Thus, a septum (column) of Bertin represents the confluence of two layers of septal cortex from two adjacent lobes. Although a lobe does not represent a functional renal unit, it may be viewed as an anatomic organizational unit (191). Lobation begins in the human kidney at six to seven weeks and proceeds to maximun development with an average of 14 lobes at 28 weeks of gestation (192 ,193). At this stage, generally 14 papillae and calyces are present, corresponding with the same number of lobes. Deep clefts on the surface separate the lobes. After the twenty-eighth week, a process of variable lobar fusion decreases the number of surface fissures, papillae, and calyces. The degree of calyceal fusion is greater than papillae fusion. In full-term infant kidneys, the mean

number reported for calyces is 9 and for papillae, it is 11 (193). Considerably more lobar fusion, creating compound papillae, occurs in the polar regions than in the midpolar region, where simple papillae are more likely to be retained.

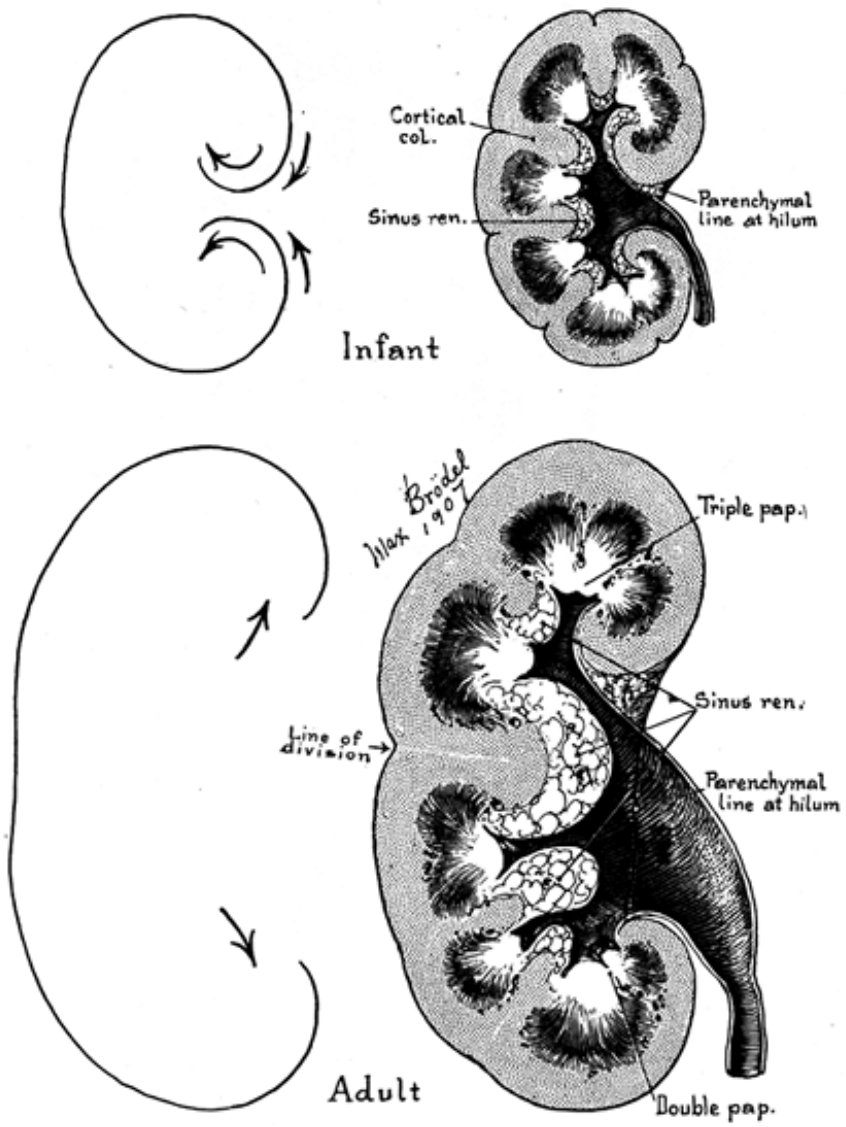

Figure 34.17 Max BrÃ¶del's classic illustration of the process of unrolling of the kidney in postnatal life (from
Kelley HA, Burnam CF. *Diseases of the Kidneys, Ureters, and Bladder* . Vol.1. New York: Appleton; 1925
). The rounded configuration of the infantile organ becomes elongated as the upper and lower poles diverge and pelvic-calyceal structures are partially everted from their original position within the renal sinus. The space thus created within the renal sinus is filled by fat, which is far more abundant in the adult kidney than in the infant kidney.

The surface of the neonatal kidney is divided into polygons by prominent fissures that correspond roughly, although not precisely, to the lobar outlines (Figure 34.16). These fetal lobations usually decrease in prominence with advancing age, persisting longer on the ventral surface than the dorsal surface of the organ. Although there is considerable individual variation in the chronology of their disappearance, they are usually inconspicuous by 4 to 5 years of age (194). The only valid generalization is that fetal lobations usually diminish in number and prominence in the first few years of life, but they remain apparent, especially on the ventral surfaces, in a significant proportion of adult kidneys. In one study, one or more interlobar fissures were detected in up to 50% of adult kidneys (193). In older children and adults, it is important to distinguish persistent fetal lobations from cortical scars. Fetal lobation is a more accurate term than fetal lobulation because a lobule is an architectural feature of the cortex, primarily observed on the histologic level.

Histology

Cortical Architecture

The developing renal cortex has unique temporal and spatial features of organization. Each generation of nephrons, most easily observed histologically by the glomeruli, forms a â€œlayerâ€• over the preceeding generation. The earliest formed nephrons are situated in the inner cortex (juxtamedullary) near the future medulla, whereas the nephrogenic zone in the outer cortex (superficial) contains the last nephrons formed. Between the thirty-second and thirty-sixth weeks of gestation, nephron formation ceases and the nephrogenic zone disappears. Although the nephrogenic zone persists in kidneys of children born prematurely (195 ,196), evidence suggests that postnatal nephrogenesis is suboptimal and does not occur after 40 days (197).

The histologic features of the developing renal cortex have been used as an index of fetal maturation (196). The ratio of the width of the nephrogenic zone to the width of the remaining cortex decreases in a linear fashion as the birth weight increases (185 ,198). This approach has been used to detect infants with reduced intrauterine growth in whom this ratio is less than expected for the birth weight. Using glomeruli as representative of nephrons, studies have employed counting the number of layers (or rows) of glomeruli from inner to outer cortex as a method to evaluate nephrogenesis (199 ,200 ,201). Each successive layer is assumed to represent a new glomerular â€œgeneration.â€• These estimates are performed on well-oriented sections that are orthogonal to the cortex and display a well-defined corticomedullary junction.

The studies are in fair agreement between gestations of 24 to 36 weeks, in which the average number of rows (nephron generations) of glomeruli are as follows: 5 to 7 (24 weeks), 8 to 9 (28 weeks), 9 to 10 (32 weeks), and 10 to 14 (36 weeks). After the full complement of nephrons is attained by the normal fetus, subsequent renal growth reflects hypertrophy and maturation of the nephrons. As tubules elongate and increase in diameter, they become interposed between glomeruli. The glomeruli in the outer cortex of newborns are crowded together (Figure 34.10), whereas the older, more mature glomeruli deeper in the cortex are more widely separated. This process of tubular growth not only separates glomeruli from one another, but it also tends to separate them from the cortical surface near where they originally developed. In a normal term newborn, one observes many glomeruli very close to the renal capsule (Figure 34.10). By about 2 months of age, the process of nephron growth has begun to separate the outermost glomeruli, and a narrow zone largely devoid of glomeruli develops beneath the renal capsule (Figure 34.18). This latter zone has been termed the *cortex corticis* (202). The cortex corticis becomes progressively wider during childhood (Figure 34.19). Although it is normal to find an occasional glomerulus adjacent to the

capsular surface in normal infants and children, the presence of numerous very superficial glomeruli suggests defective renal growth during late fetal or early postnatal life. Abnormally crowded glomeruli also can be an important clue to defects in nephron growth and differentiation, which may involve only the outer cortex or the entire cortical mantle. Thus, the cortical architecture may be viewed as a record of the developmental history of the kidney.

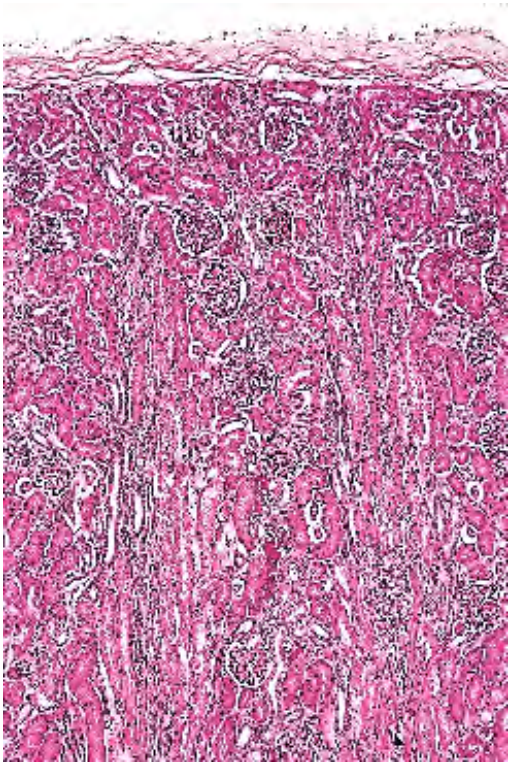

Figure 34.18 Renal cortex at 2 months of age. Glomeruli in the outer cortex are becoming more widely spaced due to tubular elongation. Superficial glomeruli are beginning to separate from the renal capsule, the first indication of the cortex corticis.

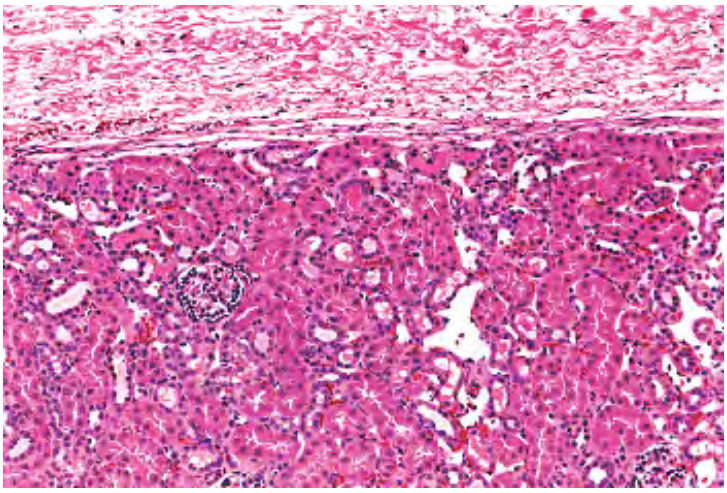

Figure 34.19 Micrograph of well-developed renal cortex corticis. The zone without glomeruli beneath the distinct renal capsule is evident. Reprinted with permission from:
Murphy WM, Grignon DJ, Perlman EJ. Tumors of the kidney, bladder, and related urinary structures. In: *Atlas of Tumor Pathology* . 4th series, fascicle 1. Washington, DC: Armed Forces Institute of Pathology; 2004.

The cortex is subdivided into distinctly demarcated *lobules* by radially oriented groups of tubules termed *medullary rays* that extend from the base of the pyramids upward into the cortex (Figure 34.20). A lobule is defined as the cortical domain surrounding a medullary ray. Despite their name, the medullary rays (of Ferrein) actually are part of the cortex and contain the straight segments of the proximal tubule, the thick ascending limbs, and the collecting ducts. Medullary rays usually extend to near the cortical surface in infants but not in older children. The presence of complete medullary rays is a good indicator that the plane of a given section is perpendicular and reflective of the true thickness of the cortex. Medullary ray nodules are complex tangled tubular configurations commonly seen in the medullary rays of infants during the early months of life, being most prominent between 1 and 6 months of age (Figure 34.21) (203). These structures apparently represent a normal transitory developmental phenomenon of variable prominence, which is pathologic only when extreme.

Nephron Number

The number of nephrons in a kidney is determined in utero. The final number is dependent on gestational age and a favorable intrauterine environment. Unbiased, precise stereological methods have been used to count glomeruli, which serve as a surrogate for nephron number. One study of human intrauterine renal growth revealed the glomerular number increased from 15,000 at 15 weeks of gestation to 740,000 by 40 weeks (204). The greatest rate of nephron induction has been observed between 15 to 17 weeks of

gestation; however, approximately 60% of the total nephrons are believed to form during the third trimester (204). Nephron number, inferred from glomerular number estimates in children and adults without renal disease, is strongly correlated with birth weight (205). Intrauterine growth retardation has been shown to impair nephron formation, as measured in fetuses and in infants dying within a year of birth (206 ,207).

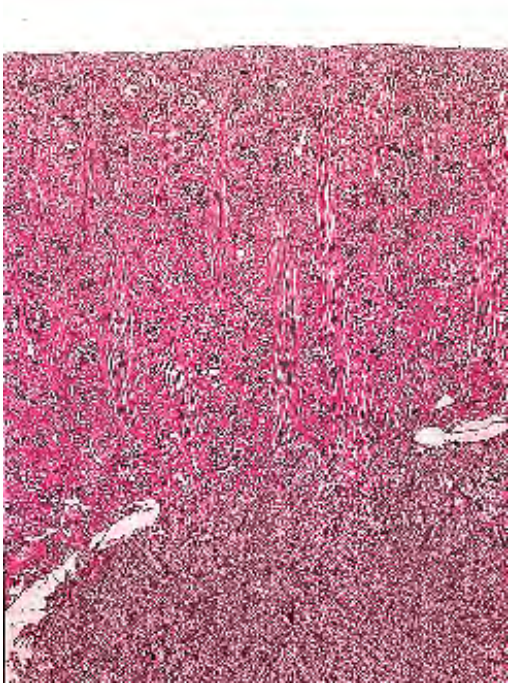

Figure 34.20 Kidney at 21 months of age. This perpendicularly oriented section illustrates the full length of several medullary rays that extend from the corticomedullary junction to a level near the cortex corticis. Each medullary ray marks the center of a cortical lobule.

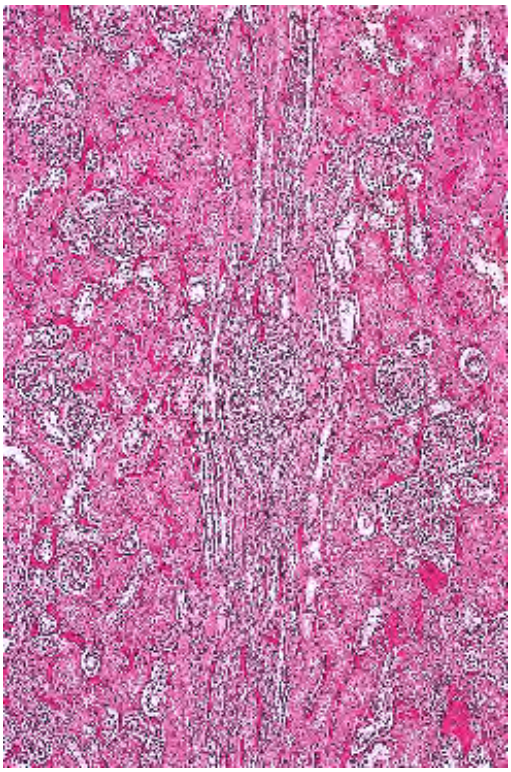

Figure 34.21 Medullary ray nodule. In the center of the micrograph, a tangled cluster of collecting ducts forms a nodule near the midportion of a medullary ray. This structure is usually transitory, being uncommon in the first month of life and extremely rare after 1 year of age.

It is apparent that a kidney having a quantitative abnormality, such as low nephron number, may not demonstrate an obvious defect of nephron spatial topography on histologic examination. However, studies have demonstrated an inverse correlation between the number of glomeruli and mean glomerular volume, suggesting glomeruli

increase in size to compensate for an innate low nephron number (205 ,207). Large glomeruli may be susceptible to scarring. Glomerulomegaly has been used as an adverse factor to assess the risk of disease progression in childhood nephrotic syndrome (208). Thus, increased glomerular size (volume or area) may be useful as an indicator for nephron deficiency in individuals susceptible to renal disease.

Until a few years ago, each human kidney was believed to contain one million nephrons. It is now appreciated that there is a remarkably wide variation in total nephrons per kidney among â€œnormalâ€• adults, ranging from as low as 227,000 to over 2,000,000 (209 ,210 ,211). Nephron endowment is programmed in the perinatal period, capping the nephron number in an individual's lifetime. Some time ago, Brenner et al. (212) postulated that an inborn deficit of nephrons predisposes to acquired renal disease, including hypertension, in adults. A study showing that hypertensive individuals had fewer nephrons but a larger glomerular volume than age-matched normotensive controls supports this hypothesis (213). The endowment of nephrons from nephrogenesis and the developmental origins of renal disease are fertile areas for investigation.

Glomerular Maturation and Growth

Newly formed glomeruli are structurally distinctive, and their evolution toward a mature form is a gradual process. Because the period of glomerular development spans a six- to seven-month period of fetal life, a spectrum of maturational stages is normally present in infant kidneys. As mentioned before, this spectrum is organized in a temporal-spatial manner in the cortex. Familiarity with normal glomerular maturation can facilitate an assessment of the renal developmental status in infants. Dramatic changes in glomerular structure and size occur through the early months and years of life. For convenience of study, several stages of glomerular development have been defined in studies (214 ,215 ,216 ,217). Figure 34.22 shows

representative glomeruli from the midcortical region of infants and children from birth to 9 years of age to illustrate the maturational changes. Figure 34.22A shows the characteristic appearance of recently formed glomeruli from a term newborn infant. In addition to their small size, the most obvious distinctions from mature glomeruli are the simple character of the tufts with relatively few capillary loops and the layer of cuboidal cells surfacing the visceral layer of the tuft. This cuboidal layer, representing developing podocytes, is often continuous and covers most of the circumference of the tufts. Ultrastructurally, these primitive podocytes are closely approximated to one another and often lack foot processes (Figure 34.23A). The glomerular basement membrane (GBM) is thin and two lamina densa structures, representing basal laminae produced by endothelial cells and podocytes prior to their fusion into a single lamina, may be focally observed. The thickness of the GBM increases progressively with age (Figure 34.23). The approximate values for GBM thickness during childhood range as follows: 100 to 130 nm in fetal kidneys; 170 nm (Â± 30) at birth; 208 nm (Â± 24) at 1 year; 245 nm (Â± 49) at 2 years; 268 nm (Â± 43) at 6 years; and 300 nm (Â± 42) by 10 years (216 ,218 ,219). The growth rate is greatest prior to 2 years of age. In contrast to adults, the GBM thickness in children appears less sex dependent (206). The data of Volger and colleagues, illustrating the increase in GBM (Figure 34.24A) and lamina densa widths (Figure 34.24B) with age are shown. Further GBM growth in adolescence, which is less documented, must occur to reach the adult GBM thickness in men (373 nm Â± 42) and women (326 nm Â± 45) (220).

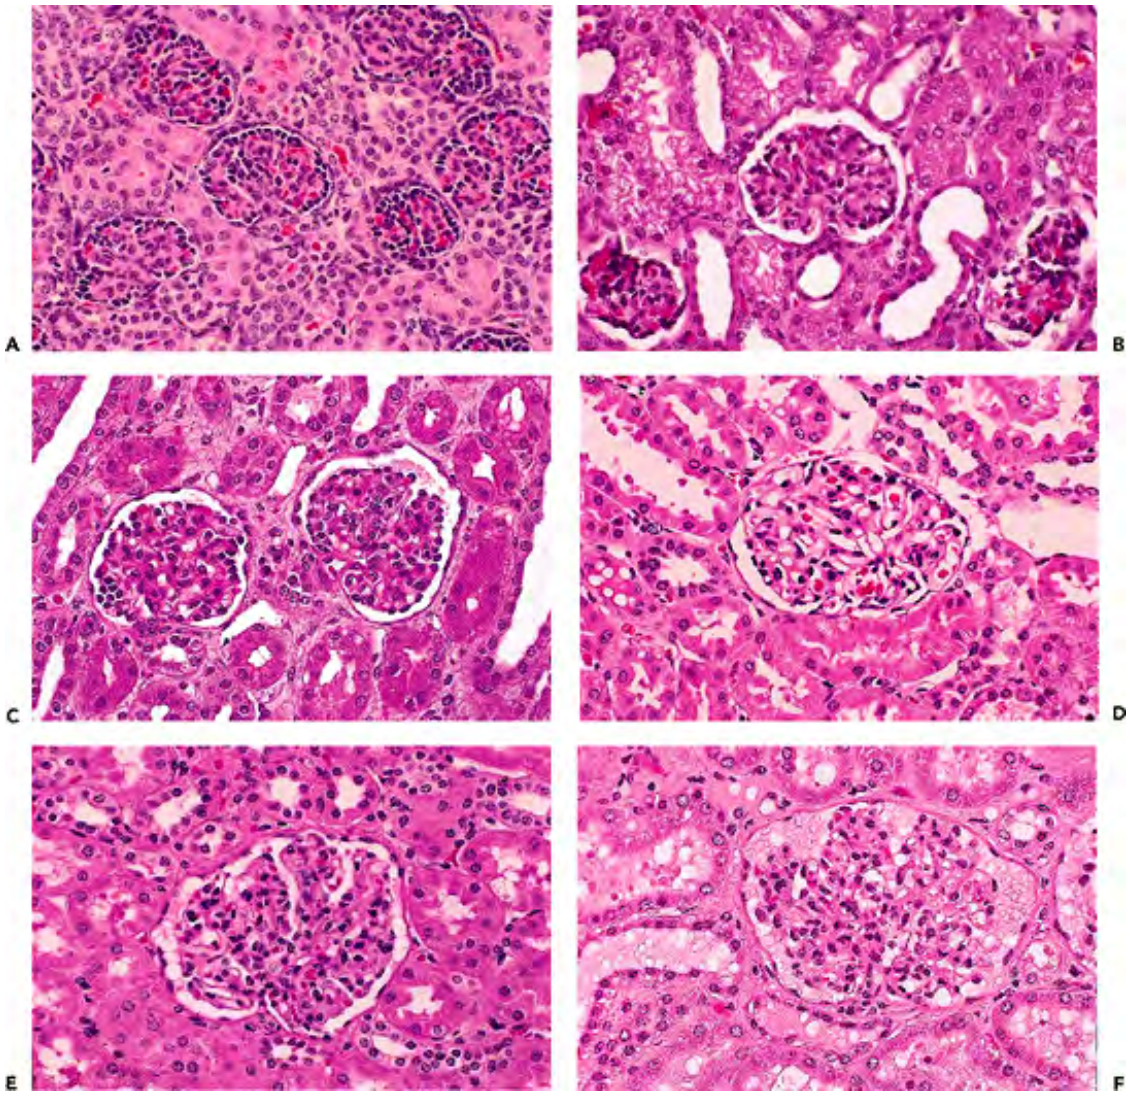

Figure 34.22 Normal midcortical glomeruli of six infants and children from birth to 9 years of age. All the micrographs were taken at the same magnification. A. Newborn. B. 6 months. C. 11 months. D. 21 months. E. 5 years. F. 9 years.

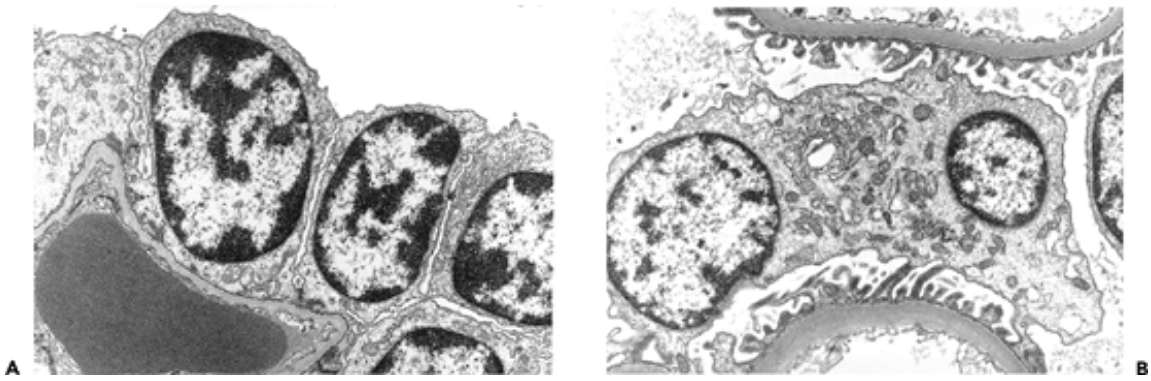

Figure 34.23 A. Electron micrograph of a normal glomerulus from an infant 2 months of age. Note the continuous layer of primitive podocytes lacking foot processes and the thin glomerular basement membrane. B. Mature glomerulus from a patient 16 years of age, photographed at the same magnification as in A. There is prominent foot process development, and the glomerular basement membrane is distinctly thicker than in the infant. (Courtesy of Dr. Gary W. Mierau.)

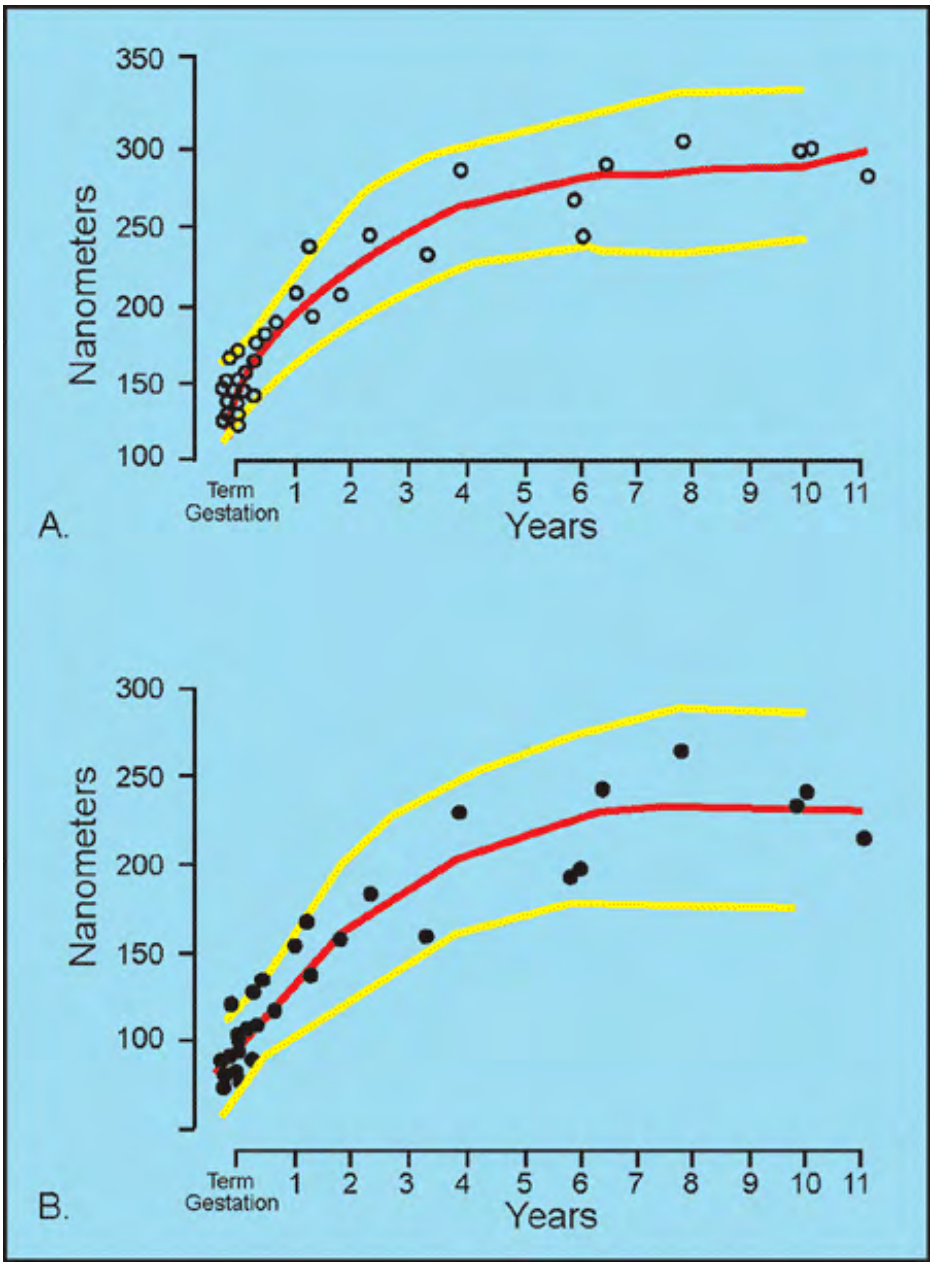

Figure 34.24 Thickness of glomerular basement membrane (GBM) in children. A. Total thickness of GBM. B. Thickness of lamina densa (LD) portion of GBM. The thickness of both the total GBM and the LD increases rapidly in early childhood and slows in growth after 3 years of age. The mean GBM and LD thicknesses (red lines) and the 95th percentile ranges (yellow lines) are shown. Modified with permission from:

Volger C, McAdams J, Homan SM. Glomerular basement membrane and

lamina densa in infants and children: an ultrastructural evaluation. *Pediatr Pathol* 1987;7:527â€“534.

The continuous cuboidal layer of cells is transient as the maturing podocytes flatten over the surfaces of the developing capillaries. A few small clusters of cuboidal podocytes remain in infant glomeruli (Figure 34.22 Bâ€“C). After a glomerulus has been in existence for more than 12 months, remnants of the cuboidal layer are usually not seen in normally developed glomeruli. In 1940, Gruenwald and Popper suggested that some podocytes may be sloughed into Bowman's space as part of the maturation process (214). In fact, several studies have demonstrated that podocytes are shed from the glomerulus and excreted in the urine in various glomerular diseases, as well as in healthy individuals (221 ,222). Moreover, most of the urinary podocytes are viable as evidenced by their ability to grow in culture under in vitro conditions. Whether podocyturia occurs in the normal neonate and infant remains to be established. The above podocyte alterations are coincident with the emergence of more conspicuous capillary loops (Figure 34.22 Câ€“D). Eventually, the capillary loops are arranged into lobules (Figure 34.22 Eâ€“F). However, an occasional glomerulus with the small size and immature appearance of a neonatal glomerulus may be observed in older infants, especially in the outer one-third of the cortex (Figure 34.25).

Glomerular growth during childhood has been evaluated in several investigations (223 ,224 ,225 ,226 ,227). In these studies, the source of renal tissue (postmortem or biopsy specimen), the observational technique (histology or microdissection), and the morphometric method varied. However, it is well established that glomerular size increases from birth into adolescence. Spouster and Emery (225) reported that the midcortical and juxtamedullary mean glomerular area in fetuses actually decreased between 12 and 20 weeks gestation. After this initial decrease, the

glomeruli remained at the same size until birth, after which they

steadily grew. Moore et al. (226) observed that the mean glomerular diameter in normal children increased from 112 to 167 Âµm between birth and 15 years of age, averaging 3.6 Âµm per year during this period. Akaoka et al. (227) found that the mean glomerular tuft area in children with minimal change nephrotic syndrome and recurrent hematuria, increased from 6,600 Âµm^2 to 11,000 Âµm^2 between 2 and 15 years of age. In the latter study, the glomerular capillary lumina area did not correlate with the glomerular tuft area, whereas the number of capillaries per glomerulus showed a positive correlation with the glomerular tuft area. Although some of the glomeruli were not normal in this study, the findings support the concept that glomerular growth occurs by an increase in the number or length of capillaries rather than by hemodynamic capillary dilatation.

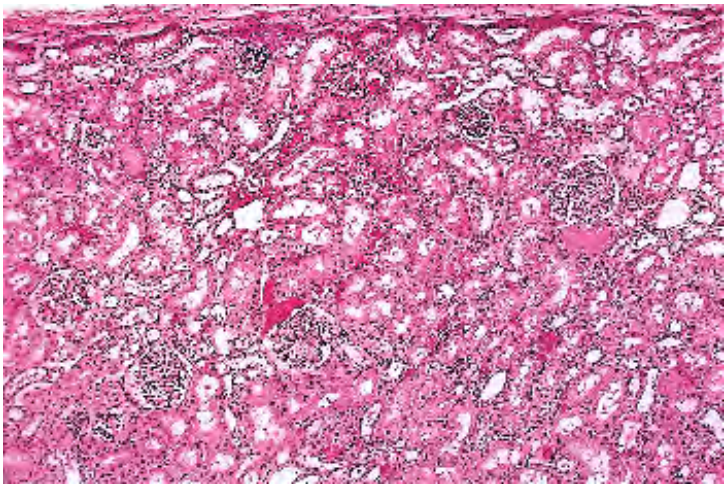

Figure 34.25 Persistent immature glomeruli at 12 months of age. Two miniature glomeruli with cuboidal cells at the periphery of the tuft are present near the renal capsule. Small numbers of defective glomeruli can be found in infant kidneys, but they are destined to undergo sclerosis and involution.

Juxtamedullary glomeruli are larger than superficial glomeruli at birth and during infancy. However, some uncertainty exists regarding these regional differences in glomerular size in later childhood and young adults. Some authors have observed no size difference between

juxtamedullary and superficial glomeruli by the fourteenth to thirty-sixth postnatal month (223 ,225), whereas others have found a size difference persists until at least 15 years of age (224 ,226). Methodological differences in the studies or the wide variation in glomerular size existing among individuals (228) may account for these disparate findings.

Investigations using stereological methods have provided estimates for the number of cells in glomeruli. Steffes et al. (229) observed that the total number of cells per glomerulus increased along with the mean glomerular volume in comparing normal individuals younger than 20 years of age to those greater than 20 years. The number of endothelial cells and mesangial cells increased with age, whereas the number of podocytes remained unchanged with age. These results are consistent with the large amount of animal data indicating that mature podocytes are largely terminally differentiated and do not replicate. This concept is also supported by the expression pattern of cell cycle regulatory proteins during glomerulogenesis (230 ,231 ,232). The proliferation marker Ki-67 is expressed in podocyte precursors in comma- and S-shaped bodies, but its expression is markedly reduced in podocytes of the glomerular capillary loop stage. The cyclin-dependent kinase (CDK) inhibitors p27 and p57 are absent in the comma- and S-shaped bodies but expressed in maturing podocytes of the capillary loop stage, as well as in mature podocytes in adult kidneys. These findings suggest the CDK inhibitors are involved with arresting the cell cycle of podocytes at the capillary loop stage and maintaining the fully mature podocytes in a quiescent differentiated state.

Early Juxtamedullary Glomeruli

The maturational process in the very early generations of glomeruli may be accelerated because, even in very young fetuses, these juxtamedullary glomeruli rarely possess a cuboidal layer and are considerably larger than their immediate superficial neighbors. Attention was drawn to these large juxtamedullary glomeruli in humans

by Kampmeier, who noted that they subsequently disappeared, suggesting that they were transient structures (233). Tsuda observed in human fetuses that the diameter of juxtamedullary glomeruli were nearly twice that of superficial glomeruli as early as three months of gestation (199). Emery and Macdonald noted that the disappearance of these large glomeruli, in the early months after birth, was associated with the presence of scarred glomeruli in the same region (234). These findings support Kampmeier's suggestion that they represent a transient population of nephrons. It is presumed that these precociously formed glomeruli are functionally important during fetal life and likely undergo involution early in the postnatal period. Relatively little study has been made of these interesting structures.

Glomerulosclerosis in Infants

Glomerulosclerosis in infantile kidneys is commonly observed. In most cases, it is a presumably normal phenomenon that must be distinguished from the pathologic changes of glomerular disease. In 1909, Herxheimer concluded that sclerotic glomeruli usually represented defective development of glomeruli in otherwise normal kidneys and were not manifestations of a disease process (235). Other investigators have suggested this context of glomerulosclerosis might result from a vascular origin, excretion of toxic substances, or renal infection (236 ,237).

Emery and Macdonald conducted thorough studies of glomerulosclerosis in children's kidneys that were

considered morphologically within normal limits (234). Their series of 475 cases included kidneys from fetuses at 24 weeks of gestation to children 15 years of age. The percentage of sclerotic glomeruli in each kidney was most often in the range of 1 to 2% (65% of cases), although higher percentages from 3 to 10% affected glomeruli (30% of cases) were observed. The proportion of infants having sclerotic glomeruli was age dependent. Scarred glomeruli occurred in 25 to 40%

of kidneys from late fetuses and newborns. They were detected in 70% of kidneys by 2 months of age, remaining near this level throughout the first year. Afterwards, their incidence steadily declined and was about 10% of children at 6 years of age.

Emery and Macdonald found that sclerotic glomeruli localized to two areas; the deep inner cortex (juxtamedullary zone near the arcuate vessels) and the superficial outer cortex (near the capsule). Sclerotic glomeruli in the juxtamedullary zone were more common in the first six months of life than in older children. Affected glomeruli in the outer cortex were most prominent in the first two years after birth. The presence of scarred glomeruli in the juxtamedullary zone coincided with the disappearance of the large glomeruli seen in this region during the months after birth, as discussed previously. Thus, it appears the sclerosing glomeruli in the juxtamedullary zone represent the involution of the large glomeruli that localize to this zone during nephrogenesis. The glomerular scarring in the outer cortex near the capsule likely reflects a different etiologic process that, if linked to nephrogenesis, is probably occurring relatively late. In a study of 800 infant kidneys, Thomas reported a similar distribution pattern of sclerotic glomeruli in the cortex (238). The general consensus is that these lesions are defects of development but without functional or clinical significance. Their major significance for pathologists is that they not be interpreted as evidence of glomerular disease, unless their number is considerably above the usual range (greater than 20%) mentioned above.

A typical example of infantile glomerulosclerosis is illustrated in Figure 34.26 . The scarred glomeruli may occur singly or in small groups. They are usually smaller than normal, immature in appearance, and variably hyalinized. The afferent arteriole is often thickened, and periglomerular fibrosis may be present as well as some chronic inflammatory cells in the interstitium. In later stages, only a small globule of hyalin material in a small focus of sclerosis without capillary lumens may be seen. The tubules associated with the sclerotic glomeruli often contain proteinaceous material and apparently

disappear along with the glomeruli.

Ectopic Glomeruli

In the kidneys from fetuses and infants, glomeruli are often found outside the confines of the renal parenchyma, either in the renal sinus (Figure 34.27) or in the connective tissue around interlobar vessels. These *ectopic* glomeruli occur in several mammalian species as well as in young humans (239). They appear to degenerate during postnatal life and are not found in adult human kidneys. It has been suggested that some vessels supplying the pelvic mucosa and medulla may be derived from degenerated ectopic glomeruli (239 ,240). The ectopic glomeruli may represent the early large juxtamedullary glomeruli, described by Kampmeier, that have persisted at least until infancy rather than degenerate.

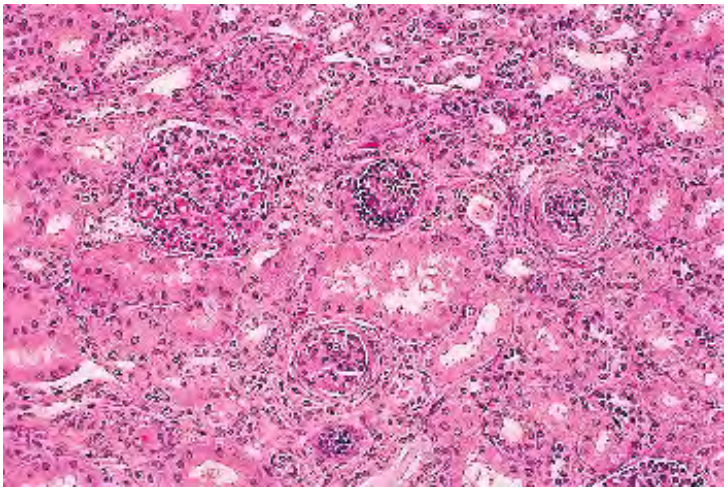

Figure 34.26 Infantile glomerulosclerosis at 9 months of age. One small, developmentally immature glomerulus is seen near the center, and two adjacent glomeruli are undergoing involutional sclerosis.

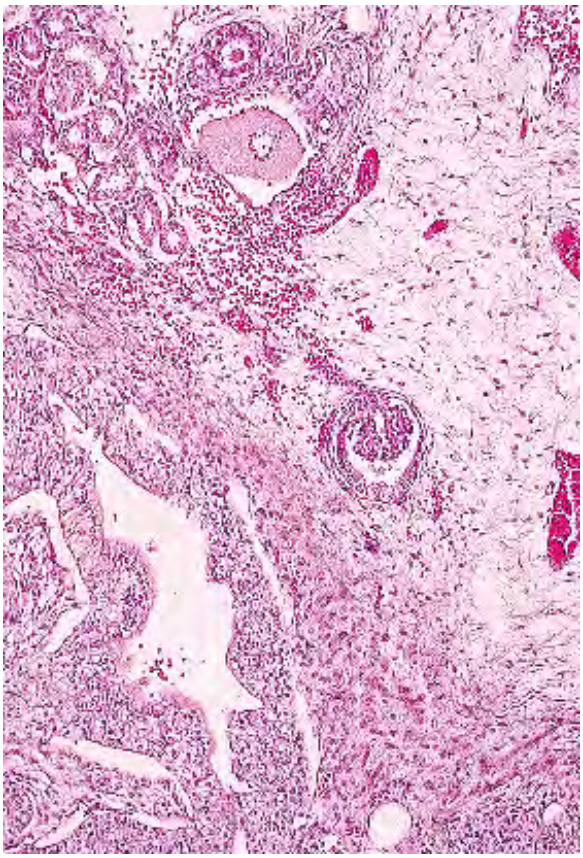

Figure 34.27 Ectopic glomerulus in the renal sinus.

Tubular Maturation and Growth

There is less known about the maturation and growth of tubules between birth and adulthood compared to glomeruli. Although all tubular segments increase in size during postnatal maturation, the proximal convoluted tubules undergo very prominent elongation and increased tortuosity (5). The results of microdissection studies reported from two laboratories were fairly similar (223 ,241). The mean lengths of proximal tubules observed were: about 2 mm at birth, 3.5 mm at 3 months, 6.5 mm at 1 year of age, 7.7 mm at 2 years, and 12.0 mm at 12 years. The mean proximal tubular length of 20 mm in adult kidney indicates that proximal tubule elongation continues through adolescence and young adulthood. Proximal tubules at birth

are less uniform in size than glomeruli. Proximal tubules in the outer cortex of the newborn kidney were observed to be the shortest, those in the midcortex intermediate in length, and those from the juxtamedullary cortex the longest, consistent with a centrifugal pattern of development (223). These regional differences in proximal tubules decreased significantly after 1 month of age and disappeared by 14 months. Whether tubular function, such as solute and volume reabsorption, of the maturing proximal tubules from different cortical regions also follows a centrifugal pattern of maturation remains uncertain (242). It is interesting that in the adult kidney, the proximal tubules from the outer cortex have been observed to be longer than those from the mid- and juxtamedullary cortex (223). The ratio of glomerular surface area to proximal tubular volume was proposed as a theoretical anatomic correlate of functional glomerulotubular balance, that is, the balance between the capacity of the glomerulus to filter and the tubule to reabsorb the filtrate (223). Values for this ratio (28 in the term newborn kidney, 13 in the 3-month kidney, 6 in the 6-month kidney, and 3 in the adult kidney) suggested morphologic dominance of glomeruli over tubules early in life until the tubules, in effect, â€œgrew up to their glomeruliâ€• (223). However, it is difficult to correlate these morphologic ratios with experimental functional data indicating proportionate increases in glomerular filtration rate (GFR) and proximal tubule reaborption after birth, consistent with maintenance of glomerulotubular balance during postnatal maturation (243).

During postnatal maturation, the loops of Henle undergo striking elongation (5). The newborn kidney lacks a well-formed inner medulla and contains loops of Henle that are relatively short (2 ,4 ,5). At birth, the loops of Henle are shortest in the younger nephrons, whereas longer loops belong to the older nephrons. As the kidney increases in size after birth, the loops of Henle elongate, the medullary interstitium increases, and the medulla becomes separated into outer and inner zones. From birth until full maturation, loops of Henle may increase in length as much as three-fold. In the mature kidney, the location of the

tips of the loops of Henle relates to the age of their associated nephrons. The loops of the last-formed nephrons (outer cortex) reach the junction between the outer and inner medulla and are known as short loops of Henle. In contrast, the loops of the earliest formed nephrons (juxtamedullary cortex) extend deep into the inner medulla near the tip of the papilla and are referred to as long loops of Henle. Prior to birth, thin portions of loops of Henle are only observed in the long loops of Henle. These thin portions are present in the *descending* limbs of the long loops of Henle and continue to lengthen after birth. *Descending* thin limbs are not seen in short loops of Henle until after birth. Only long loops of Henle develop *ascending* thin limbs, which are derived from the thick ascending limbs, likely by an ascending process of apoptotic remodeling (55 ,244).

Adult Kidney

Gross Anatomy

The kidneys lie within the retroperitoneum and extend from the twelfth thoracic (T12) to the third lumbar (L3) vertebrae, with the right kidney usually slightly more caudad. They are situated within the perirenal space, which contains abundant fat and is traversed by fine fibrous septae (245 ,246 ,247). Visualization of the renal fascia with radiologic procedures has been reported in normal individuals (248 ,249). Each kidney weighs 125 to 170 grams in men and 115 to 155 grams in women (250). If differences in body build are considered, kidney weight correlates best with body surface area, whereas age, sex, and race have less influence (251). Each kidney is 11 to 12 cm in length, 5 to 7.5 cm in width, and 2.5 to 3 cm in thickness. The left kidney tends to be slightly larger and may demonstrate irregularities of the lateral contour from compression by the spleen in up to 10% of normal individuals (252). A glistening tough fibroelastic capsule surrounds the kidney.

In the hilar region, the main renal artery branches to form anterior and

posterior divisions (Figure 34.28), which in turn divide into segmental arteries that supply the apical, upper, middle, lower, and posterior segmental regions of the parenchyma (253 ,254). No collateral circulation has been demonstrated between the segmental arteries. Some of the so-called accessory arteries actually represent normal segmental arteries with an early origin from the main-stem renal artery or aorta (254). Therefore, ligation of such a segmental artery in the belief that it is an accessory vessel results in necrosis of the corresponding parenchymal segment. The intrarenal veins do not follow a segmental distribution, and there are numerous anastomoses of the veins throughout the kidney. There are variable drainage patterns of the large extra-renal veins that join to form the main renal vein (255). A relatively common occurrence is a posterior primary venous tributary, whose retropelvic

position should be remembered during renal surgical intervention. An outer pale region (the cortex) and an inner darker region (the medulla) can be distinguished on the cut surface of a bisected kidney. The presence of glomeruli and convoluted tubules results in the cortex having a more granular appearance.

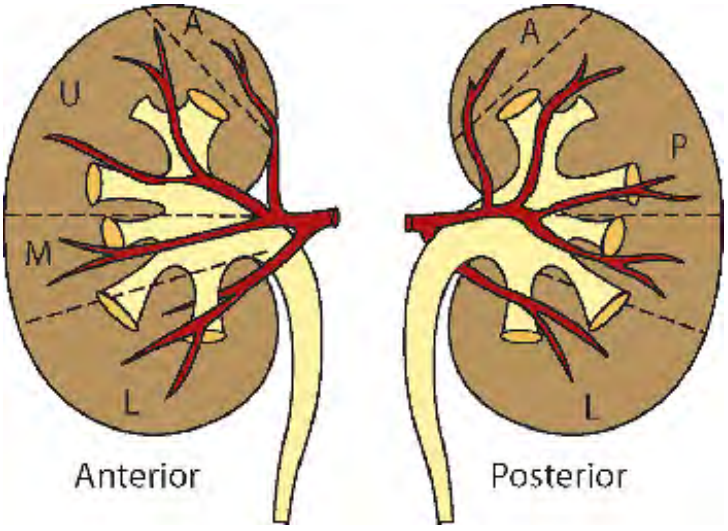

Figure 34.28 Diagram of the vascular supply of the human kidney. The anterior division of the renal artery divides into three segmental

branches that supply the upper (*U*) and middle (*M*) segments of the anterior surface and most of the lower (*L*) segment. The small apical (*A*) segment is usually supplied by a branch from the anterior division. The posterior division of the renal artery supplies the posterior (*P*) segment, which represents more than half of the posterior surface of the kidney. Modified with permission from:
Graves FT. The anatomy of the intrarenal arteries and its application to segmental resection of the kidney. *Br J Surg* 1954;42:132â€“139.

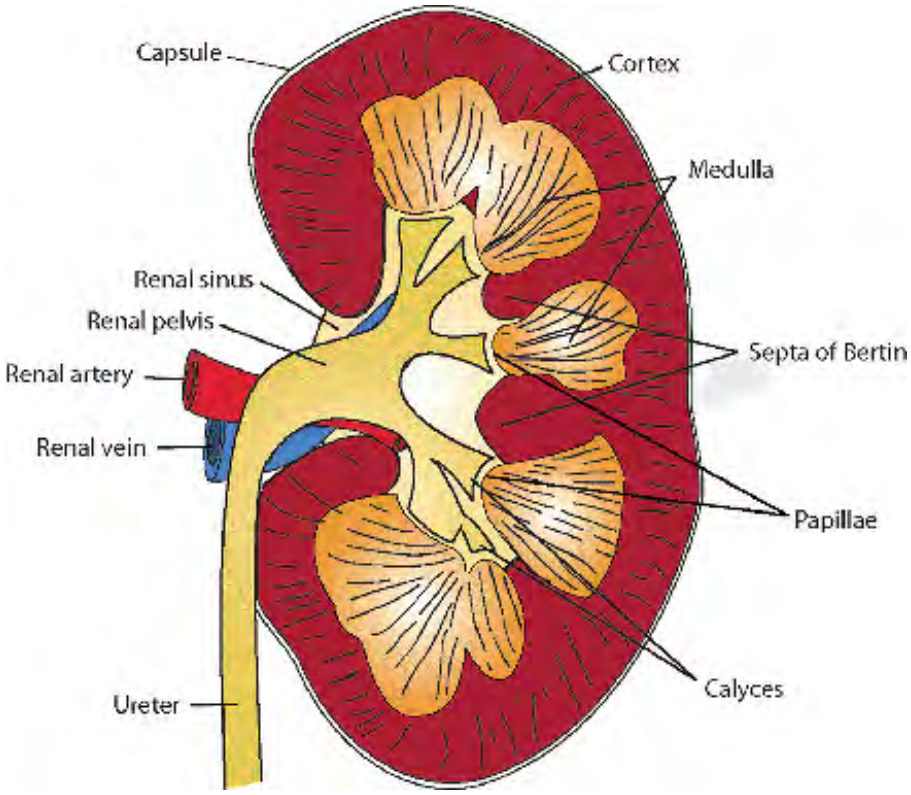

Figure 34.29 Diagram of a bisected kidney illustrating major anatomic structures.

The human kidney is a multipapillary type of mammalian kidney (256), with the medulla divided into 8 to 18 striated conical masses called pyramids (Figure 34.29). The striated appearance reflects the parallel linear orientation of the loops of Henle and collecting ducts. The base of each pyramid is located at the corticomedullary junction, whereas

the apex extends toward the renal pelvis, forming a papilla. The tip of each papilla is perforated by 20 to 70 small openings (6) that represent the distal ends of the collecting ducts (of Bellini). The cortex is about 1 cm in thickness, encircles the base of each pyramid, and extends downward between pyramids to form the septa (columns) of Bertin. Despite well-described radiologic features (257 ,258), an enlarged septum of Bertin on occasion has been clinically mistaken for a renal tumor. Longitudinal striations extending from the base of the pyramids out into the cortex are termed the medullary rays (of Ferrein). Regardless of their name, they are actually part of the cortex and are formed by the straight segments of the proximal tubules (PSTs), the thick ascending limbs (TALs), and the collecting ducts. The medullary rays may be visualized during excretory urography in conditions with tubular fluid stasis (259).

A single pyramid with its surrounding cortical parenchyma constitutes a renal lobe (191 ,260) (Figure 34.30). The human kidney has an average of 14 lobes (102). During development, variable lobar fusion leads to coalescence of some papillae and remodeling of the corresponding calyces, gradually reducing the number of papillae and calyces. The mean number of calyces and papillae

reported is 9 and 11, respectively (193). There is a greater degree of lobar fusion in the polar regions than in the midpolar region of the kidney. A degree of persistent fetal lobation may be observed in some adult kidneys.

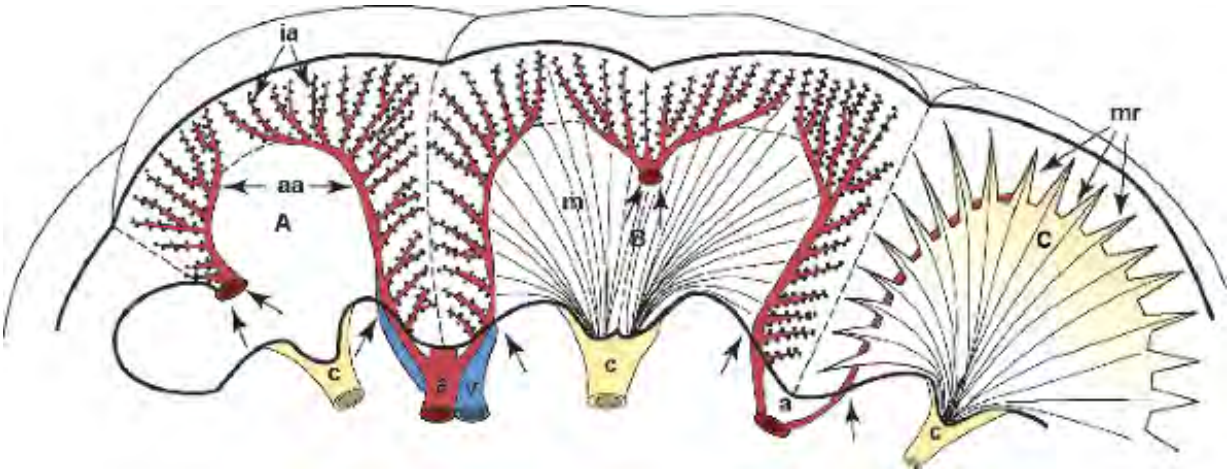

Figure 34.30 Diagram of three renal lobes. A. Arcuate (*aa*) and interlobular (*ia*) arteries. B. Cortex and medulla (*m*) are illustrated in a double lobe with fused double papillae. C. Lobe showing medullary rays (*mr*). A septum of Bertin represents the approximation of two layers of septal cortex from two adjacent lobes. (*Small double arrows* in A and B, subsidiary septal arteries; *single arrows,* location where arcuate vessels enter the renal parenchyma; *a,* interlobar arteries; *v,* interlobar vein; *c,* calyces). Modified with permission from: Hodson CJ. The renal parenchyma and its blood supply. *Curr Probl Diagn Radiol* 1978; 7:1â€“32.

There are two main types of renal papillae (261). Simple papillae drain only one lobe and have convex tips containing small, often slitlike orifices. Compound papillae drain two or more adjacent fused lobes and have flattened, ridged, or concave tips with round, often gaping orifices. The distribution of papillae types within the kidney is related to the embryologic pattern of fusion involving the lobes, papillae, and calyces (Figure 34.31). It is believed that the more open orifices of compound papillae are less capable of preventing intrarenal reflux (262), which may be associated with an increase in intrapelvic pressure. This concept is supported by the observation that pyelonephritic scars associated with intrarenal reflux are present more commonly in the renal poles, where the compound papillae predominantly occur.

The renal pelvis is the saclike expansion of the upper ureter. Two or

three outpouchings or major calyces (infundibula) extend from the pelvis and divide into the minor calyces, into which the papillae protrude. In addition, elaborate leaflike extensions, termed fornices, extend from the minor calyces into the medulla, and secondary pouches increase the pelvic surface area (263).

The renal sinus is located on the medial or concave aspect of each kidney (Figure 34.32) (264 ,265). It contains the renal pelvis, the major renal arteries and veins, the lymphatics, and neural structures that supply the kidney. The renal hilus is the entry into the sinus. Fat fills the renal sinus

and is contiguous with the perirenal fat. Within the renal sinus, the renal capsule does not enclose the cortical parenchymal surface. Beckwith called attention to the importance of the renal sinus as a pathway for tumor dissemination in Wilms' tumor (266), and this has also been shown in renal cell carcinomas (267 ,268). A detailed description of the gross anatomy of the kidney is provided elsewhere (9).

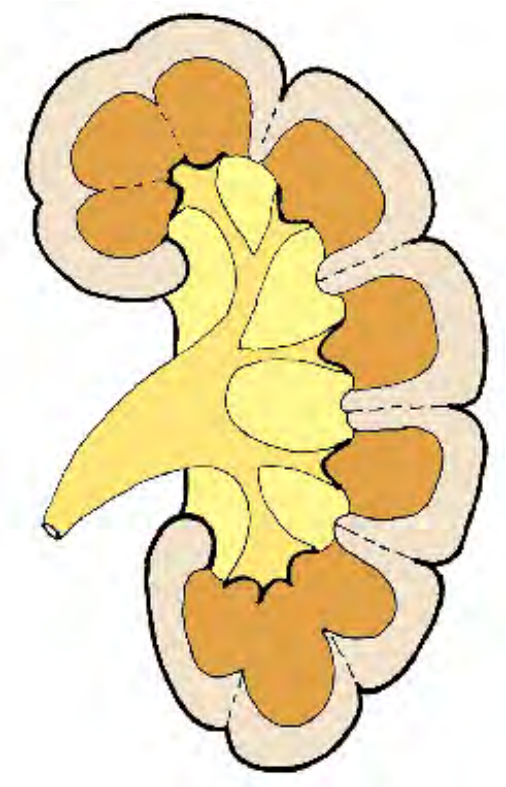

Figure 34.31 Schematic representation of the lobar architecture. In the polar regions, there is a greater degree of lobe fusion, resulting in the formation of compound papillae and calyces and the loss of septal cortex. The individual lobes tend to be retained in the midpolar region, and the septal cortex extends between renal pyramids, as septa of Bertin, to the renal sinus. Modified with permission from:
Hodson CJ. The renal parenchyma and its blood supply. *Curr Probl Diagn Radiol* 1978; 7:1â€“32.

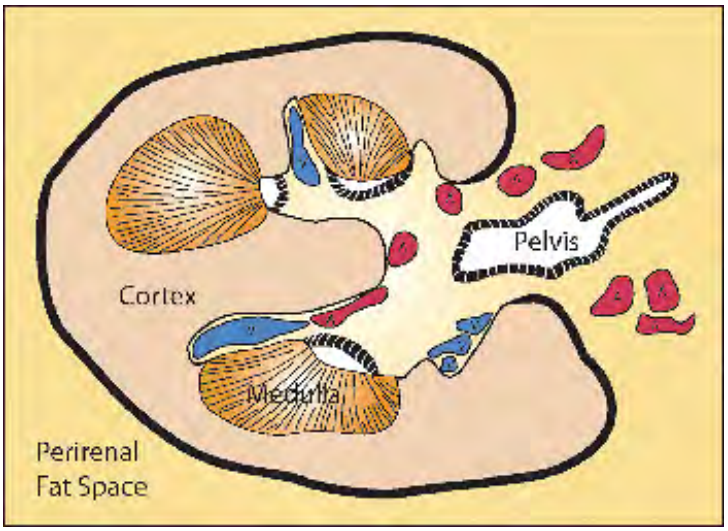

Figure 34.32 Diagram of kidney cross section, showing the renal sinus which is filled with fat (yellow). The renal sinus contains the pelvic-calyceal system and the major renal vessels. The renal capsule (thick black line) surrounds the convex surface of the kidney but disappears from the cortical surface as the latter enters the renal sinus. The cortical surfaces, including the septa of Bertin, facing the renal sinus lack a capsule. The capsule surrounding the pelvic-calyceal system is indicated by a cross-hatched thick black line. The capsule covering the calyces, appears to extend over the medullary pyramids on cross section, and it envelopes the renal pelvis as well. Modified with permission from:

Nephron

The structural and functional unit of the kidney is the nephron, which consists of the renal corpuscle (glomerulus and Bowman's capsule), proximal tubule, thin limbs, and distal tubule, all of which originate from the metanephric blastema. The total number of nephrons in a human kidney varies markedly among normal individuals (209 ,210

,211). Although a tenfold variation in nephron number has been reported, the usual range is about 600,000 to 1,200,000 nephrons per kidney. Nephrons can be classified according to the position of their glomeruli in the cortex or the length of their loop of Henle (Figure 34.33). In the former scheme, superficial, midcortical, and juxtamedullary nephrons are distinguished. Superficial nephrons have glomeruli located in the outer cortex, and their efferent arterioles usually ascend to the cortical surface. The glomeruli of juxtamedullary nephrons are located immediately above the corticomedullary junction in the inner cortex, and their efferent arterioles form the descending vasa recta. The glomeruli of midcortical nephrons are situated in the midcortex above the juxtamedullary region but below the superficial nephrons.

In the more commonly used classification, there are two main populations of nephrons: those with a short loop of Henle and those with a long loop. The length of the loop of

Henle is generally related to the location of its parent glomerulus in the cortex. The short loops form their bend at various levels within the inner stripe of the outer medulla, whereas the long loops of Henle enter and turn back within the inner medulla. Although there are numerous gradations between these two main types of nephrons, there are seven times more short than long loop nephrons in human kidneys (269). A correlation between the urinary concentrating ability and the relative length of the medulla has been established in several mammalian kidneys (270).

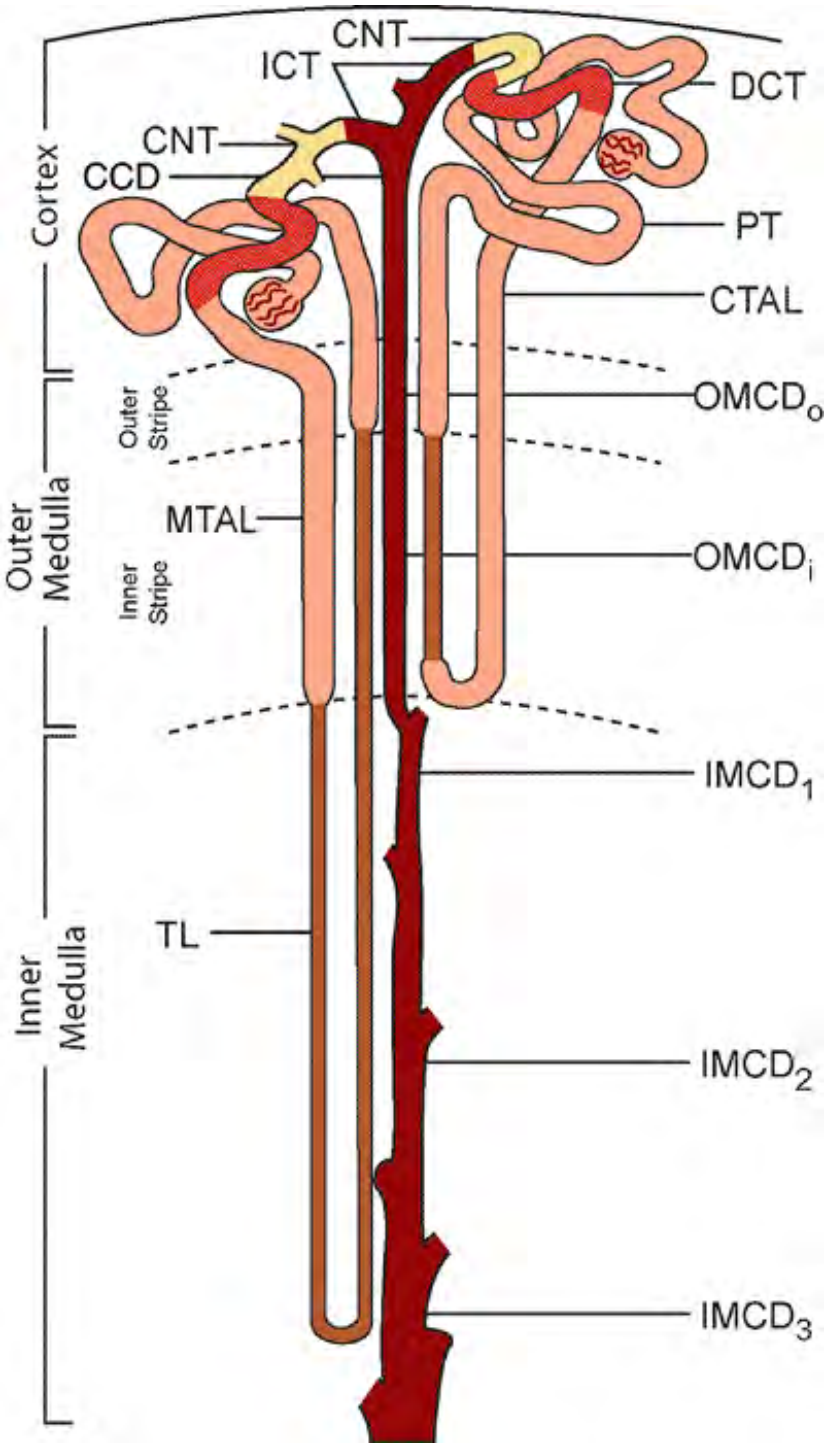

Figure 34.33 Diagram illustrating the segments of the nephron and the zones of the kidney. (*PT,* proximal tubule; *TL,* thin limb of Henle's loop; MTAL, medullary thick ascending limb; CTAL, cortical thick ascending limb; DCT, distal convoluted tubule; CNT, connecting tubule; ICT, initial collecting tubule; CCD, cortical collecting duct; *OMCD$_o$* ,

collecting duct in outer stripe of outer medulla; $OMCD_i$, collecting duct in inner stripe of outer medulla; $IMCD_1$, outer third of inner medullary collecting duct; $IMCD_2$, middle third of inner medullary collecting duct; $IMCD_3$, inner third of inner medullary collecting duct. Modified with permission from:
Madsen KM, Tisher CC. Structural-functional relationships along the distal nephron. *Am J Physiol* 1986;250(pt 2):F1â€“F15.

The connecting tubule, a transitional segment, joins the nephron to the collecting duct system, which originates from the ureteric bud. Although not correct in a strict anatomic sense, for practical considerations, the term *nephron* is commonly used to include the connecting segment and entire collecting duct. The collecting duct system can be divided into the cortical, outer medullary, and inner medullary collecting ducts (271 ,272). Structural and functional heterogeneity exist along the nephron (273). Internephron heterogeneity refers to the differences between analogous segments in superficial and juxtamedullary nephrons. Intranephron or axial heterogeneity may be defined as the differences between early and successive later portions of an individual nephron segment.

Architecture

The renal cortex can be divided into lobules. A renal lobule consists of a centrally positioned medullary ray and its surrounding cortical parenchyma, containing all nephrons draining into the collecting ducts of the medullary ray. In contrast to lobules of other organs, renal lobules are not distinctly separated by fine connective tissue septa; therefore, they are difficult to distinguish histologically. Furthermore, because it has been difficult to establish any structural-functional significance, the concept of the renal lobule is not commonly used.

The nephron segments and blood vessels in the cortex and medulla have a specific geometric arrangement (274). This intricate architecture allows integration (axial) of complex transport functions

along the length of a specific nephron segment, as well as integration (regional) between different nephron segments in a specific region or zone (275).

Two architectural regions of the renal cortex can be distinguished: the cortical labyrinth and the medullary rays (Figure 34.34). The cortical labyrinth represents a continuous parenchymal zone that surrounds the regularly distributed medullary rays. Glomeruli, proximal and distal convoluted tubules, interlobular vessels (also termed cortical radial vessels), and a rich capillary network are situated in the cortical labyrinth. The large majority of convoluted tubular profiles are proximal tubules. Connecting tubules of juxtamedullary nephrons fuse and form so-called arcades, which are adjacent to the interlobular vessels within the cortical labyrinth. Individual nephrons with their interlobular vessels, glomeruli, and attached tubular segments, are difficult to distinguish in this complex topography by histology. The medullary rays (Figures 34.35 ,34.36) contain the proximal and distal straight tubules and collecting ducts, all of which enter into the medulla. The distal straight tubules are the thick ascending limbs. Within an individual medullary ray, the straight tubules of superficial nephrons are situated centrally, the straight tubules of midcortical nephrons are localized peripherally, and the collecting ducts occupy a position between the two groups. The straight tubules of juxtamedullary nephrons decend directly into the medulla without ever entering the medullary rays.

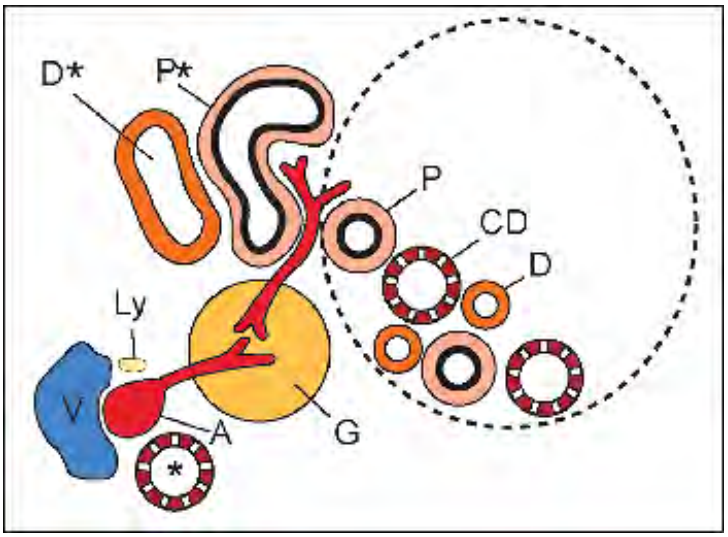

Figure 34.34 Diagram of architectural regions of the renal cortex. A medullary ray is encircled by the *dotted line* , and the cortical labyrinth is outside the *dotted line* . The proximal straight (*P*) and distal straight ascending limb (*D*) tubules and the collecting ducts (*CD*) are located in the medullary ray. The adjacent cortical labyrinth contains the interlobular vessels: arteries (*A*), veins (*V*), and lymphatics (*Ly*); arcades (*) of connecting tubules; glomeruli (*G*); and the proximal (*P**) and distal (*D**) convoluted tubules. Modified with permission from: Kriz W, Kaissling B. Structural organization of the mammalian kidney. In: Seldin DW, Giebisch D, eds. *The Kidney: Physiology and Pathophysiology* . 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:587â€“654.

The localization of specific segments of the nephrons at various levels in the medulla account for the division of the medulla into an outer and inner zone, with the former subdivided into an inner and outer stripe (Figure 34.33). The relative tissue volumes for the cortex and the outer and inner medulla are 70, 27, and *3* % respectively (272).

The outer stripe of the outer medulla is relatively thin. It contains the terminal portions of the proximal straight tubules, the thick ascending limbs, and the collecting ducts. The outer stripe is also distinguished by the absence of thin limbs of Henle. Glomeruli are not present in the

medulla. In contrast to the outer stripe, the inner stripe of the outer medulla is thicker. It contains thin descending limbs, thick ascending limbs, and collecting ducts. It is further characterized by the absence of the proximal straight tubules. Aggregations of descending and ascending vasa recta, known as vascular bundles, develop in the

outer stripe but are located predominantly in the inner stripe. Compared with the kidneys of some mammals with very high urine concentrating ability, the human kidney has a simple medulla (274). In contrast to the complex medulla, the vascular bundles of the simple medulla do not fuse to form larger vascular structures, and they do not incorporate the descending thin limbs of short loops (Figure 34.37). The inner medulla contains the thin descending and thin ascending limbs of long loops, as well as the collecting ducts. Thick ascending limbs are absent in the inner medulla.

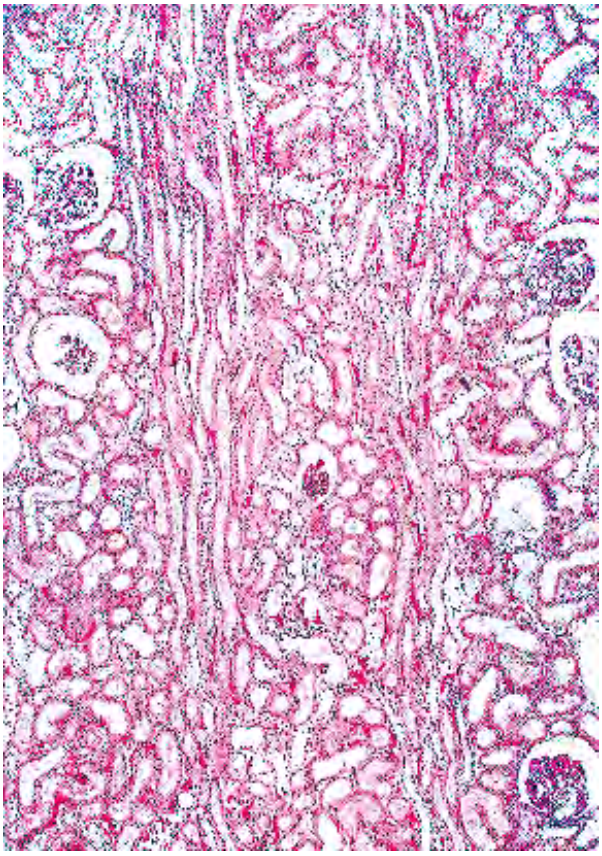

Figure 34.35 Longitudinal section of cortex demonstrating two linear

aggregates of tubules representing medullary rays (original magnification Ã—50).

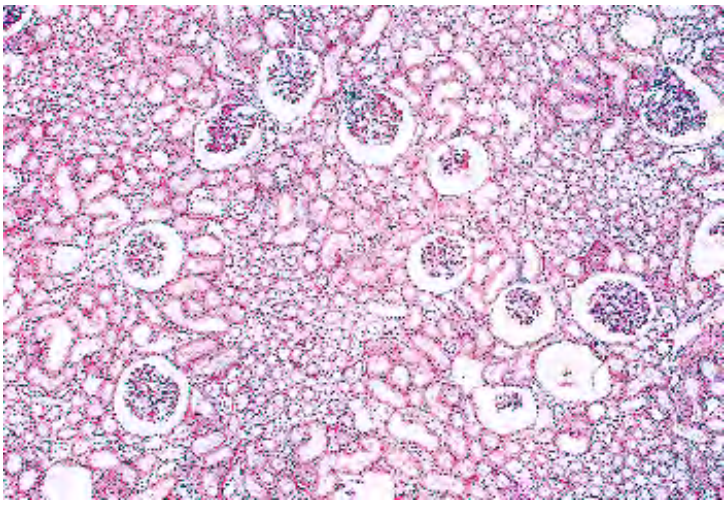

Figure 34.36 Cross section of cortex illustrating medullary rays that are regularly distributed within the cortical labyrinth (original magnification Ã—50).

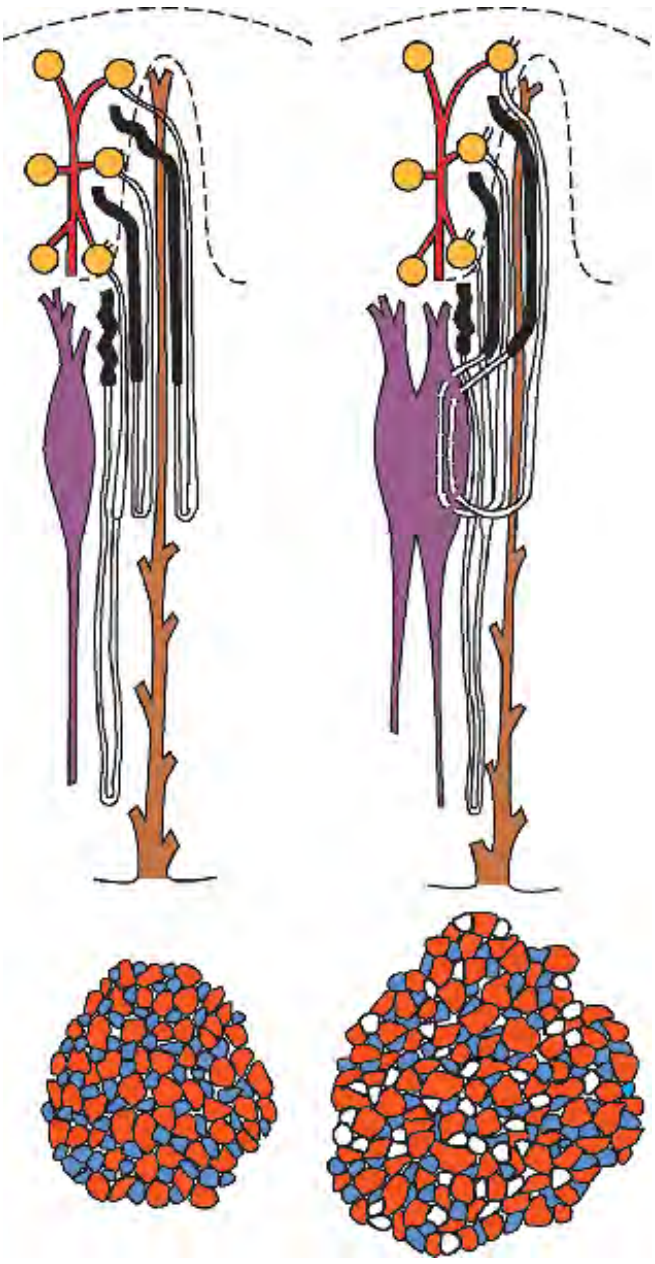

Figure 34.37 Schematic diagram demonstrating the simple and complex types of medulla. Upper left : In the simple medulla, the loops of Henle remain separate from the vascular bundle (purple). The vascular bundle itself (lower left cross section) contains only descending (red) and ascending (blue) vasa recta. Upper right : In the complex medulla, the descending thin limbs (DTLs) of short loops of Henle descend within the vascular bundles (purple), which tend to fuse. Therefore, the complex bundles (lower right cross section) contain the DTLs of short loops (white) in addition to descending (red)

and ascending (blue) vasa recta. Modified with permission from: Jamison RL, Kriz W. *Urinary Concentrating Mechanism: Structure and Function* . New York: Oxford University Press;1982.

Parenchyma

An accurate morphologic evaluation of the kidney requires a detailed systematic examination of the glomeruli, tubules, interstitium, and blood vessels of the renal

parenchyma. A standard nomenclature for structures of the kidney exists (276). A detailed approach to the histopathologic evaluation of the kidney has been described (277), and technical guidelines for handling the renal biopsy are available (278 ,279). The following discussion emphasizes normal morphologic aspects and structural-functional relationships in the kidney. The reader is directed to detailed discussions for more information (274 ,280).

Glomerulus

Overview

In 1666, Malpighi first described the glomeruli and demonstrated their continuity with the renal vasculature (281 ,282). About 175 years later, Bowman elucidated in detail the capillary architecture of the glomerulus and the continuity between its surrounding capsule and the proximal tubule (283 ,284). The renal corpuscle consists of a tuft of interconnected capillaries and an enclosing capsule named after Bowman. The term *glomerulus* is commonly used to refer to the glomerular capillary tuft and Bowman's capsule, although the term *renal corpuscle* is more accurate in a strict anatomic sense. The glomerulus does not simply represent a ball of capillaries. Providing structural support for the capillary tuft is a central region termed the mesangium, which contains cells and their surrounding matrix material.

The capillaries are lined by a thin layer of endothelial cells, contain a basement membrane, and are covered by epithelial cells (also called podocytes) that form the visceral layer of Bowman's capsule. The parietal epithelium is continuous with the visceral epithelium at the vascular pole where the afferent arteriole enters the glomerulus and the efferent arteriole exits. The glomerulus somewhat resembles a blind-pouched extension (Bowman's capsule) of the proximal tubule invaginated by a tuft of capillaries (Figure 34.38) (285). The cavity situated between the two epithelial layers of Bowman's capsule is called Bowman's space, or the urinary space. At the urinary pole, this space and the parietal layer of Bowman's capsule continue into the lumen and epithelium of the proximal tubule. The glomerular tuft originates from the afferent arteriole, which enters the glomerulus at the vascular pole and divides into several lobules. Anastomoses are believed to exist between individual capillaries within a lobule, as well as between lobules (274 ,286 ,287).

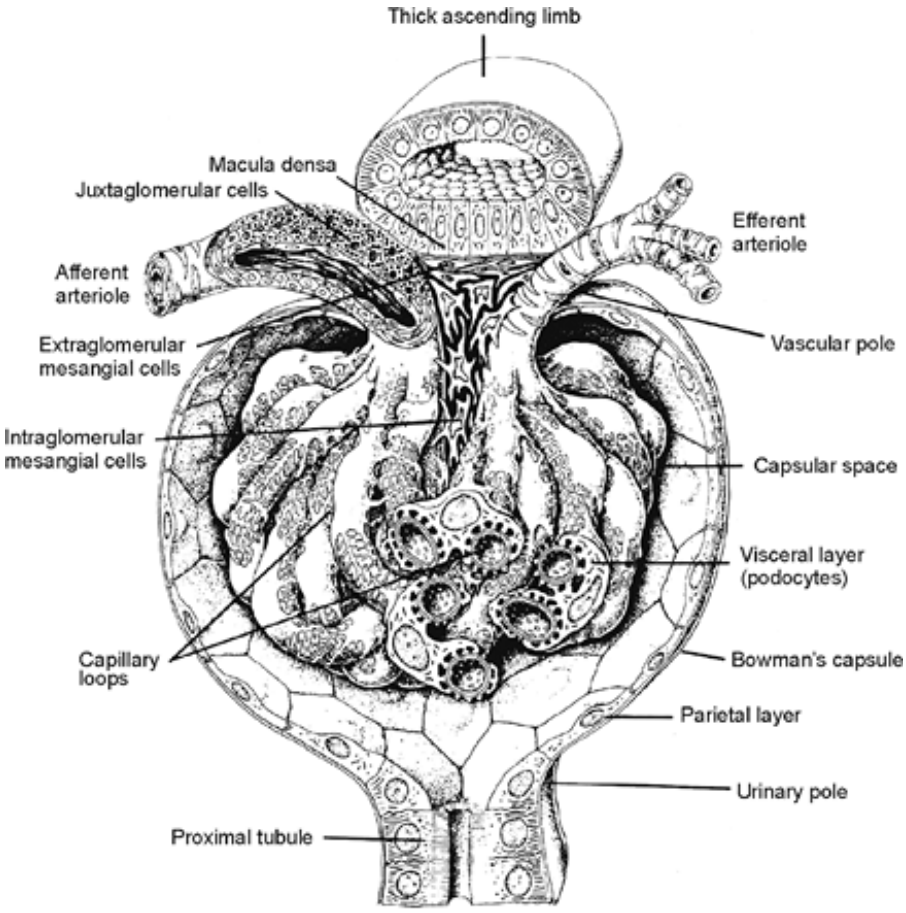

Figure 34.38 Schematic three-dimensional representation of the glomerulus. Modified with permission from:
Geneser F. *Textbook of Histology* . Philadelphia: Lea & Febiger; 1986.

The efferent arteriole is formed by rejoined capillaries and leaves the glomerulus at the vascular pole. In contrast to the afferent arteriole, the efferent arteriole has a more continuous intraglomerular segment. The glomerulus is responsible for the ultrafiltration of plasma. The glomerular filtration barrier consists of the fenestrated endothelium, the peripheral glomerular basement membrane (GBM), and the slit diaphragms between the podocyte foot processes.

The glomerulus has a round configuration and an average diameter of about 200 Âµm (274 ,280). Although the diameter of juxtamedullary glomeruli has been reported up to 20 to 50% greater than that of

superficial glomeruli (274), other researchers have found no significant size difference between these glomerular populations in the normal adult kidney (288). It has been reported that the glomeruli in solitary functioning kidneys are significantly larger than those in control patients with two kidneys (289). Although the glomerulus has a lobular architecture, the lobulation is often inconspicuous in light microscopic sections. An accentuated degree of lobulation may be more prominent in autopsy kidneys than in biopsy specimens (277). An apparent increase in the number of glomerular cells can be observed with an increased section thickness, therefore an accurate assessment of glomerular cellularity requires histologic sections 2 to 4 Âµm thick (Figure 34.39). Generally, the presence of more than three cells in a mesangial area away from the vascular pole constitutes hypercellularity. The delicate character of the glomerular capillary walls can be observed on thin histologic and frozen sections (Figure 34.40) (290).

Global glomerulosclerosis may occur as part of aging, without renal disease. The mean percentage of global glomerulosclerosis in normal kidneys was reported as follows: less than 1% between 1 and 20 years of age; 2% between 20 and 40 years; 7% between 40 and 60 years; and 11% between 60 and 80 years (291 ,292 ,293). There are no differences between the sexes in the development of glomerulosclerosis in aging humans (294). The 90th percentile for global glomerulosclerosis may be generally estimated for any age by subtracting 10 from half the patient's age (293).

Endothelial Cells

A thin fenestrated endothelium lines the glomerular capillaries. By light microscopy, the endothelial cells have light eosinophilic cytoplasm and slightly oval nuclei. Their nuclei are present within the capillary lumina. The endothelial cells are extremely attenuated around the capillary lumen, and the thicker portions of the cells containing the nuclei lie adjacent to the mesangium away from the urinary space. The

cytoplasm contains microtubules, microfilaments, and intermediate filaments (295). The attenuated portion of endothelial cytoplasm is perforated by fenestrae 70 to 100 nm in diameter (286). It has been argued that endothelial fenestrae do not simply arise from fusion of plasma membrane invaginations, called caveolae (296). It has been widely stated that glomerular endothelial fenestrae lack diaphragms, but thin bridging diaphragms have been observed when certain methods of fixation are used (297). The endothelial cell surface carries a negative charge because of the presence of polyanionic glycoproteins, including podocalyxin, a major sialoprotein of glomerular endothelial cells and podocytes (298 ,299). Results from recent studies have suggested that glomerular endothelial cells have a glycocalyx surface layer about 60 nm thick, and this surface coat fills the fenestrae forming â€œsieve plugsâ€• (300 ,301). There is emerging evidence that the glomerular endothelial glycocalyx may be an important component of the glomerular filtration barrier (302 ,303). Vascular endothelial growth factor (VEGF), produced by podocytes, is an important regulator of glomerular endothelial cell function; VEGF induces fenestrae and increases permeability of endothelial cells, both in vivo and in vitro (304 ,305).

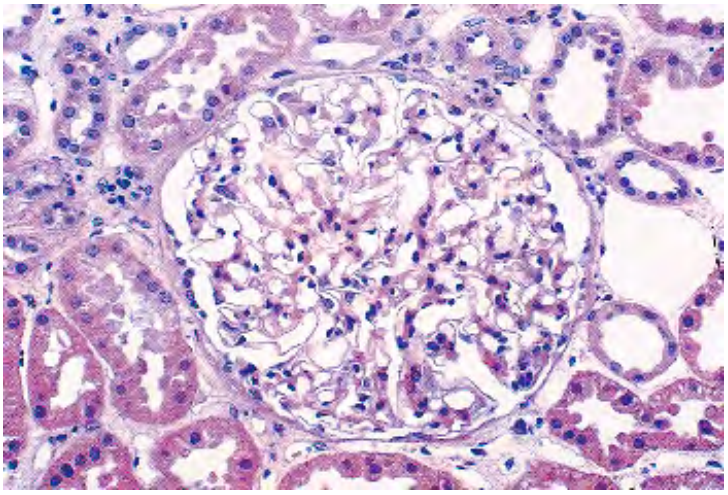

Figure 34.39 Glomerulus exhibiting round configuration and normal cellularity (original magnification Ã—250).

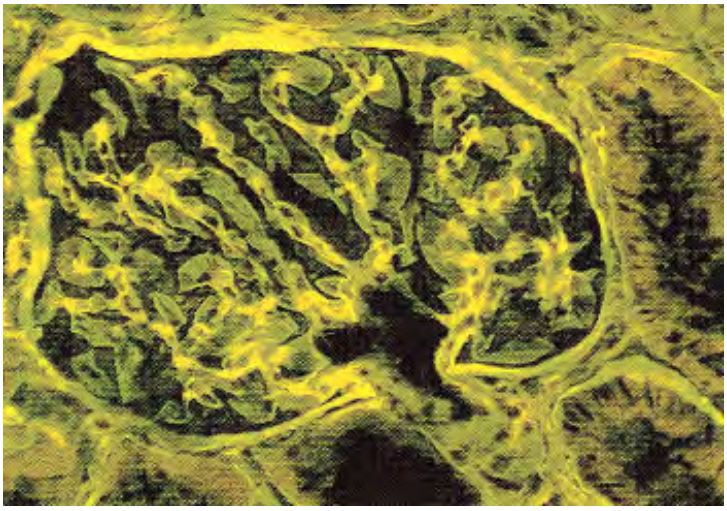

Figure 34.40 Fluorescent micrograph of an H&E-stained frozen section. Note the delicate character of the glomerular capillaries. (Courtesy of Dr. Stephen M. Bonsib.)

Current evidence indicates that maintenance of glomerular endothelial differentiation appears dependent on podocyte-derived VEGF (306). Glomerular endothelial cells synthesize nitric oxide (NO) and endothelin-1, a vasoconstrictor (307). There is strong expression of CD34 in glomerular endothelial cells (Figure 34.41).

Mesangial Cells

The mesangium, composed of mesangial cells and their surrounding matrix, is observed as a periodic acid-Schiff

(PAS)- and methenamine silver-positive structural support for the glomerular capillary loops (Figure 34.42). By light microscopy, the mesangial cells usually can be distinguished by their mesangial location and dark-staining nuclei. Ultrastructurally, they are irregular in shape and have elongated cytoplasmic processes that may extend between the endothelium and the glomerular basement membrane. The mesangial cell processes have microfilaments that contain actin, myosin, and Î±-actinin (308 ,309). With smooth muscle contractile properties, the mesangial cell has been proposed to be a specialized

pericyte that likely modulates glomerular filtration (310). Whereas the endothelium forms a continuous layer around the inner circumference of the glomerular capillary, the basement membrane and the visceral epithelial cell layer do not completely encircle the capillary but enclose the mesangial matrix and cells between the capillaries (Figure 34.43). The mesangial matrix is similar but not identical to the GBM and contains several types of collagen, as well as fibronectin and small proteoglycans. The matrix is especially rich in microfibrils, unbranched, noncollagenous structures that contain fibrillins and microfibril-associated glycoproteins (MAGPs) (311 ,312). The presence of microfibril-mediated attachments between mesangial cell processes and the GBM suggests that the mesangial cell and the GBM represent a biomechanical functional unit (313 ,314 ,315). It has been proposed that the contractile apparatus of the mesangium appears to maintain the structure of the capillary walls by counteracting the distention caused by the intracapillary hydraulic pressure (316). The mesangial cell also has phagocytic capability and plays a role in the clearance of macromolecules and debris from the mesangium (317). Mesangial cells can respond to, as well as generate, a variety of molecules, including interleukin-1, platelet-derived growth factor, and arachidonic acid metabolites, which may play a central role in the response to glomerular injury (318). It is recognized that a small subpopulation of cells in the mesangium are bone marrow-derived macrophages and play a role in immune responsiveness (Figure 34.44) (319 ,320 ,321). Occasional leukocytes are observed in the

normal glomerulus and label with leukocyte common antigen (CD45 and CD45RB) staining (322 ,323 ,324).

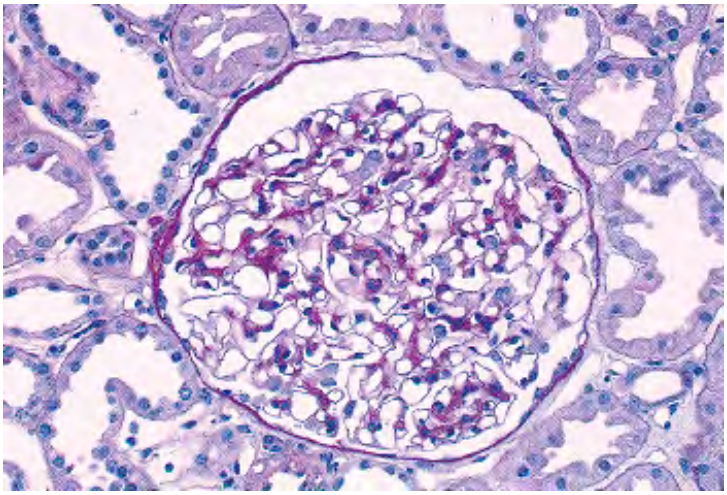

Figure 34.42 PAS-stained normal glomerulus illustrating the PAS-positive mesangium within the central regions of the glomerular capillaries (original magnification Ã—250).

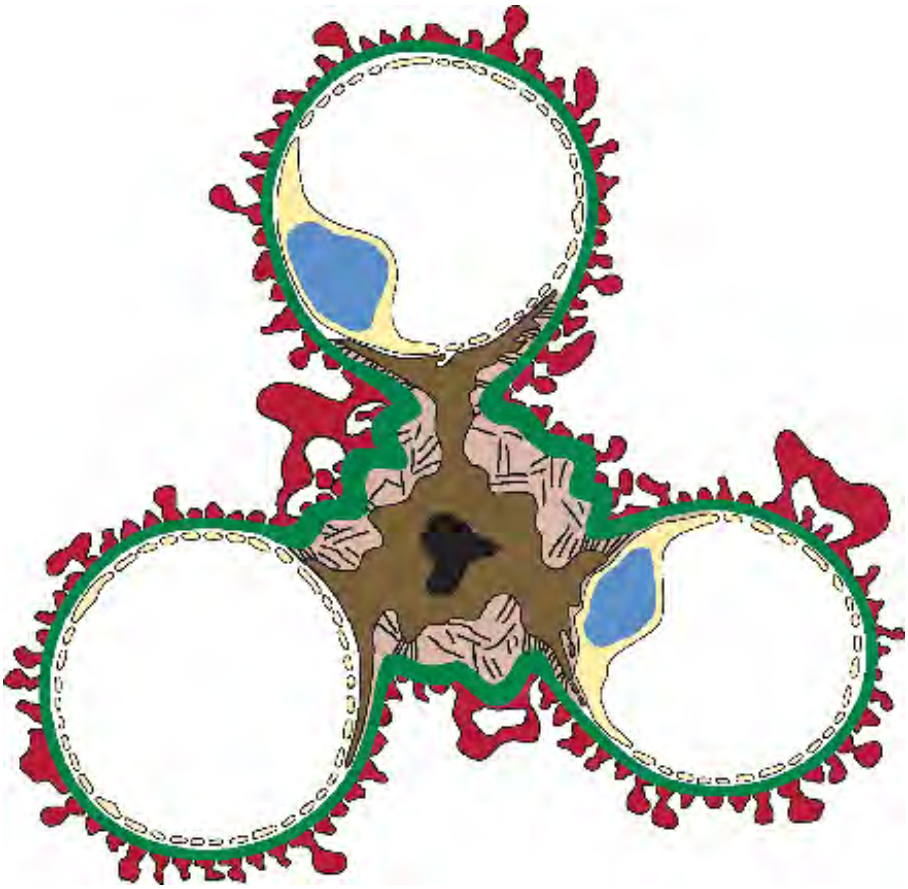

Figure 34.43 Schematic diagram illustrating the relationship between the mesangium and the glomerular capillaries. The visceral epithelial cell (podocyte) cytoplasm (red) and endothelial cell cytoplasm (yellow) are depicted. Note that the glomerular basement membrane (green) encloses the mesangium and its attached capillaries. The central mesangial cell is represented by dark brown cytoplasm and a black nucleus, and the mesangial matrix is represented by the tan fibrillar texture. The cytoplasmic processes of mesangial cells are connected to the glomerular basement membrane directly or indirectly by microfibrils in the mesangial matrix. Modified with permission from: Kriz W, Elger M, Lemley K, Sakai T. Structure of the glomerular mesangium: a biomechanical interpretation. *Kidney Int Suppl* 1990;30:S2â€“S9

.

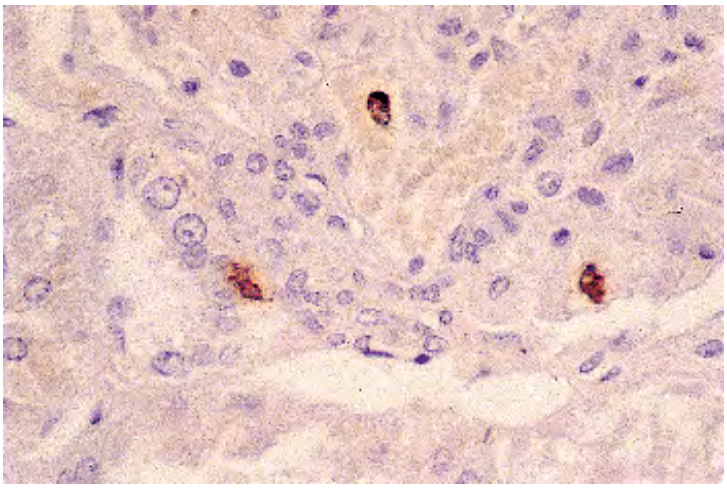

Figure 34.44 KP-1 immunohistochemical stain illustrating that a small percentage of cells in the mesangium label as tissue monocytes. (KP-1 immunoperoxidase, original magnification Ã—210.)

Interestingly, it has been demonstrated that mesangial cells residing in the extraglomerular mesangial region of the juxtaglomerular apparatus (JGA) may migrate and repopulate the intraglomerular mesangium upon glomerular injury (325).

Glomerular Basement Membrane

The glomerular basement membrane (GBM) can be demonstrated on light microscopy by PAS and methenamine silver stains (Figure 34.45). The silver preparation is more specific. Examination of a normal peripheral capillary loop away from the vascular pole and the mesangium shows a delicate basement membrane (Figure 34.46). Hematoxylin and eosin (H&E) and PAS preparations may stain capillary luminal contents and the cytoplasm of the endothelial and podocyte cell layers, resulting in an apparent thickening of the GBM. The basement membrane is situated between the endothelium and the podocytes in the glomerular capillary wall. On ultrastructural examination, the GBM consists of a central dense layer (the lamina densa) and two surrounding thinner electron-lucent layers (the lamina rara interna and the lamina rara externa). In comparison with

laboratory animals, the electron-lucent layers appear less prominent in the human glomerulus (Figure 34.47). This may be due in part to different fixation conditions.

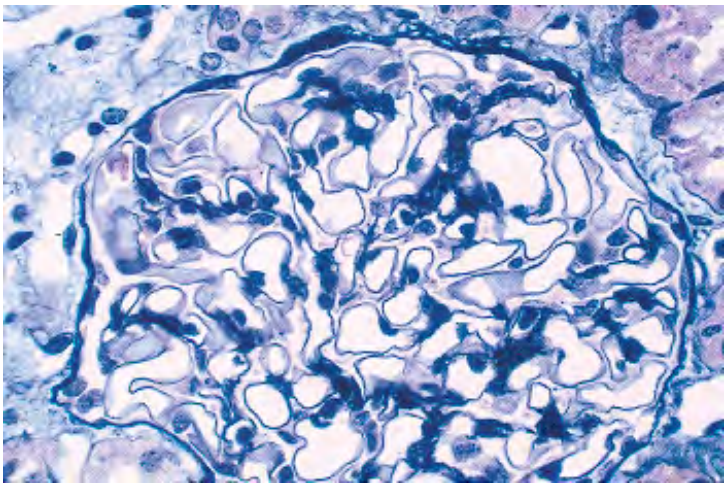

Figure 34.45 Silver methenamine-stained normal glomerulus illustrating the silver-positive glomerular basement membrane and positive basement membrane of Bowman's capsule (original magnification Ã—500).

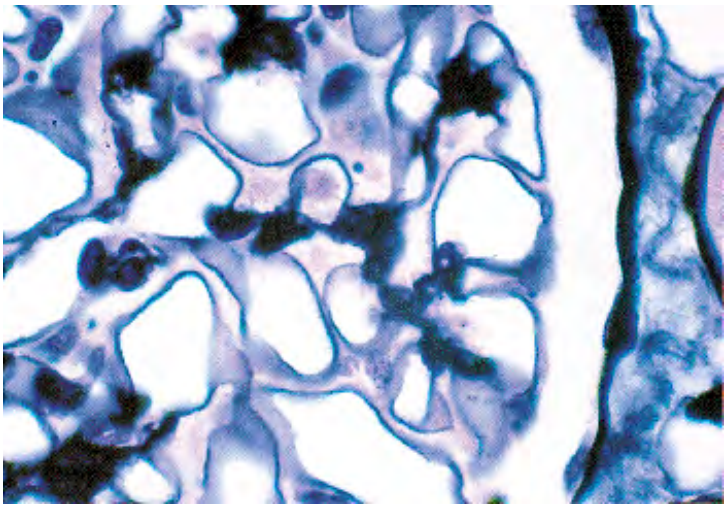

Figure 34.46 Higher magnification micrograph demonstrating thin regular glomerular basement membranes of peripheral capillary loops. (Silver methenamine stain, original magnification Ã—1250.)

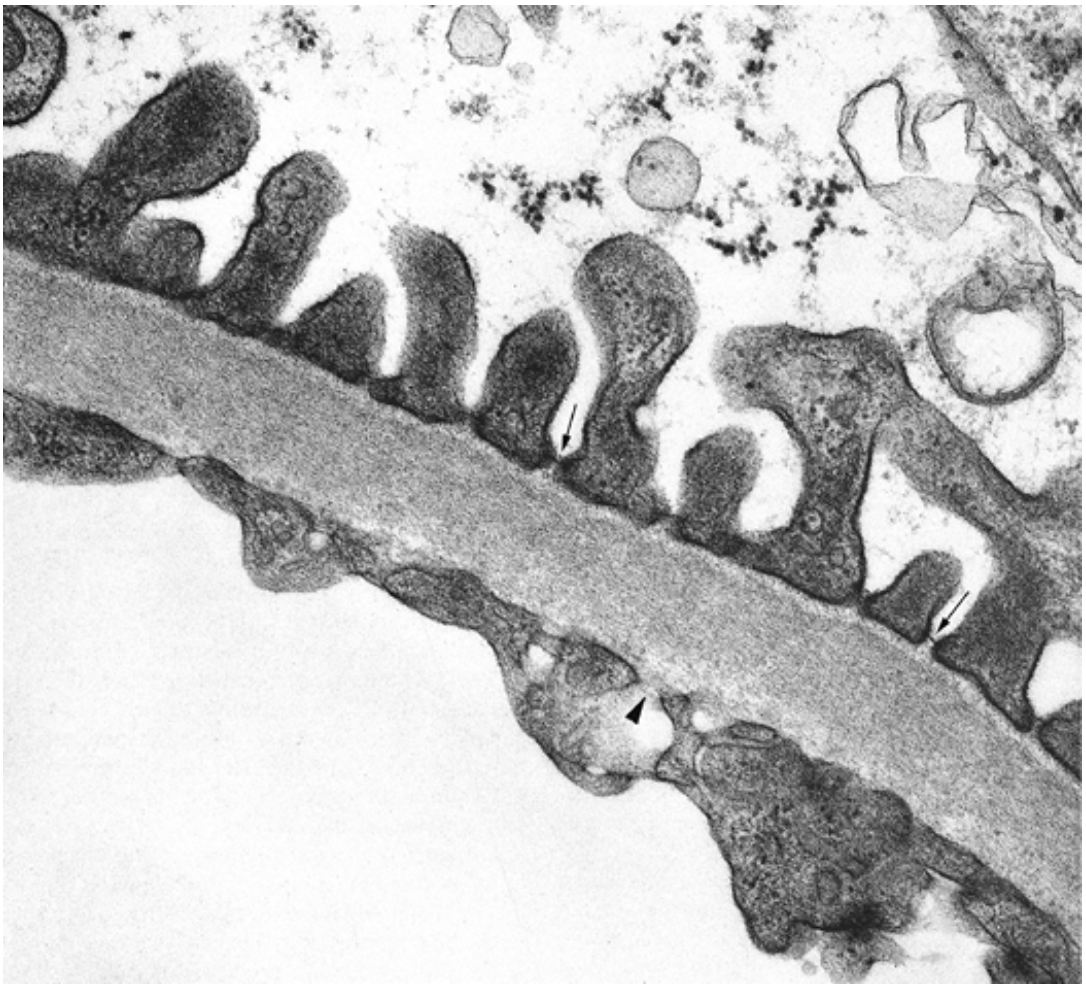

Figure 34.47 Transmission electron micrograph of a glomerulus. Bowman's space is above and the capillary lumen is below the glomerular capillary wall. A fenestra or pore (*arrowhead*) in the endothelium is evident. Note the regular alignment of the foot processes of the podocytes. Filtration slit diaphragms (*arrows*) are present between individual foot processes. The glomerular basement membrane consists primarily of the lamina densa. The electron-lucent lamina rara interna and lamina rara externa are not prominent (original magnification Ã—48,000).

The adult GBM ranges between 310 and 380 nm in mean thickness (326 ,327 ,328). It is significantly thicker in men (mean 373 nm) than

in women (mean 326 nm) and increases in width until the fourth decade of life (220). Quantitative data on the normal adult glomerular capillary structure include the following values: mean glomerular volume of 1.38 Ã— 10^6 Âµm^3 , average capillary diameter of 6.75 Âµm, and capillary filtration surface/glomerulus of 200 Ã— 10^3 Âµm^2 (329).

The major components of the GBM include type IV collagen, laminin, nidogen (also called entactin), and proteoglycans, including perlecan and agrin (26). Collagen IV is the major constituent of the GBM. Six chains, Î±1(IV) through Î±6(IV), make up the collagen IV protein family (330 ,331). Three chains of collagen IV self-associate to form triple-helical molecules called protomers. Despite many possible combinations, the six chains of collagen IV form only three types of protomers, which are designated as Î±1.Î±1.Î±2(IV), Î±3.Î±4.Î±5(IV), and Î±5.Î±5.Î±6(IV). The triple helical protomers unite at the noncollagenous domain (NC1) at the carboxy terminus to form hexamers, which in turn, assemble to form a polymerized network that serves as a scaffold for integration of other GBM components (330 ,331). Three canonical sets of hexamers form three distinct networks in basement membranes: the Î±1.Î±1.Î±2(IV)â€“Î±1.Î±1.Î±2(IV), the Î±3.Î±4.Î±5(IV)â€“Î±3.Î±4.Î±5(IV), and the Î±1.Î±1.Î±2(IV)â€“Î±5.Î±5.Î±6(IV) networks (332). The Î±3.Î±4.Î±5(IV)â€“Î±3.Î±4.Î±5(IV) network predominates in the adult GBM, and mutations of the genes encoding the Î±3, Î±4, and Î±5(IV) chains cause Alport syndrome (333). In Goodpasture syndrome, autoantibodies are targeted to the Î±3(IV) chain (333).

Laminins are heterotrimers composed of three chains; Î±, Î² and Î³. Laminin-11, containing the Î±5, Î²2, and Î³1 chains, is the major laminin isoform in the adult GBM (33). Nidogen/entactin binds to laminin and is present in the GBM (334). Proteoglycans consist of glycosaminoglycan (GAG) chains bound to a core protein (335). They are primarily responsible for the negative charge of the GBM (336 ,337). Of three heparan sulfate proteoglycans, agrin (338) and collagen type XVIII (339) are more abundant in the GBM than is perlecan (340

). Bamacan, a chondroitin sulfate proteoglycan, is present in the immature GBM but disappears from the adult GBM, remaining in the mesangial matrix (341).

Podocytes

The podocytes (visceral epithelial cells) are the largest cells in the glomerulus. By light microscopy, they are positioned on the outside of the glomerular capillary wall, often bulge into the urinary space, and have prominent nuclei and abundant light eosinophilic cytoplasm. Scanning electron microscopy shows that the podocytes have long cytoplasmic ramifications, the primary processes that surround the glomerular capillaries and divide into individual foot processes (Figure 34.48) (342). The foot processes cover the capillary wall, contact the lamina rara externa of the GBM, and interdigitate with foot processes from different podocytes. It is generally believed that the cell body and primary processes of the podocyte are not directly attached to the GBM and are suspended within Bowman's space. There is morphologic evidence for an even more complex cytoarchitecture of the podocyte. Neal et al. (343) demonstrated foot processes (termed anchoring processes) directly between the podocyte cell body and the GBM. Moreover, their study characterized three distinct compartments of Bowman's space. The subpodocyte space (SPS), first described by Gautier et al. in 1950 (344), exists as a restricted area under the podocyte cell body and is associated with a reported 60% of the glomerular filtration surface (343). The interpodocyte space (IPS) was characterized as a narrow anastomosing region interconnecting the subpodocyte space with the main peripheral Bowman's space (343). The physiologic role of these podocyte partitions of Bowman's space remains to be clarified. By transmission electron microscopy, the cells have abundant rough endoplasmic reticulum, a well-developed Golgi apparatus, and prominent lyosomes. There are numerous intermediate filaments, microtubules, and microfilaments in the cytoplasm (295). The intermediate filaments (vimentin, desmin) and microtubules predominate in the cell body and primary processes, whereas the foot

processes contain a dense microfilament contractile apparatus (345 ,346 ,347). The latter, containing actin, myosin, Î±-actinin, talin, and vinculin, connects to the intermediate filaments and microtubules of primary processes (348).

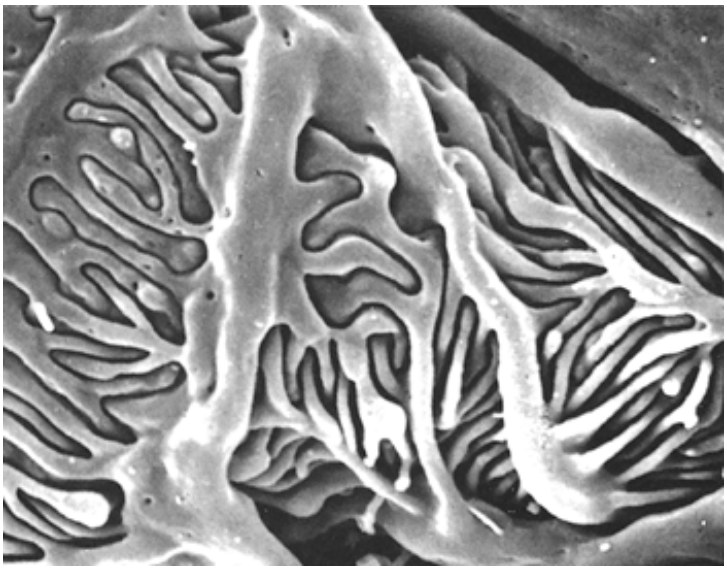

Figure 34.48 Scanning electron micrograph of glomerulus illustrating the primary processes of podocytes wrapping around the capillary loops. Note the interdigitation of the foot processes (original magnification Ã—13,000; courtesy of Dr. Jill W. Verlander).

This ultrastructural arrangement of contractile proteins may allow the podocytes to play an active role in modifying

the glomerular filtration surface area. Although the GBM is synthesized by both endothelial cells and podocytes, the latter play a greater role in the adult (349).

The adjacent foot processes near the GBM are separated by a 30- to 40-nm space termed the filtration pore (or slit), which is bridged by a thin extracellular structure called the filtration slit diaphragm. On ultrastructural examination, the slit diaphragm has always attracted the attention of pathologists. Over 30 years ago, based on electron microscopy, Karnovsky and co-workers proposed an isoporous

zipperlike structural model for the slit diaphragm (350 ,351 ,352). In this model, a central filament, corresponding to the central dot of the diaphragm on cross section, is connected to the adjacent foot processes by spaced crossbridges, between which are rectangular pores. Recent three-dimensional reconstruction of the slit diaphragm by electron tomography has provided results that generally agree with the Karnovsky model (353). The electron tomographic study showed that the slit diaphragm consists of a network of winding strands, about 30 to 35 nm long, which merge centrally into a longitudinal density. The strands, which create a slit diaphragm thickness between 5 and 10 nm, surround pores that are the same size or smaller than albumin molecules. The pores appear more irregular than previously supposed.

The slit diaphragm appears unique but shares similarities with tight and adherens junctions (354 ,355). It separates the different membrane surfaces of the podocyte. Podocytes, similar to other epithelial cells, are polarized with distinct membrane domains (356) (Figure 34.49). The basal membrane domain and the apical membrane domain are located below and above the slit diaphragm, respectively. The slit diaphragm area (including the bridging diaphragm, adjacent podocyte foot process membrane, and cytoplasm) may also be considered a surface domain, a very specialized one.

A major advance in our understanding of the podocyte was the identification of the protein nephrin, encoded by *NPHS1* , the gene mutated in congenital nephrotic syndrome of the Finnish type (30 ,32). Nephrin, a transmembrane adhesion protein of the immunoglobulin superfamily, localizes to strands of the slit diaphragm (353 ,357). Lack of nephrin in humans or animals leads to the loss of the slit diaphragm, foot process effacement, and massive proteinuria (32 ,148). An increasing number of other proteins localize to the slit diaphragm domain, where they interact with nephrin and other partners, forming a multifunctional complex (Figure 34.50) (348 ,356 ,358 ,359 ,360). Some proteins are present in the actual slit diaphragm itself. For example, there is evidence nephrin and Neph1, a protein similar to nephrin, each form homodimers and form heterodimeric interactions

with each other in the slit diaphragm (361 ,362 ,363 ,364).

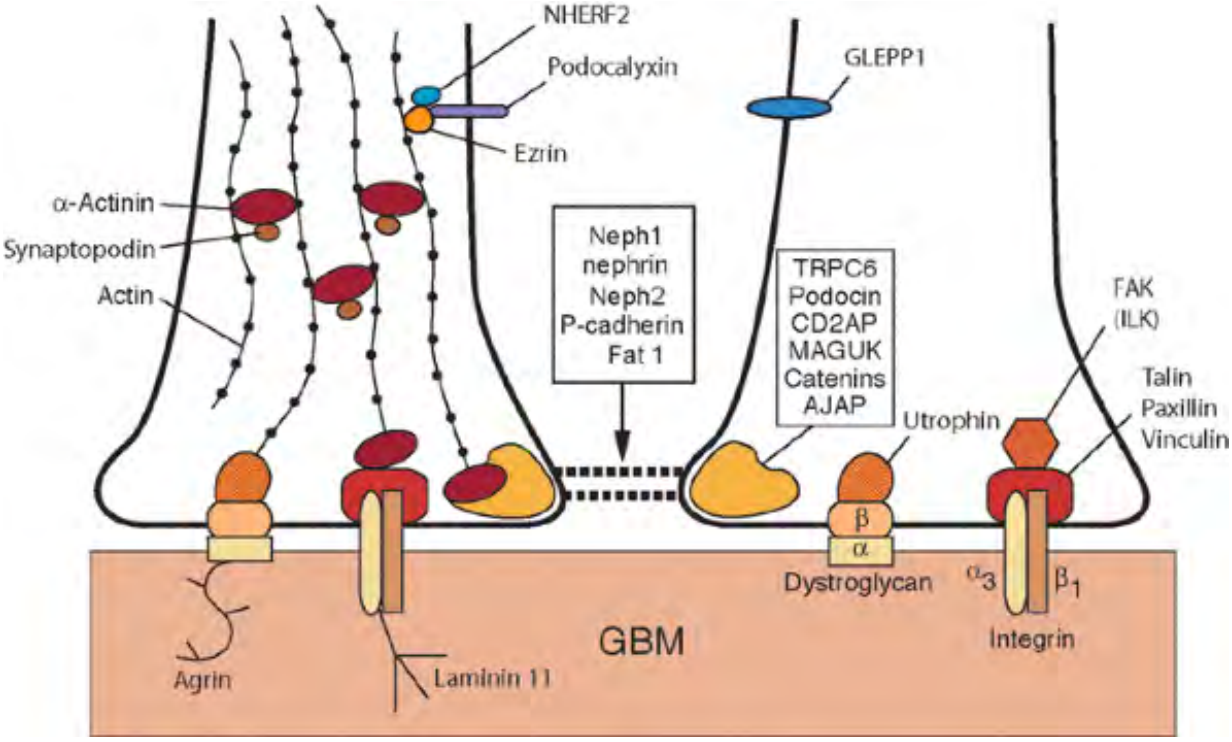

Figure 34.49 Schematic drawing of the membrane domains of the podocyte: the filtration slit diaphragm, basal membrane, and apical membrane domains. Molecular interactions within these domains of the podocyte foot processes are represented. See the text for further explanations. Modified from:

Another member in the Neph protein family, Neph2, localizes to the slit diaphragm, homodimerizes, and forms heterodimers with nephrin but not with Neph1 (365). Other proteins are present in the podocyte cytoplasm or plasma membrane adjacent to the slit diaphragm. For example, members of the membrane-associated guanylate kinase

(MAGUK) family of scaffolding proteins (including MAGI-1, MAGI-2, CASK, and ZO-1) localize adjacent to the slit diaphragm (358 ,359 ,360). These scaffolding proteins connect junctional membrane proteins to the actin cytoskeleton and signaling cascades. In addition, multiple adherens junctionâ€“associated proteins (AJAP) (including Î±-actinin, IQGAP1, Î±II spectrin, and Î²II spectrin) are also components of this expanding nephrin-associated multiprotein complex (358 ,359 ,360).

Mutations or deficiencies of genes encoding some of the proteins that comprise the slit diaphragm domain complex, including nephrin (32 ,148), Neph1 (155), Fat1 (156), podocin (150), CD2AP (149), Î±-actinin (151 ,152), and TRPC6 (153 ,154), cause glomerular diseases in humans and animals as characterized by absent slit diaphragms, foot process effacement, and proteinuria (Table 34.1). In addition to functioning as a critical barrier to

filtration, the slit diaphragm appears to regulate actin cytoskeletal dynamics in the foot processes (366). For example, Î±-actinin, an important protein in the slit diaphragm domain, interacts with synaptopodin (another actin-associated protein) to facilitate the formation of long unbranched parallel actin filaments in differentiated podocytes (367). The slit diaphragm also functions as a signaling center (368). For example, nephrin and CD2AP interact to stimulate antiapoptotic signaling in podocytes by activating the serine/threonine kinase AKT (369).

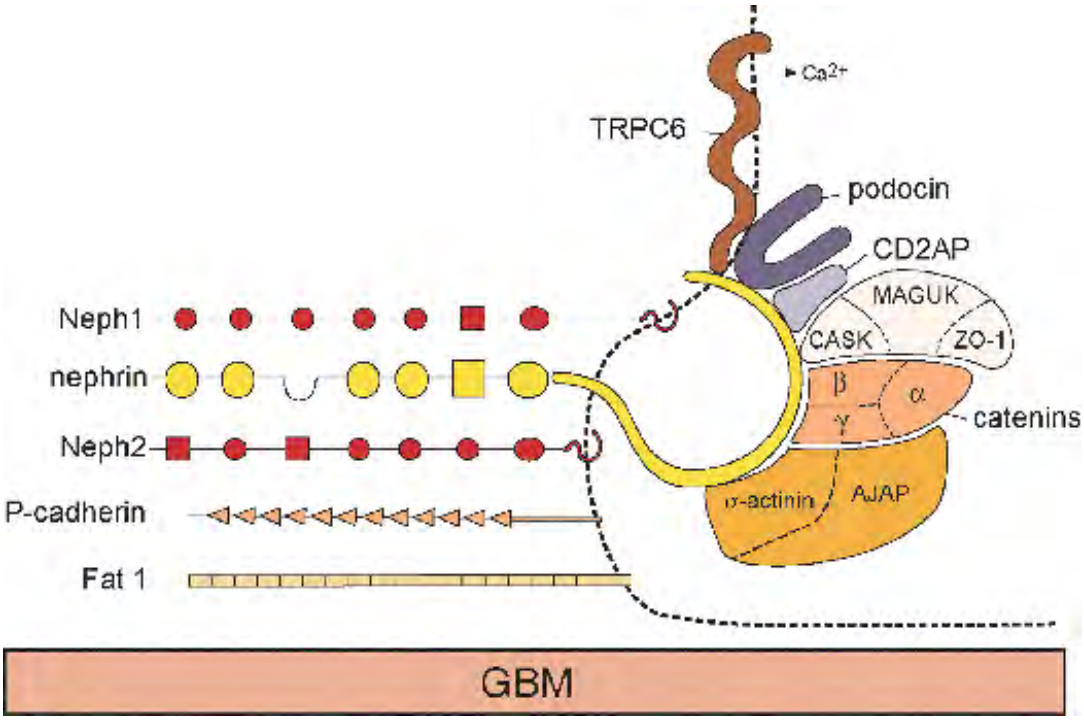

Figure 34.50 Schematic drawing of a working model of the podocyte filtration slit diaphragm domain. The *left* side portrays the molecular composition of the slit diaphragm itself, which spans between adjacent foot processes. The *right* side illustrates the molecular interactions of the nephrin-associated multiprotein complex within the podocyte foot process membrane and cytoplasm. See the text for further explanations. The basal membrane domain, the â€œsoleâ€• of the podocyte foot process, is embedded in the underlying GBM (Figure 34.49). Two types of surface receptors in the basal membrane, integrins and dystroglycan, anchor the foot processes by binding to their ligands in the GBM (370 ,371). The Î±3Î²1 integrin binds to collage type IV, laminin, and nidogen/entactin, whereas dystroglycan binds to laminin, agrin, and perlecan (348). Both integrins and dystroglycan are coupled by adapter molecules to the actin cytoskeleton.The integrins bind the talin, paxillin, vinculin complex (346), and dystroglycan binds utrophin (371). The induction of cellular responses from integrin-ligand interactions, known as â€œoutside-inâ€• signaling, is believed to be mediated by FAK (focal adhesion kinase) and ILK (integrin-linked kinase) (348 ,372). Similar to the filtration slit domain, an intact basal membrane domain is required to maintain foot process integrity.

The apical membrane domain, above the slit diaphragm, has a prominent glycocalyx surface of negatively charged glycoproteins (Figure 34.49) (373). These include podocalyxin (374) and GLEPP1 (375). Podocalyxin interacts with a complex composed of ezrin and NHERF2 (Na^+ /H^+ exchanger-regulatory factor 2), which in turn, associates with the actin cytoskeleton (376 ,377). Genetic evidence exists indicating podocalyxin is important for foot process stability (159). The development of the glomerulus as a vascular structure distinct from the remainder of the nephron is reflected in the intrarenal distribution of intermediate filaments. Vimentin is present in glomerular endothelial and mesangial cells and podocytes (Figures 34.51 ,34.52) (347 ,378 ,379 ,380 ,381).

Human podocytes often do not stain for desmin, however rat podocytes may show desmin expression, especially in response to injury (381 ,382). The glomerular tuft does not stain for keratins.

The Wilms' tumor suppressor gene, *WT1,* plays an indispensable role in the regulation of cell growth and differentiation during early

nephrogenesis. Embryonic mice homozygous for a targeted mutation of *WT1* fail to develop kidneys (77). Striking evidence also exists for the importance of *WT1* in glomerular podocyte differentiation. During kidney development, *WT1* expression is detected in the metanephric mesenchyme and becomes stronger in the

renal vesicle, but highest levels occur during glomerulus formation within the podocyte cell layer (383 ,384). Expression of the *WT1* protein, a transcription factor, in the nuclei of podocytes does not disappear with glomerular maturation but persists in the adult kidney (Figure 34.53). Greater than 95% of patients with the Denys-Drash syndrome (nephrotic syndrome and genital anomalies and/or Wilms' tumor), characterized by shrunken glomeruli with hypertrophied podocytes, have point mutations affecting the zinc finger DNA-binding domain of *WT1* (385). These findings provide a functional link between a molecular defect of *WT1* and podocyte pathology and suggest that *WT1* has a role in maintenance of podocyte structure and function in the mature kidney.

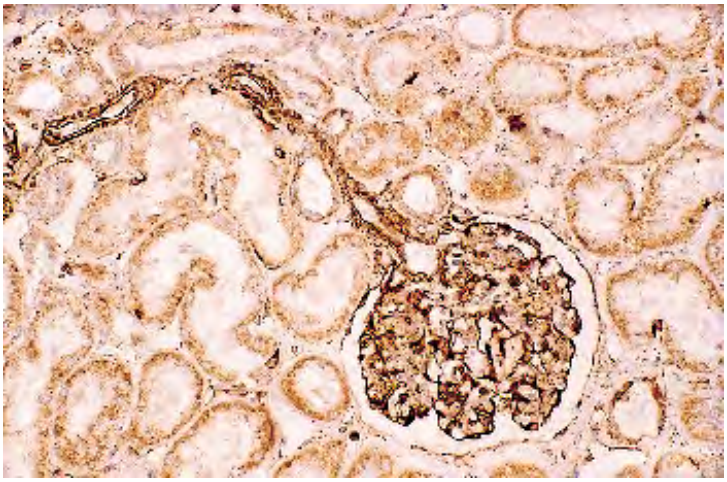

Figure 34.51 Vascular structures including the glomerulus are heavily labeled with antibody to vimentin. Tubular and interstitial components show weaker and sparse labeling. (Vimentin immunoperoxidase, original magnification Ã—62.)

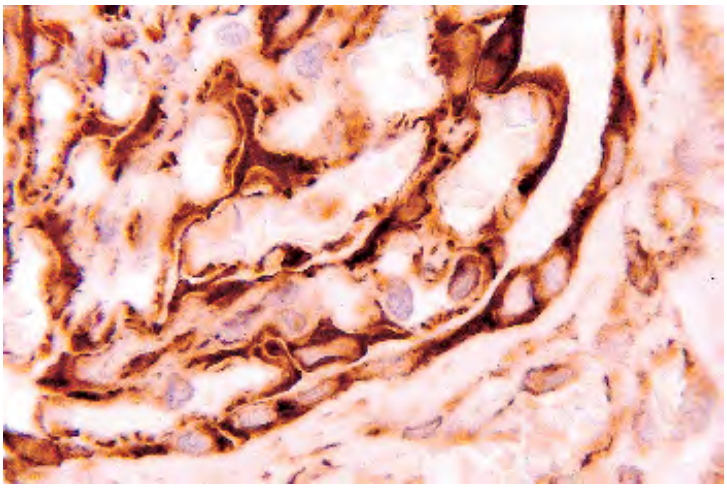

Figure 34.52 Prominent expression of vimentin is seen in glomerular endothelium, podocytes, and parietal epithelium. (Vimentin immunoperoxidase, original magnification Ã—300.)

Glomerular Filtration Barrier

The glomerular capillary wall functions as a filter that is selective for the size and charge of molecules. To pass through the capillary wall, a molecule must journey along an extracellular pathway through the fenestrated endothelium, the GBM, and the filtration slit diaphragm. Historically, the GBM has been considered the main barrier to filtration. More recently, the role of the podocyte slit diaphragm has emerged. The permeability of the glomerular capillary wall to water and small molecules is very high, whereas its permeability to molecules the size of albumin and larger is very low. Studies employing mathematical modeling have suggested that the GBM and filtration slits contribute equally to the total resistance to water filtration (386). A model incorporating ultrastructural data has shown that the slit diaphragm is the most restrictive part of the barrier to the filtration of macromolecules (387).

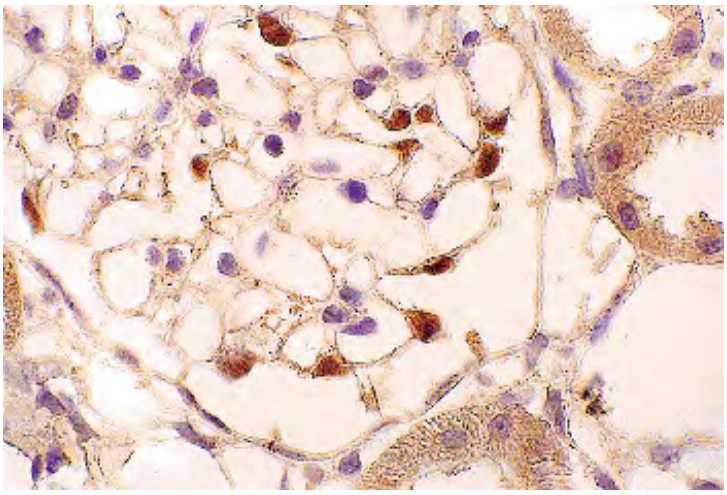

Figure 34.53 Light micrograph demonstrating expression of the WT1 protein in podocyte nuclei of an adult glomerulus. (WT1 immunoperoxidase, original magnification Ã—210.)

Mutations or deficiencies of genes encoding proteins of the filtration slit diaphragm domain, including nephrin and several of its interacting protein partners, result in massive proteinuria, providing genetic evidence for the crucial role of the slit diaphragm in glomerular permselectivity (348 ,358). Although the protein networks within the GBM contribute to the size selectivity of the filtration barrier, the slit diaphragm appears to be the most important size-selective filter.

The GBM has been favored as the principal structure responsible for the charge-selective permeability of the glomerular capillary wall (388). This charge selectivity in the GBM has been associated with the presence of polyanionic molecules, such as heparan sulfate proteoglycans. Therefore, it was somewhat surprising that mice deficient for the heparan sulfate side chains of Perlecan were found to have no morphologic GBM defects and exhibited no proteinuria (389).

However, since agrin appears to be the major heparan sulfate proteoglycan in the GBM (338), it will be important to evaluate its contribution to the charge barrier in the GBM. The distribution of negatively charged molecules in the cellular layers of the glomerular capillary wall are also likely important. Experimental removal of

polyanionic sialic acids from the plasma membrane of podocytes leads to proteinuria (390). Although relatively neglected, there is emerging evidence that negative charges within the glomerular endothelial glycocalyx may play a role in charge selectivity (302 ,303).

The â€œintegrated viewâ€• of the glomerular filtration barrier is that the endothelium, the GBM, and the podoctyes and their slit diaphragms do not act independently but are linked to one another in a functional unit. Each of these components is important for normal glomerular filtration. Detailed reviews of the the filtration barrier are available (391 ,392 ,393).

Parietal Epithelial Cells

The parietal layer of Bowman's capsule consists of relatively flat squamous epithelial cells. They have prominent proliferative potential (394). Keratins, cadherens, and the transcription factor Pax-2 are expressed in parietal epithelial

cells (Figure 34.54) (347 ,379 ,380 ,381 ,395). Cytokeratin 8 has been reported to be a marker for activated parietal epithelial cells (394). The cells are 0.1 to 0.3 Âµm in height but may increase to 2 to 3.5 Âµm at the nucleus (284). The epithelium rests on the basement membrane of Bowman's capsule, which has been reported to range from 1,200 to 1,500 nm in thickness and may have a lamellated appearance (284). In contrast to the GBM, the basement membrane of Bowman's capsule expresses the Î±6 chain of type IV collagen, which is part of the Î±1.Î±1.Î±2(IV)â€“Î±5.Î±5. Î±6(IV) network (396), and bamacan, a chondroitin sulfate proteoglycan (397).

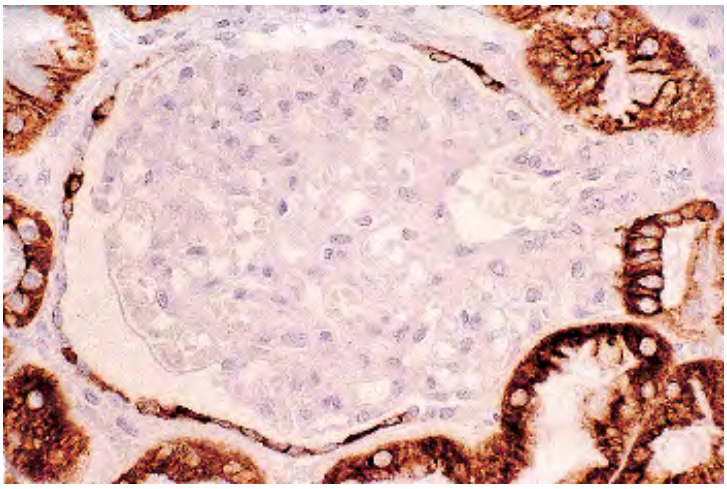

Figure 34.54 Keratin expression is not observed in the glomerular tuft, but immunoreactivity is seen in the parietal epithelial cells. The vascular pole is on the *right* . The macula densa (*far right center*) and other tubule segments are immunoreactive for keratin. (CAM 5.2 immunoperoxidase, original magnification Ã—120.)

Peripolar Cells

A peripolar cell, situated between the visceral and parietal epithelial cell layers at the origin of the glomerular tuft in Bowman's space, has been most commonly observed in sheep but also identified in humans (398 ,399 ,400 ,401). However, these cells have been detected only in approximately 1% of human glomeruli by light microscopy (399). Ultrastructurally, the peripolar cell contains multiple membrane-bound electron-dense secretory type granules. It has been proposed that this cell represents a component of the juxtaglomerular apparatus (398). The exact function of the peripolar cells is unknown, but they may have a secretory function and discharge their contents into Bowman's space.

Juxtaglomerular Apparatus

The juxtaglomerular apparatus (JGA), discovered by Golgi (402), is situated at the vascular pole of the glomerulus and includes the

afferent and efferent arterioles, extraglomerular mesangial region, and macula densa (MD) (Figure 34.55). The JGA is the major structural unit of the renin-angiotensin system. Although the general outline of this anatomical unit usually can be observed in light microscopic sections (Figure 34.56), histochemical or immunocytochemical methods are usually required to demonstrate the distinctive juxtaglomerular granular cells. These cells tend to occur in clusters and are most

abundant in the wall of the afferent arteriole, but they are also found in the wall of the efferent arteriole and the extraglomerular mesangial region (403 ,404 ,405). Ultrastructural analysis shows the presence of myofilaments, attachment bodies, a well-developed endoplasmic reticulum and Golgi apparatus, and numerous membrane-bound granules (Figure 34.57). The granules are variable in shape and size. It is believed that the smaller, often rhomboid-shaped granules with a crystalline substructure (called protogranules) observed in the Golgi region represent mature granules. Renin and angiotensin II have been immunolocalized to the granules of these cells (406 ,407). Renin release occurs by exocytosis. It is believed to be modulated by adrenergic nerve activity (408 ,409).The extraglomerular mesangium, also called the lacis or the cells of Goormaghtigh, is located between the afferent and efferent arterioles and has extensive contact with the basal surface of the MD. This extraglomerular region is continuous with the intraglomerular mesangium, and the Goormaghtigh's cells are similar in ultrastructure to the mesangial cells. There are numerous gap junctions between the extraglomerular mesangial cells and the cells of the intraglomerular mesangium and glomerular arterioles (410 ,411). These morphologic features and the central position within the JGA suggest that the extraglomerular mesangium may represent the structural-functional link between the MD and the glomerular arterioles and mesangium. The MD represents a plaque of specialized tubular cells within the cortical thick ascending limb of Henle adjacent to the hilus of the glomerulus. The cells are low columnar and may protrude

into the tubular lumen (Figure 34.58). By electron microscopy, they have apical nuclei, cellular organelles largely lateral to and beneath the nuclei, and basal cellular processes that interdigitate with the extraglomerular mesangial cells. The lateral intercellular spaces between the MD cells vary in width but usually are more dilated compared with the lateral intercellular spaces of other nephron segments (412). In contrast with contiguous portions of the thick ascending limb, there is evidence that the MD lacks epidermal growth factor and Tamm-Horsfall protein but may be water permeable (Figure 34.59) (413 ,414 ,415).

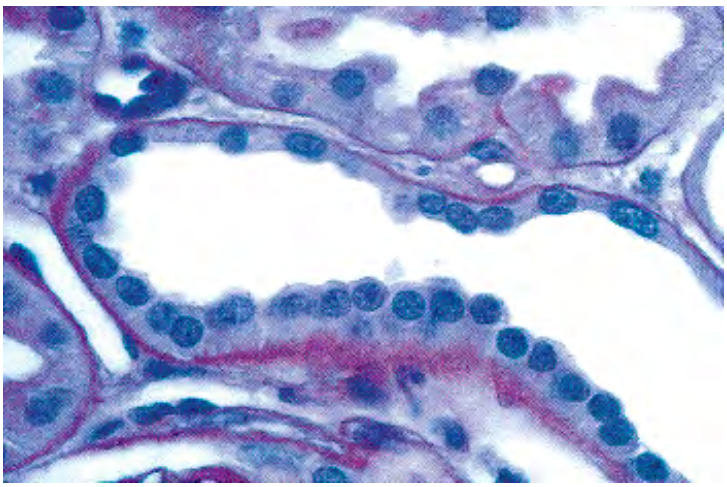

Figure 34.58 Macula densa characterized as a morphologically distinct plaque of low columnar cells with apically situated nuclei (PAS stain, original magnification Ã—750).

The anatomic arrangement of the juxtaglomerular apparatus is suited for functional regulation of the adjacent structures. The MD plays a role in tubuloglomerular feedback, a mechanism whereby luminal concentrations of

sodium and/or chloride are sensed by the MD, leading to the transfer of a signal to the glomerular arterioles to regulate the glomerular filtration rate (GFR) (416). For example, increased luminal salt concentration at the MD results in a decreased GFR. The neuronal isoform of nitric oxide synthase (nNOS) and the cyclooxygenase enzyme COX-2 immunolocalize to the MD (417 ,418 ,419). There is evidence that both nitric oxide (NO)- and COX-2â€“generated prostaglandins play a role in the signaling between the MD and the renin-secreting cells in the afferent arteriole (420 ,421).

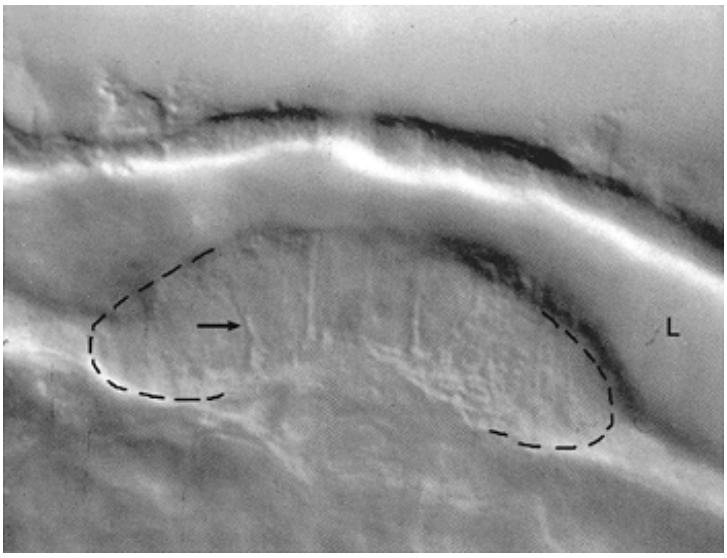

Figure 34.59 Differential interference contrast image of an isolated thick ascending limb segment perfused in vitro. The tubular lumen (*L*) and macula densa (*dashed lines* enclose the ends of the macula densa plaque) are observed. In response to a reduction in tubular luminal osmolality, there is dilatation of the lateral intercellular spaces (*arrow*) in the macula densa, suggesting increased water flow (original magnification Ã—1250) Modified with permission from:

Proximal Tubule

The proximal tubule is divided into an initial convoluted portion (PCT), the pars convoluta, and a straight portion (PST), the pars recta. The convoluted portion forms several coils around its parent glomerulus in the cortex and continues into the straight portion, which is located in the medullary ray.

The human proximal tubule is approximately 14 mm in length (422). In histologic sections of the cortex, sectioned profiles of proximal convoluted tubules represent the major parenchymal component. The

appearance of the cortex and especially the proximal tubules varies, according to the method of fixation. A decrease in blood pressure results in decreased filtration and renal volume (423 ,424). After immersion fixation of excised pieces of renal tissue, the cortex has a more homogeneous compact appearance, and there is collapse of the proximal tubular lumens (Figure 34.60) (425). Free nuclei and vesicular membranous material may be observed in the proximal tubular lumens. Fixation of an experimental functioning kidney in situ by rapid freezing, dripping of fixative on the renal surface, or vascular perfusion results in more conspicuous intertubular interstitial spaces and widely open lumens of the proximal tubules. The cells of the proximal tubule are cuboidal to low columnar with eosinophilic, often granular cytoplasm and round nuclei situated in the center or near the base of the cells (Figure 34.61). The lateral cell borders are indistinct because of extensive interdigitations of lateral cellular processes from adjacent cells (Figure 34.62). In the basal part of the cells there are vertical striations that represent numerous elongated mitochondria. Cytoplasmic apical vacuoles and granules correspond to a well-developed endocytic-lysosomal apparatus. There is a prominent PAS-positive luminal brush border composed of the numerous densely packed long microvilli (Figure 34.63). The brush border, apical cytoplasmic vacuoles, and basal striations are less prominent in the pars recta. Lectins have been used as selective probes to delineate renal tubular segments (426 ,427 ,428).

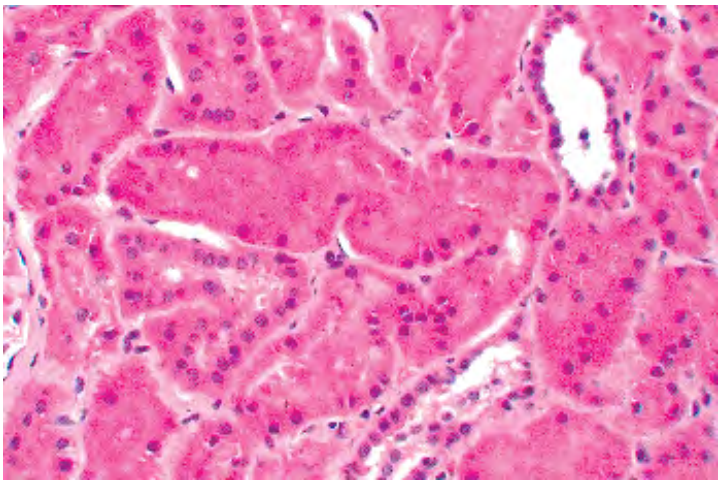

Figure 34.60 Immersion-fixed renal biopsy specimen demonstrating diffuse collapse of the proximal tubular lumens. Note the patent lumens of the distal nephron segments. (Original magnification Ã—250.)

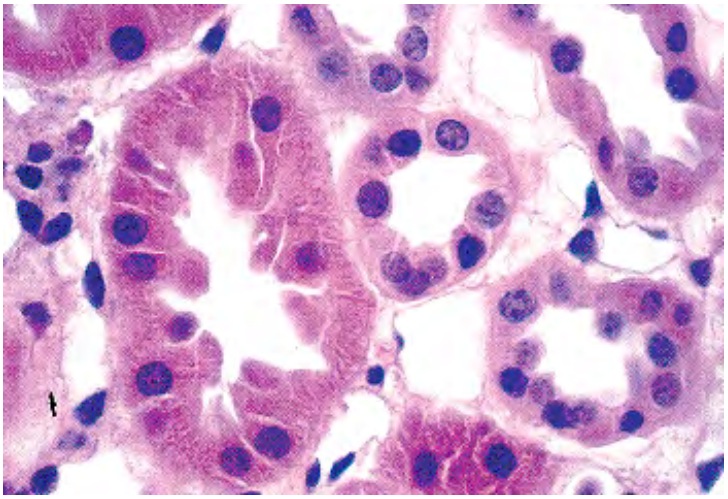

Figure 34.61 Cross section of a proximal tubule (*left* of *center*). The proximal tubular cells are taller and more eosinophilic than the cells of the distal nephron segments (*right*). (Original magnification Ã—750.)

Although a certain degree of nonspecificity has been reported, the lectin *Lotus tetragonolobus* has been used as a marker of proximal tubular epithelium (Figure 34.64).

Keratins 8 and 18 are expressed in both the convoluted and straight portions of the proximal tubule, whereas keratin 19 is focally expressed in the straight portion (379 ,380 ,429). The specific expression of the cell adhesion protein cadherin-6 in the proximal tubule has been reported (430).

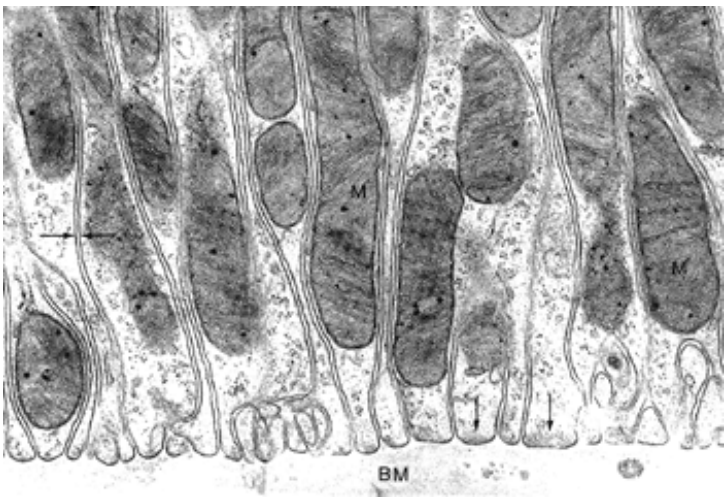

Figure 34.62 Electron micrograph illustrating extensive interdigitation of cellular processes in the basal region of proximal tubular cells. The mitochondria (*M*) are elongated. The width of the extracellular space (*opposing arrows*) is constant, and there are bundles of cytoplasmic filaments (*single arrows*) adjacent to the basement membrane (*BM*) (original magnification Ã—40,000). New York: Oxford University Press; 1992:41â€“107.

In most mammals, distinct segments of the tubule portion of the nephron can be distinguished by structural and functional differences. The structural differences have been characterized mainly on the ultrastructural level (431). However, these tubule segments often can be detected on light microscopy because of their known distribution within specific zones of the kidney (Figure 34.33). In general, the degree of tubule segmentation has not been characterized in detail in the human kidney. In several mammals, the proximal tubule can be

divided into three morphologically distinct segments (Figure 34.65) (431). The S_1 segment originates at the glomerulus and constitutes one-half to two-thirds of the pars convoluta. The S_2 segment represents the remainder of the pars convoluta and the initial part of the pars recta. The S_3 corresponds to the remainder of the pars recta and is located in the inner cortex and outer stripe of the outer medulla. Although a pars convoluta and a pars recta have been described in the human kidney (432), the segmentation of the proximal tubule into three divisions has not been closely examined.

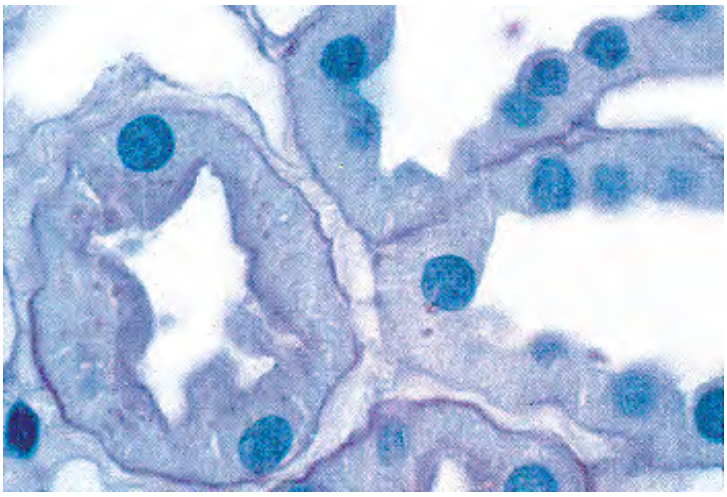

Figure 34.63 PAS-stained cross section of proximal tubule to the left of the center of the micrograph. Note the prominent PAS-positive brush border (original magnification Ã—1250).

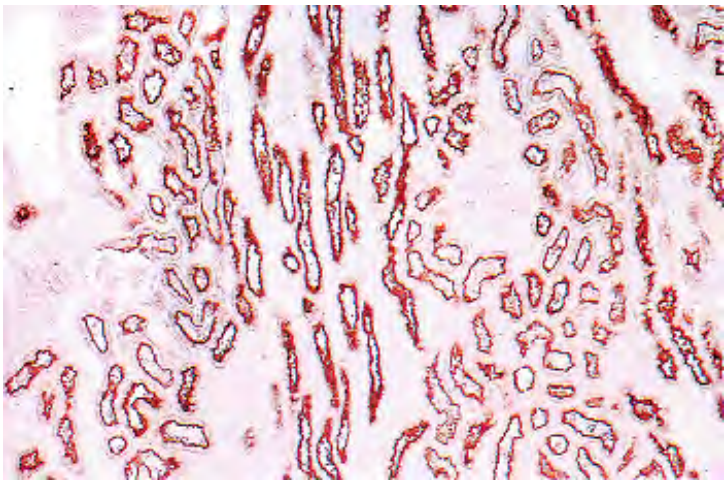

Figure 34.64 Staining of the brush border of the proximal tubules with lectin *Lotus tetragonolobus* . The distal nephron segments and glomeruli are negative. (Courtesy of Dr. Randolf A. Hennigar.)

The cells in the S_1 segment have a tall brush border, a well-developed endocytic lysosomal apparatus, numerous elongated mitochondria, and extensive basolateral invaginations and interdigitations.

The cells in the S_2 segment are similar to those in the S_1 segment; however, the brush border is shorter, and the endocytic organelles, mitochondria, and basolateral invaginations and interdigitations are less prominent (Figure 34.66). The cells in the S_3 segment are more cuboidal and have relatively fewer endocytic organelles, small mitochondria, and inconspicuous membrane invaginations and interdigitations. The length of the brush border in the S_3 segment varies among species.

The proximal tubule is responsible for the reabsorption of about 60% of the glomerular ultrafiltrate. The reabsorption of chloride, bicarbonate, glucose, amino acids, and fluid is coupled to the active transport of sodium (433). An excellent correlation exists along the length of the proximal tubule between the elaborately developed basolateral membrane expressed as surface area (Figure 34.67), the high sodium potassium (Na^+ /K^+)-ATPase activities that are localized to the basolateral membrane, and the capacity

to transport sodium and ions (434 ,435). The Î±1Î² 1 heterodimer is the main Na^+ /K^+ -ATPase isozyme of the kidney, but the Î±2- and Î±3-isoforms have been detected (436 ,437). This sodium pumpâ€“mediated active transport of Na^+ out of the cell across the basolateral membrane establishes a lumen-to-cell concentration gradient for Na^+ .

The transport of Na^+ from the lumen into the proximal tubule cell, down its concentration gradient, is mediated by the Na^+ /H^+ exchanger, NHE3, expressed in the brush border (438 ,439). The numerous mitochondria located in close proximity to the plasma membrane provide a source for the cellular energy required for active transport. In general, the intrinsic rates at which fluid and solutes are transported decrease along the proximal tubule from S_1 to S_3 . The discovery of the aquaporins, a family of water channel proteins, has enhanced our understanding of the kidney's role as the primary organ that regulates water balance (440 ,441). Aquaporin-1 (AQP1), abundant in both the apical and basolateral membranes of the proximal tubule, is believed to mediate osmotic water permeability in this segment (442 ,443).

The well-developed endocytic-lysosomal apparatus in the proximal tubule (Figure 34.68) plays an important role in reabsorption and degradation of albumin and low-molecular weight proteins filtered by the glomerulus (444). Proteins are absorbed by endocytosis and transferred through the endosomal compartment to the lysosomes, where they are degraded. This is a selective process dependent upon the size and charge of the protein molecule (445 ,446 ,447). The capacity for protein degradation decreases from the S_1 to the S_3 segment (448). Upon exposure to an acidic environment in the endosomes (449), the internalized ligand-receptor complexes are segregated, and the receptors are recycled back to the luminal membrane via small vacuolar structures, termed apical dense tubules (450). Megalin and cubilin are multiligand endocytic receptors

expressed throughout the endocytic apparatus of the proximal tubule (451). The receptors function independently but also interact as a dual complex to facilitate the uptake of albumin (452), as well as numerous ligands, including low-molecular weight proteins, vitamin-binding proteins, hormones, lipoproteins, and drugs (453).

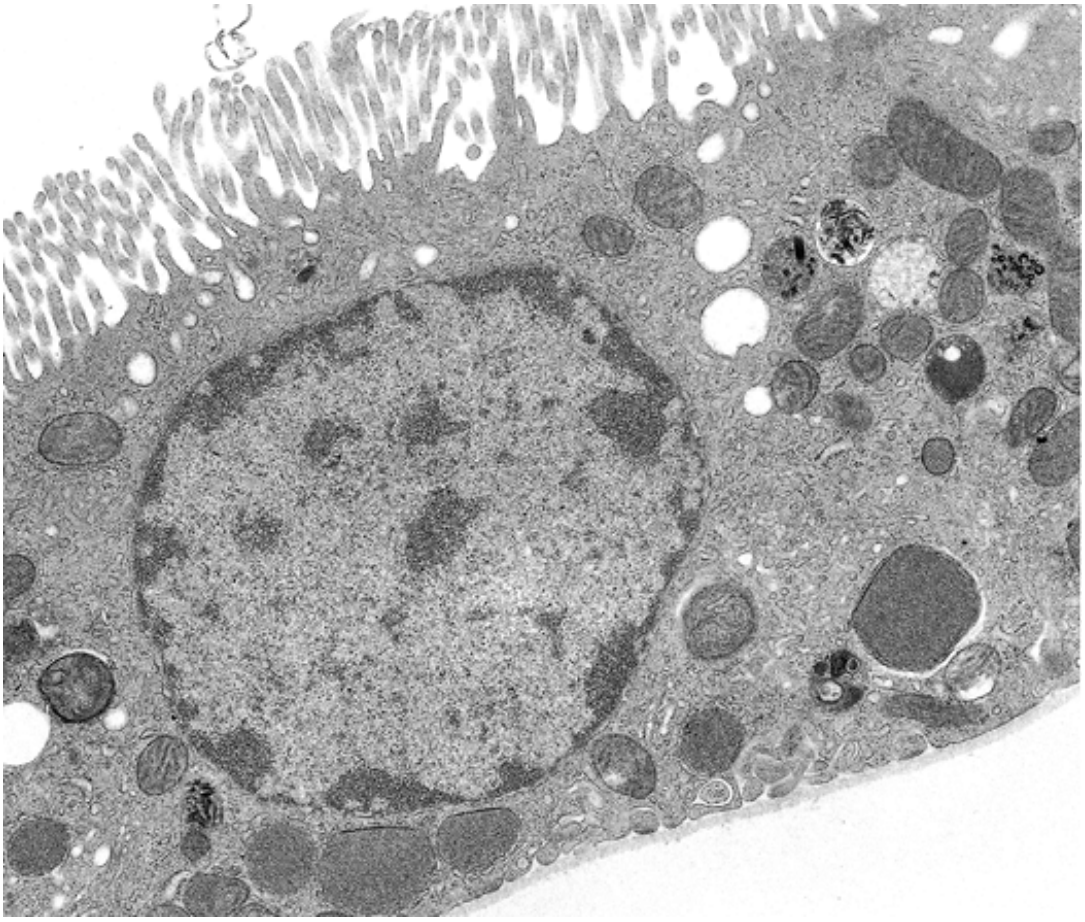

Figure 34.68 Electron micrograph illustrating an isolated perfused S_2 segment of the rabbit proximal tubule. Note the endocytic compartment consisting of coated pits and vesicles, apical tubules, small endocytic vesicles, and larger endocytic vacuoles. The lysosomes are heterogeneous and contain electron-dense material. The mitochondria are numerous (original magnification Ã—15, 000).

The normal adult kidney has a relatively low rate of cell turnover with little proliferation (454 ,455 ,456). However, renal cell proliferation is accelerated during hypertrophy and following injury. Histologic assessment of cell proliferation can be made by determining a mitotic index or immunostaining with an antibody that detects proteins present during the cell cycle (457). During recovery after tubular injury, such as ischemia or toxin exposure, cell proliferation in tubular cells, especially in the proximal tubule, increases markedly (Figure 34.69) (458 ,459). Apoptosis has been documented in the adult kidney during the repair response to various forms of tubular injury, including ischemia, toxic insults, and hydronephrosis (Figure 34.70) (460 ,461 ,462 ,463).

Thin Limbs of Henle's Loop

The transition of the thin limbs of Henle's loop with other nephron segments marks the borders between certain zones of the kidney (Figure 34.33). Between the outer and inner stripes of the outer medulla, there is an abrupt transition from the proximal tubule to the descending thin limb (DTL) of Henle's loop. Short-looped nephrons have only a short DTL located in the inner stripe of the outer medulla. Near the hairpin turn of the short loop, the DTL continues into the thick ascending limb. Long-looped

nephrons have both a long DTL and a long ascending thin limb (ATL). The long DTL traverses the inner stripe of the outer medulla and enters the inner medulla, whereas the long ATL resides entirely within the inner medulla. At the border between the outer and inner medulla, the long ATL continues into the thick ascending limb. By light microscopy, the thin limb is lined with a flat, simple epithelium about 1 to 2 Âµm thick (Figure 34.71). The lenticularly shaped nucleus bulges slightly into the lumen. Four types of epithelium have been described in the thin limb in several mammals (Figure 34.72) (272 ,464). It is not

known if four types exist in humans, but at least two different types of epithelium have been demonstrated (465). Type I is present in the DTL of short-looped nephrons. It is an extremely thin, simple epithelium with few cellular interdigitations and cell organelles. Type II epithelium lines the initial part of the DTL of long-looped nephrons located in the outer medulla. This epithelium exhibits species variation and is characterized by taller cells, short microvilli, and more prominent cell organelles than in the other epithelial types. In the rat and mouse, type II epithelium is complex and characterized by extensive lateral interdigitations; whereas in the rabbit and human kidney, the interdigitations are less prominent (272). Type III epithelium, found in the DTL of long-looped nephrons in the inner medulla, is composed of simple cells with few organelles and without lateral interdigitations. Type IV epithelium forms the bends of the long loops and lines the entire ATL in the inner medulla. It is characterized by low, flattened cells with few organelles and no microvilli but abundant lateral interdigitations. Thin limb epithelium has been reported to be immunoreactive for keratins 7, 8, 18, and 19 (379 ,380).

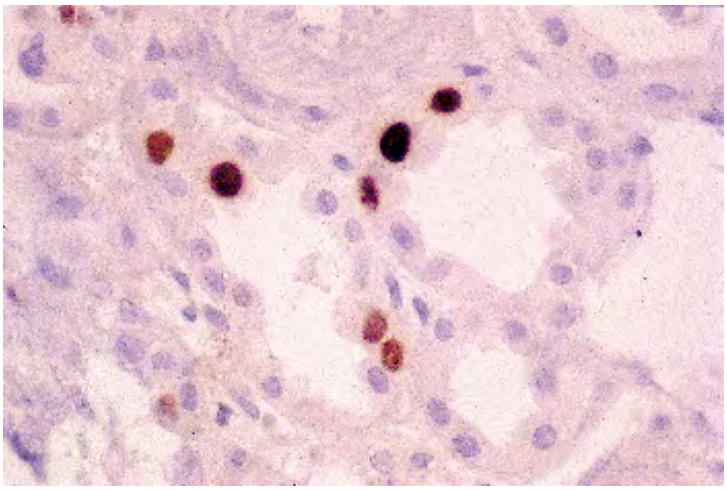

Figure 34.69 Biopsy of kidney allograft with cyclosporin A toxicity. Normally there is sparse labeling for Ki-67, a nuclear protein expressed by proliferating cells. In this example, there is a prominent increase in labeling of the tubular nuclei. (Ki-67 immunoperoxidase, original

The thin limb of Henle's loop plays an important role in the countercurrent multiplication component of urinary concentration. Physiologic studies have demonstrated that the DTL is permeable to water but has low permeability to sodium chloride, whereas the thin ascending limb is largely impermeable to water but has a high permeability to sodium chloride (272 ,466). These physiologic investigations are supported by immunohistochemical studies. The

aquaporin water channel protein, AQP1, is prominently expressed in the DTL but not in the ATL (442 ,467). The kidney-specific chloride channel C1C-K1 is expressed exclusively in the ATL (468 ,469). Mice and humans lacking AQP1 (470 ,471) and mice deficient for C1C-K1 (472) have impaired urine concentrating ability. In the passive model proposed by Kokko and Rector (473) and Stephenson (474), a hypertonic medullary interstitium concentrates sodium chloride in the DTL by extraction of water. The fluid that then enters the ATL has a higher sodium chloride concentration, resulting in passive salt absorption and dilution of the fluid of the ATL. Thus, the thin limb contributes to the maintenance of a hypertonic medullary interstitium and delivers a dilute fluid to more distal segments. The morphologic features of a simple epithelium with few organelles in the ATL are consistent with the lack of demonstrable active transport in this segment.

Distal Tubule

The distal tubule consists of three distinct segments: the thick ascending limb of Henle's loop (TAL), the macula densa (MD), and the distal convoluted tubule (DCT) (Figure 34.33). The MD, as previously discussed (in the section entitled Juxtaglomerular Apparatus), is a specialized plaque of cells within the TAL. In short-looped nephrons, the transition from the descending thin limb to the TAL occurs before the hairpin turn. In long-looped nephrons, the transition from the thin ascending limb to the TAL marks the border between the inner medulla and the inner stripe of the outer medulla. The TAL can be divided into a medullary (MTAL) and a cortical segment (CTAL). The cells are eosinophilic and cuboidal, and the round nucleus tends to be located in the apical region and causes a bulge of the cell into the lumen (Figure 34.73). Similar to the proximal tubule cells, the cells of the TAL have indistinct lateral cell borders because of elaborate basolateral membrane invaginations and interdigitations. They also have cytoplasmic basal striations because of elongated mitochondria. These

morphologic features are characteristic for epithelial cells involved in active transport. However, in contrast to the proximal tubule, the cells are lower and less eosinophilic, and there is no brush border in the TAL. As the TAL ascends into the cortex, there is a gradual decrease in cell height, basolateral membrane area, and size of the mitochondria (475). Scanning electron microscopy has shown two luminal surface configurations of cells in the TAL (476). Cells with a relatively smooth surface are most commonly found in the medullary segment, whereas cells with a rough surface due to luminal microprojections and apical lateral membrane invaginations predominate in the cortical segment. The functional significance of these structural findings remains unexplained. The TAL continues into the distal convoluted tubule just beyond the MD. The cells of the TAL synthesize Tamm-Horsfall protein and secrete it into the tubular lumen (414). This segment expresses keratins 8 and 18 (378 ,380 ,429), and also kidney-specific (Ksp) cadherin (477).

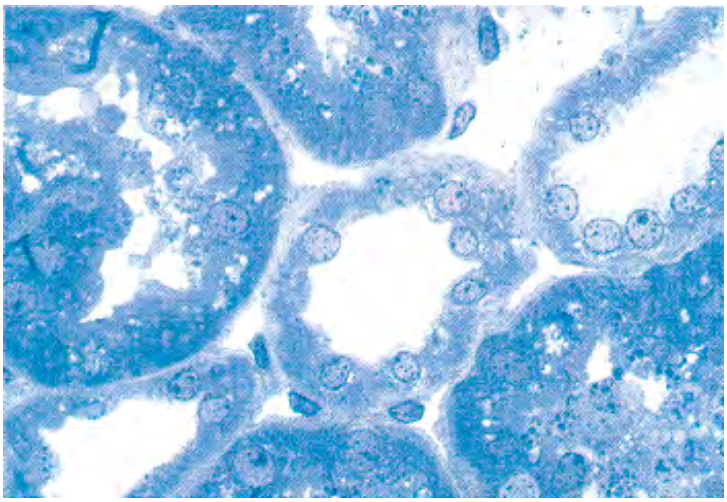

Figure 34.73 Light micrograph demonstrating a cross section of a thick ascending limb in the center. There is no brush border, and the cells are lower than the adjacent proximal tubular cells. (Toluidine blue-stained, 1-Âµm Epon section, original magnification Ã—750.)

An important function of the TAL is the active reabsorption of sodium chloride. There is a correlation between structure and function in the

ascending limb. The basolateral membrane surface area, the Na^+ /K^+ -ATPase activity, and the reabsorptive capacity for sodium chloride are all greater in the medullary segment than in the cortical segment of the TAL (433 ,475 ,478). The reabsorption of sodium chloride in both the medullary and cortical segments of the TAL is mediated by a bumetanide-sensitive Na^+ /K^+ /2Cl^- cotransporter (BSC-1), which localizes to the TAL apical plasma membrane (479). This reabsorption of salt coupled with the water impermeability of the TAL results in a hypertonic interstitium and delivery of a hypotonic fluid to more distal tubular segments.

The DCT begins just beyond the MD in the cortex and represents the terminal part of the distal tubule. The cells of the DCT are similar to those of the TAL and contain numerous mitochondria. However, the DCT cells are taller, characteristically have nuclei closer to the lumen, and lack lateral interdigitations in the apical region between adjacent cells (Figure 34.74). In comparison with the proximal tubule, the cells of the DCT are lower and less eosinophilic, have a less prominent apical endocytic apparatus, and lack a brush border. More nuclei are observed in a cross section than in the proximal tubule, and the lumen is normally open. The epithelium of the DCT shows immunoreactivity for keratins 8, 18, and 19 (379 ,429) and for Ksp-cadherin (477). In the DCT, reabsorption of sodium chloride is mediated by the Na^+ /Cl^- cotransporter, TSC, which localizes to the apical plasma membrane and apical cytoplasmic vesicles (480 ,481). The cotransporter TSC, the target of thiazide diuretics, is distinct from the cotransporter BSC-1,

present in the thick ascending limb. Biochemical studies have demonstrated that the DCT has a higher level of Na^+ /K^+ -ATPase activity than any other tubular segment (116). Morphologic and physiologic studies have provided evidence that the DCT, similar to the TAL, is relatively impermeable to water but responsible for the reabsorption of sodium chloride (482 ,483 ,484).

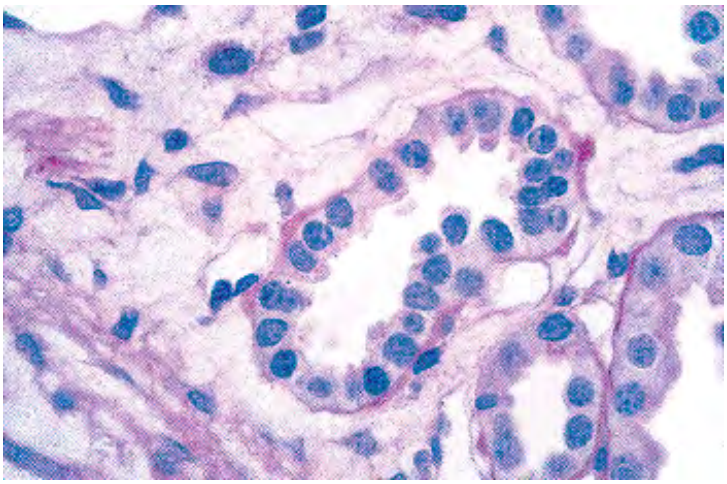

Figure 34.74 Light micrograph showing a distal convoluted tubule. Note the absence of a brush border and the nuclei situated close to the lumen. (PAS stain, original magnification Ã—750.)

Connecting Segment

The connecting segment (or tubule) is a transitional segment that joins the DCT with the collecting duct system. In superficial nephrons, the connecting segment (CS) continues directly into an initial collecting tubule (Figure 34.75). In contrast, the connecting segments of juxtamedullary nephrons and of many midcortical nephrons join to form an arcade that ascends in the cortex before draining into an initial collecting tubule. In humans, most nephrons empty individually into initial collecting tubules (272).

Fourteen percent of the nephrons are connected to arcades, and each arcade consists of about three nephron attachments (6). Each cortical collecting tubule receives an average of 11 nephrons (6). In most species, including humans, the CS contains different cell types as a result of an intermixing of cells from the adjacent DCT and cortical collecting duct (485). The connecting tubule cell is the most characteristic cell type of this transitional segment. They display ultrastructural features intermediate between the DCT cells and the principal cells of the cortical collecting duct and contain deep true

infoldings of the basal cell membrane (486). The connecting tubule cell appears to be the only cell type in the kidney (of those thus far identified) that shows immunoreactivity for the proteolytic enzyme kallikrein (487 ,488). The physiologic relevance of this finding remains uncertain. Various types of intercalated cells, similar to those in the cortical collecting duct, are also present in the CS and are likely involved in tubular acid-base regulation. The CS is an important site of potassium secretion regulated by mineralocorticoids (484). An ATP-sensitive K^+ channel, ROMK, localizing to the apical membrane of connecting tubule cells, likely mediates the potassium secretion (489 ,490). The expression of a Na^+ /Ca^{2+} exchanger and a Ca^{2+} -ATPase in the basolateral membrane of the connecting tubule cells suggests the CS has a significant role in calcium reaborption (491 ,492).

Collecting Duct

The collecting duct begins in the cortex and descends to the tip of the papilla, also called the area cribrosa, where the inner medullary segments terminate as the ducts of Bellini. These terminal collecting duct segments were apparently described by Eustachio nearly 100 years before the observation of Bellini (493). During its course, there is an increase in diameter from the cortical portion to the terminal segments at the area cribrosa. The collecting duct can be divided into the cortical (CCD), outer medullary (OMCD), and inner medullary collecting ducts (IMCD). Significant cellular heterogeneity exists along the collecting duct (271). Although there is a degree of nonspecificity, the lectins *Dolichos biflorus* and *Arachis hypogaea* have been used as markers for collecting duct epithelium (Figure 34.76) (427). The distal tubules and collecting ducts show variable but generally more intense staining for keratins than do the proximal tubules (Figures 34.77 ,34.78). Keratins 8, 18, and 19 are prominently expressed throughout the cortical and medullary collecting ducts (379 ,380 ,429). There is less

staining for keratin 7. Scattered keratin 7- and 19-negative cells have

been observed to be intercalated cells (379). Keratins 5/6, 17, and 20, as well as vimentin, are restricted primarily to medullary collecting ducts (429). There is less immunoreactivity for Ksp-cadherin in collecting ducts compared to the thick ascending limbs and distal convoluted tubules (477).

Cortical Collecting Duct

The cortical collecting duct can be subdivided further into the initial collecting tubule and the medullary ray portion. By light microscopy, the epithelium of the cortical collecting duct consists of cuboidal cells with distinct lateral cell borders and central round nuclei (Figure 34.79). The lumen is prominently open, and there is no brush border. The cortical collecting duct is composed of principal cells and intercalated cells. Principal cells are mainly responsible for salt and water transport, and the intercalated cells are involved in acid-base regulation. It is difficult to distinguish principal cells from intercalated cells on H&E paraffin sections. The principal cells on light microscopy have an extremely light or clear cytoplasm. By electron microscopy, the principal cells have relatively few cell organelles and no interdigitations of lateral cellular processes from adjacent cells, which accounts for the distinct cell borders observed on light microscopy (Figure 34.80). However, there are prominent infoldings of the basal plasma membrane, which gives the basal region an accentuated clear appearance on light microscopy (494). The principal cell has a fairly

smooth luminal surface with short microvilli and a single cilium by scanning electron microscopy (Figure 34.88).

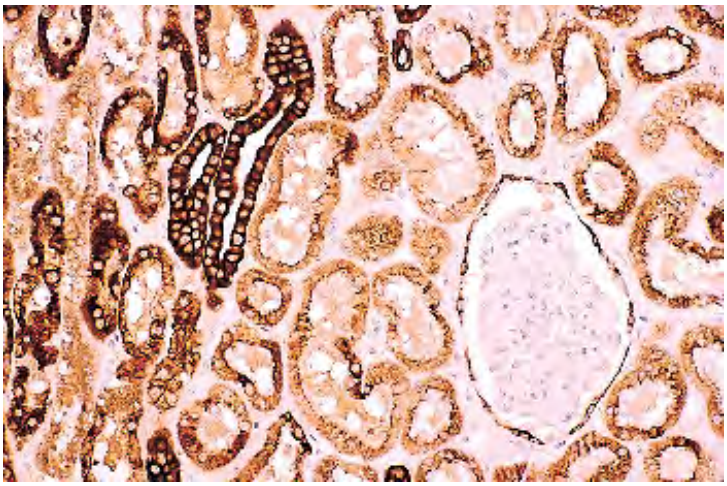

Figure 34.77 Distal tubules, collecting ducts, proximal tubules, and parietal epithelium lining Bowman's capsule showing expression of keratins. The distal tubules and collecting ducts label more intensely than do the proximal tubules. (CAM 5.2 immunoperoxidase, original magnification Ã—62.)

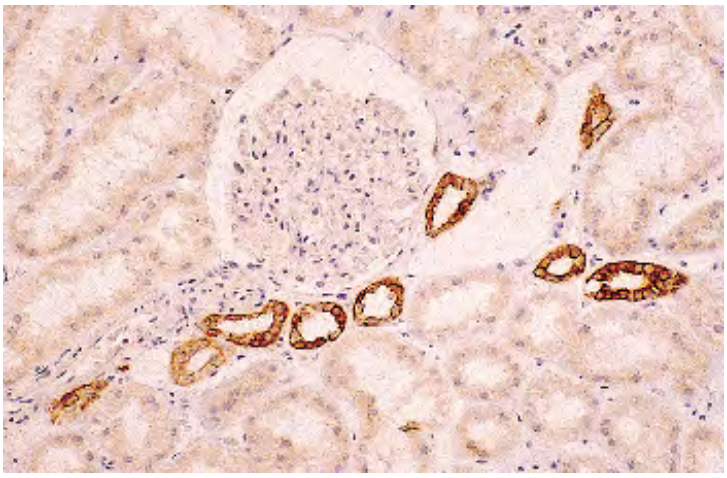

Figure 34.78 Detection of keratin expression varies depending on the specificity and dilution of the antibody. In this micrograph, there is prominent immunoreactivity of the distal tubules and collecting ducts. (35Î²H11 immunoperoxidase, original magnification Ã—62.)

Principal cells are involved in sodium reaborption and potassium secretion. Sodium reaborption is mediated by

an amiloride-sensitive sodium channel, ENaC, located in the apical membrane of principal cells throughout the entire collecting duct (495 ,496). Experimental conditions of dietary potassium loading or mineralocorticoid stimulation have shown increases in potassium secretion and Na^+ /K^+ -ATPase activity in the cortical collecting duct, along with an increase in the surface area of the basolateral membrane of the principal cells (497 ,498 ,499 ,500 ,501). These findings indicate that the principal cells are involved in potassium secretion in the cortical collecting duct. The entire collecting duct becomes permeable to water in the presence of the antidiuretic hormone vasopressin. After vasopressin binds to its receptor on the basolateral membrane of principal cells (502), small apical cytoplasmic tubulovesicles (called aggrephores) containing the aquaporin water channel AQP2 are shuttled to the apical membrane, which markedly increases water permeability (503 ,504). The presence of the aquaporin water channels AQP3 and AQP4 in the basolateral membranes of principal cells facilitate the final exit of water into the interstitium (505 ,506).

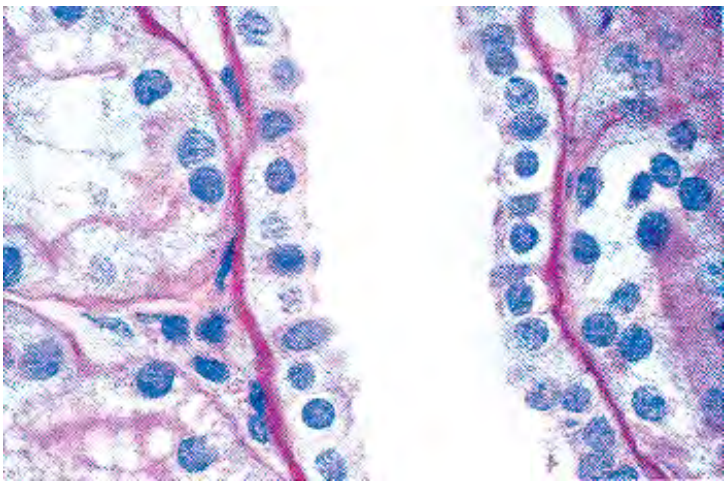

Figure 34.79 Micrograph illustrating a cortical collecting duct. Note the distinct lateral cell orders (original magnification Ã—500).

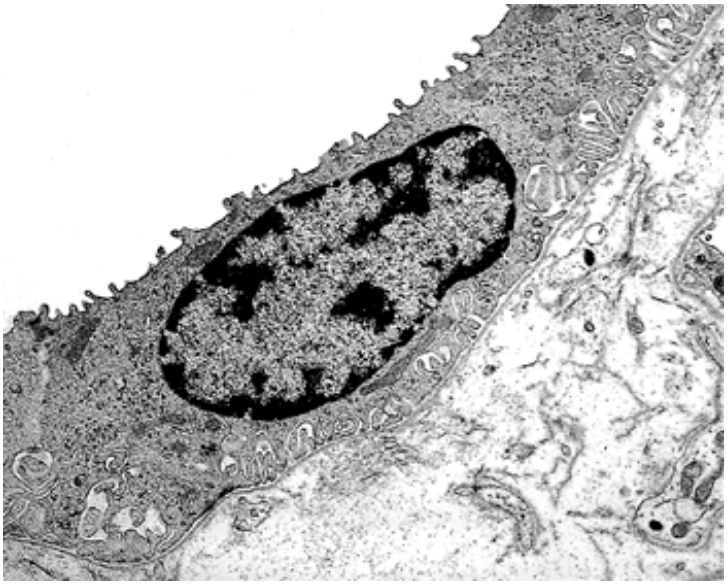

Figure 34.80 Electron micrograph of principal cell from the collecting duct. Note the relatively prominent infoldings of the basal plasma membrane (original magnification Ã—12,500).

The intercalated or â€œdarkâ€• cells are interspersed in the lining epithelia of the collecting duct. Although intercalated cells usually represent the minority cell type in epithelia where they are found, they constitute 30 to 40% of the cells in the cortical collecting duct in some mammals (271 ,280). They are also present in the connecting segment, the outer medullary collecting duct, and the initial portion of the inner medullary collecting duct. Intercalated cells may be identified on 1-Âµm thick toluidine blue-stained Epon sections by their densely staining cytoplasm and their often convex luminal surface covered with numerous microprojections (Figure 34.81). The darkly staining cytoplasm is due in part to the presence of relatively more organelles, especially mitochondria. Two distinct populations of intercalated cells, types A and B, have been described in the cortical collecting duct of mammals (507 ,508). On ultrastructural examination, the type A intercalated cells have prominent microprojections of the apical membrane and extensive tubulovesicular structures in the apical cytoplasm (Figure 34.82). In comparison with the type A cells, the

type B intercalated cells have a denser cytoplasm, more mitochondria, a smaller apical membrane area, a small number of microprojections on the apical surface, more spherical vesicular structures throughout the cytoplasm (but fewer vesicles beneath the apical membrane), and a larger basolateral membrane surface area (Figure 34.83). By scanning electron microscopy, the type A cells have a large convex luminal surface covered with numerous complex microprojections called microplicae (Figure 34.84), whereas the type B cells display a small angular luminal surface with relatively small microvilli (Figure 34.85) (508). The type B intercalated cells may be inconspicuous on scanning electron microscopy. More recently, a third type of intercalated cell has been characterized in the cortical

collecting duct of some mammals (509 ,510). They account for 40 to 50% of intercalated cells in the mouse connecting segment and initial collecting duct. The non-Aâ€“non-B intercalated cells are larger than type A and type B intercalated cells, have abundant mitochondria, and have prominent apical microprojections similar to those of type A cells. Compared to the type A and B intercalated cells, the non-Aâ€“non-B intercalated cells have been studied in fewer species, mainly the rat and mouse. There are significant differences in the prevalence and distribution of the different types of intercalated cells throughout the connecting segment and cortical collecting duct among mammalian species (280).

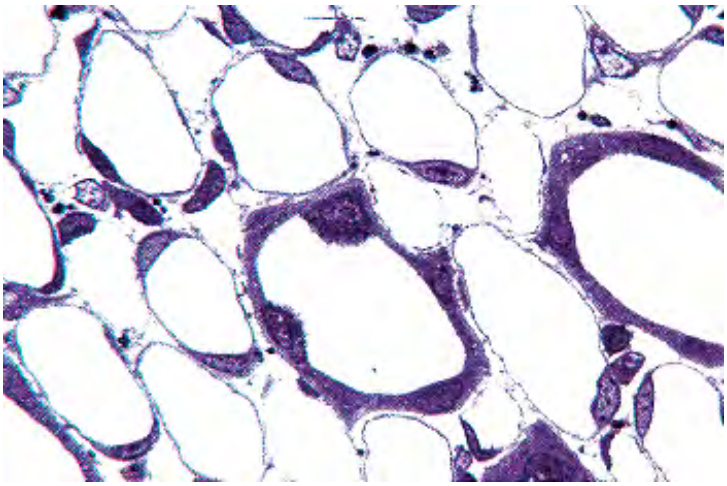

Figure 34.81 Light micrograph of the outer medulla showing intercalated cells in the collecting ducts. The intercalated cells exhibit a bulging apical surface covered with microprojections and dark-staining cytoplasm. (One-micron toluidine blue-stained Epon section, original magnification Ã—160.)

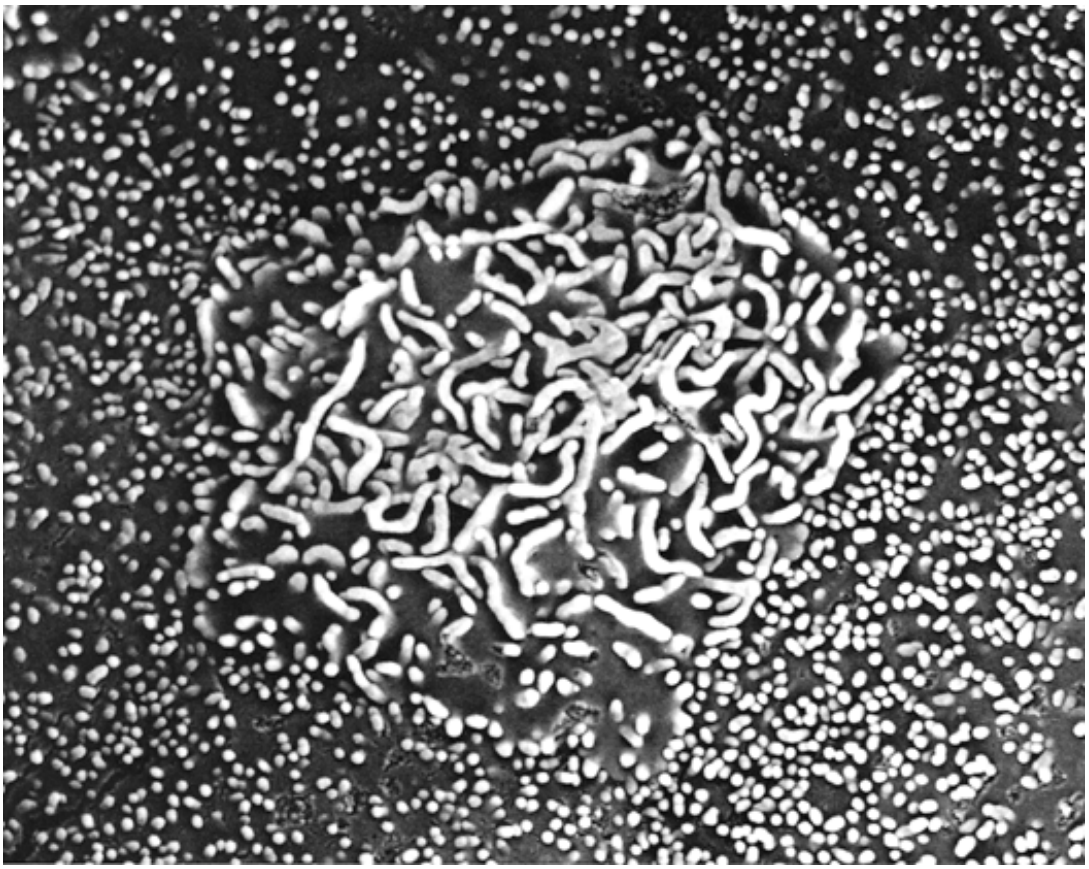

Figure 34.84 Scanning electron micrograph of the luminal surface of a type A intercalated cell in the cortical collecting duct. The type A cell is well demarcated and has a large luminal surface covered primarily with microplicae but also microvilli. (Original magnification Ã—15,000; courtesy of Dr. Jill W. Verlander.).

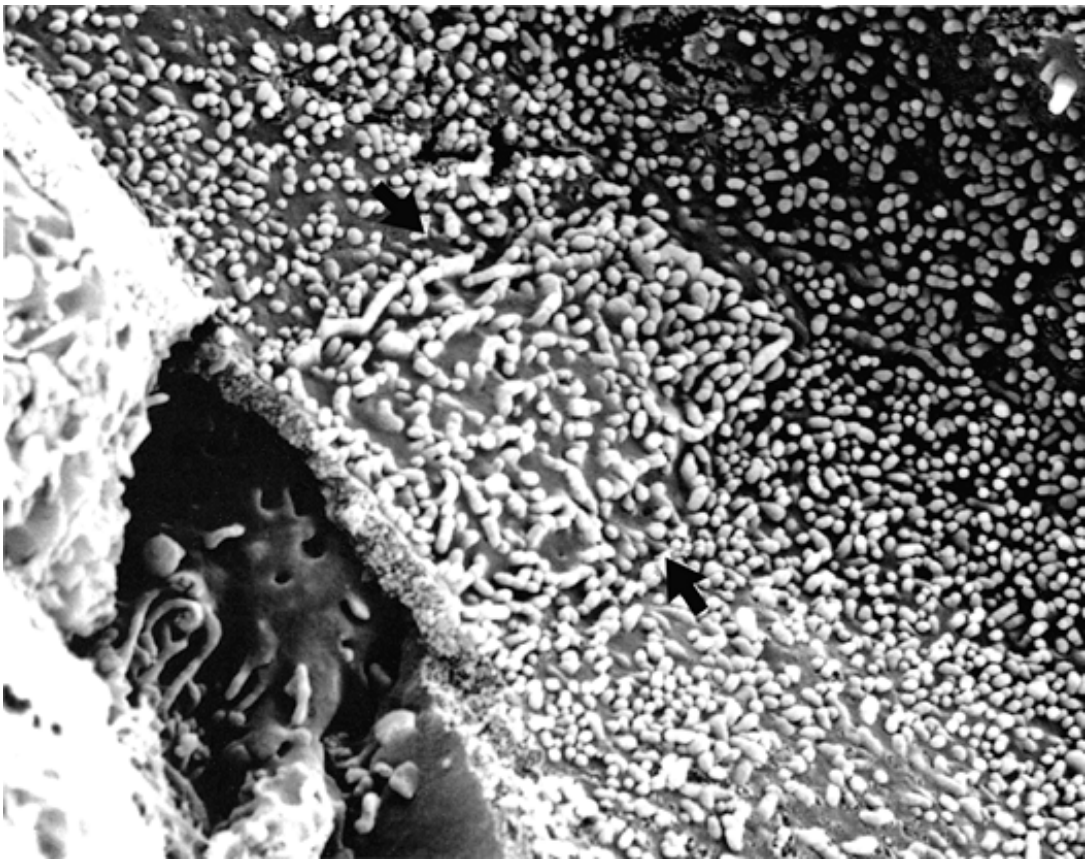

Figure 34.85 Scanning electron micrograph of the luminal surface of a cortical collecting duct. A type B intercalated cell (*arrows*) displays a small angular luminal surface covered with short microprojections, mainly microvilli. (Original magnification Ã—15,000; courtesy of Dr. Jill W. Verlander.)

Intercalated cells are typified by their high levels of carbonic anhydrase, the enzyme that catalyzes the interconversion of carbon dioxide (CO_2) to bicarbonate (HCO_3^-), suggesting they are involved in urine acidification (511). Physiologic studies have demonstrated that the cortical collecting duct reabsorbs bicarbonate in acid-loaded animals (512) and secretes bicarbonate in alkali-loaded animals (513). In a study of experimental acute respiratory acidosis, there was a striking increase in the apical membrane surface area of the type A intercalated cells, whereas no morphologic changes were observed in the type B cells (508).

Studies have immunolocalized the vacuolar-type proton pump H^+ -ATPase in the apical membrane (514 ,515 ,516) and the Cl^- /HCO_3^- exchanger, AE1 (Band 3), in the basolateral membrane (507 ,516 ,517 ,518) of type A intercalated cells. These findings indicate that type A cells are responsible for H^+ secretion in the cortical collecting duct. The immunolocalization of the H^+ -ATPase to the basolateral membrane of type B intercalated cells (515 ,516) and the physiologic evidence for an apical Cl^- /HCO_3^- exchange in these cells (519) indicate that type B cells are involved in bicarbonate secretion. Evidence has accumulated to indicate that the apical Cl^- /HCO_3^- exchange in the type B cell is mediated by the protein pendrin, which immunolocalizes to the apical membrane and apical cytoplasmic vesicles of the B cell (520 ,521 ,522). Furthermore, the renal cortical expression of pendrin is increased in alkali-loaded animals and decreased in acid-loaded animals (523). Type B intercalated cells are most numerous in the cortical collecting duct. Pendrin is not in the same protein family as AE1 (524). Mutations of the gene encoding pendrin result in

Pendred's syndrome, a disorder mainly associated with a thyroid goiter and deafness (525). The non-Aâ€“non-B intercalated cells express pendrin in the apical membrane and cytoplasmic vesicles like type B intercalated cells but also express the H^+ -ATPase in the apical membrane-like type A intercalated cells (522 ,526). It is unclear whether the non-Aâ€“non-B cells function as H^+ - or HCO_3^- -secreting cells or possibly switch between these two functions. Thus, the types of intercalated cells may be defined by their cellular distribution of the H^+ -ATPase and the presence or absence of the anion exchangers, AE1 and pendrin (527). Alternatively, it has been proposed that intercalated cells exhibit a high degree of plasticity and may reverse their apical-basolateral polarity in response to changes in the acid-base status (528). For example, it has been reported that type B intercalated cells can convert to type A cells in response to metabolic acidosis (529).

Outer Medullary Collecting Duct

The collecting duct traverses the outer medulla without receiving tributaries. The outer medullary collecting duct is lined by principal cells and intercalated cells (Figure 34.86). The principal cells in this segment are similar to those in the cortical collecting duct but are taller and have fewer organelles and basal membrane infoldings. The intercalated cells constitute 18 to 40% of the cells in the outer medullary collecting duct in some species and gradually decrease along this segment (530 ,531). The intercalated cells in the outer medullary collecting duct resemble the type A intercalated cells in the cortical collecting duct but are taller and have a less dense cytoplasm.

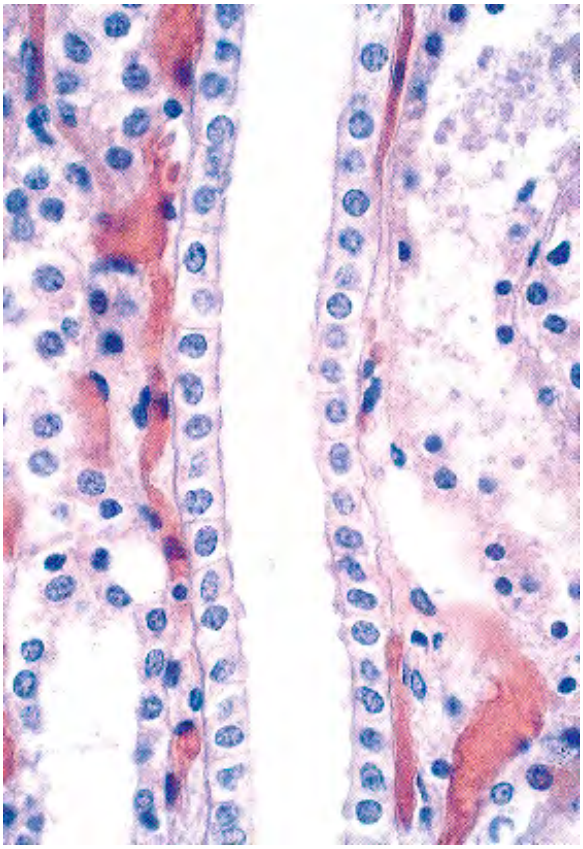

Figure 34.86 Light micrograph illustrating longitudinal section of an outer medullary collecting duct (original magnification Ã—250).

The outer medullary collecting duct plays a major role in urine

acidification. An increase in the surface area of the apical plasma membrane of the intercalated cells in this segment has been demonstrated after hydrogen ion stimulation (532 ,533). The apical and basolateral membranes of these cells label with antibodies against the H^+ -ATPase and the chloride/bicarbonate exchanger, respectively (514 ,518). These findings suggest that the intercalated cells in the outer medullary collecting duct are responsible for hydrogen ion secretion. In addition, this segment may be an important site of potassium reabsorption. The functional presence of H^+ /K^+ -ATPase activity in the outer medullary collecting duct (534 ,535) and the immunohistochemical (536) and in situ hybridization (537 ,538) localization of H^+ /K^+ -ATPase in the intercalated cells of this segment indicate that these cells are involved in potassium reabsorption in exchange for hydrogen ion secretion.

Inner Medullary Collecting Duct

The inner medullary collecting duct (IMCD) represents the terminal portion of the collecting duct. Although the IMCD is often called the papillary collecting duct, only the inner two-thirds of the IMCD are located in the papilla.

Descending through the inner medulla, the collecting ducts join in successive fusions, which result in an arborescent architectural arrangement. There is a significant increase in diameter and height of the epithelium as the ducts descend (539). The height of the cells increases gradually from cuboidal to columnar (Figure 34.87). However, in the terminal portion of the human inner medulla there is often an abrupt transition between collecting ducts lined with cuboidal cells and the ducts of Bellini, which are composed of tall columnar cells.

Structural and functional heterogeneity exist along the IMCD (539). It can be subdivided arbitrarily into three portions:

the outer third ($IMCD_1$), middle third ($IMCD_2$), and inner third ($IMCD_3$

). However, there is physiologic evidence for the division of the IMCD into two functionally distinct segments, which are termed the initial IMCD and the terminal IMCD (540 ,541).

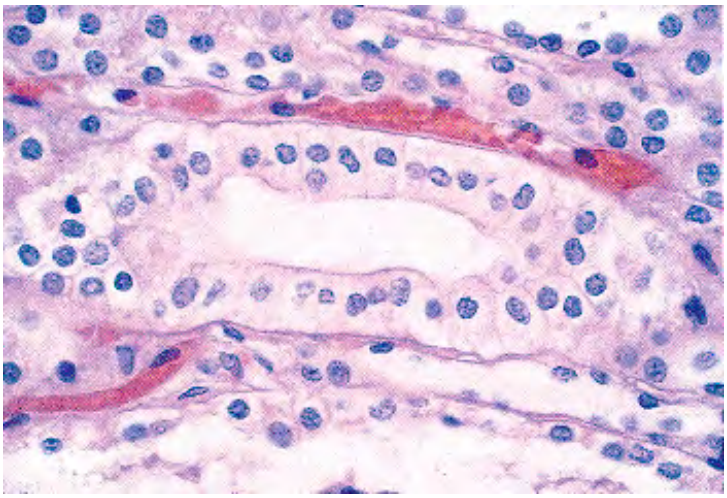

Figure 34.87 Micrograph illustrating columnar cells of the collecting duct in the inner medulla (original magnification Ã—500).

The initial IMCD is the outer segment and mainly corresponds to the $IMCD_1$, whereas the terminal IMCD includes most of the $IMCD_2$ and the $IMCD_3$. The initial IMCD consists mainly of principal cells that are similar in structure to the principal cells in the OMCD. In the rat, intercalated cells similar to the type A intercalated cells in the OMCD comprise approximately 10% of the cells in the initial IMCD (Figure 34.88) (542). Intercalated cells are rare to absent in the initial IMCD of the human (485) and rabbit (530). The terminal IMCD is composed of mainly one cell type, the IMCD cell. Compared with principal cells, the IMCD cells are taller and have lighter staining cytoplasm containing numerous ribosomes, small lysosomes in the basal cytoplasm, and fewer infoldings of the basal plasma membrane (Figure 34.89) (543). By scanning electron microscopy, the IMCD cells display more numerous small microvilli and lack the central cilium characteristic of principal cells (Figure 34.90).

The inner medullary collecting duct has an important role in urinary

concentration. The reabsorption of urea and water in this segment causes the formation of a concentrated urine. Physiologic studies demonstrated that urea and water permeabilities are low in the initial IMCD and relatively high in the terminal IMCD (540 ,541). Water permeability is increased by vasopressin in both subsegments and is mediated by the aquaporin water channel AQP2 present in the apical membrane of the IMCD cells (503). Vasopressin increases urea permeability only in the terminal IMCD. The urea transporters UT-A1 and UT-A3 immunolocalize to the terminal IMCD and mediate urea transport in this segment (544 ,545 ,546). There is evidence that the IMCD is also involved in urine acidification. Acid secretion mediated by an H^+ /K^+ -ATPase has been demonstrated in isolated perfused segments from this region, although no immunoreactivity for this transport protein has been demonstrated in the IMCD (547).

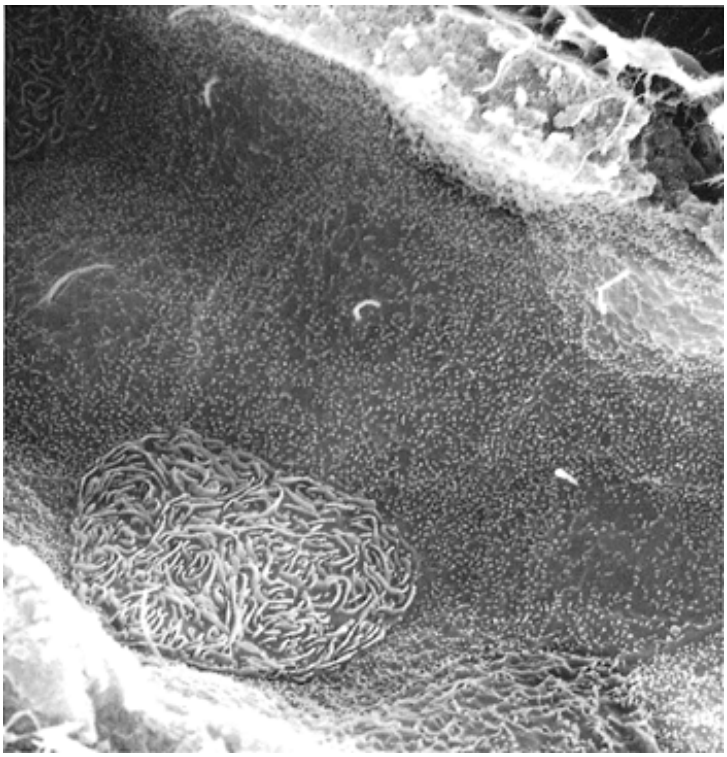

Figure 34.88 Scanning electron micrograph of the inner medullary collecting duct. The intercalated cell is round and exhibits a convex luminal surface covered with microplicae without cilia. The adjacent principal cells are characterized by short microvilli and a single central

cilium on their luminal surface. (Original magnification Ã—12,000.) Reprinted with permission from:

Interstitium

The renal interstitium consists of an extracellular matrix containing sulfated and nonsulfated glucosaminoglycans and interstitial cells (548). In humans, estimates of the relative

cortical interstitial volume range from 5 to 20%, with a mean of 12% (549 ,550 ,551). A significant increase with age has been reported (551). The peritubular interstitial tissue in the normal cortex is inconspicuous on light microscopy, and the tubules and capillaries often have a back-to-back architectural appearance (Figure 34.91). Types I and III collagen and fibronectin are present (552). The periarterial connective tissue constitutes a loose sheath around the intrarenal arteries and contains the lymphatic vessels (553). The periarterial connective tissue should not be overinterpreted as representing focal interstitial fibrosis in the cortex. Two types of cortical interstitial cells have been described: a fibroblast-like cell and a lymphocyte-like cell (548). The fibroblast-like cells show immunoreactivity for ecto-5-nucleotidase (5-NT) (554). These 5-NT-postive interstitial fibroblasts are the erythropoietin-producing cells in the kidney (555 ,556).

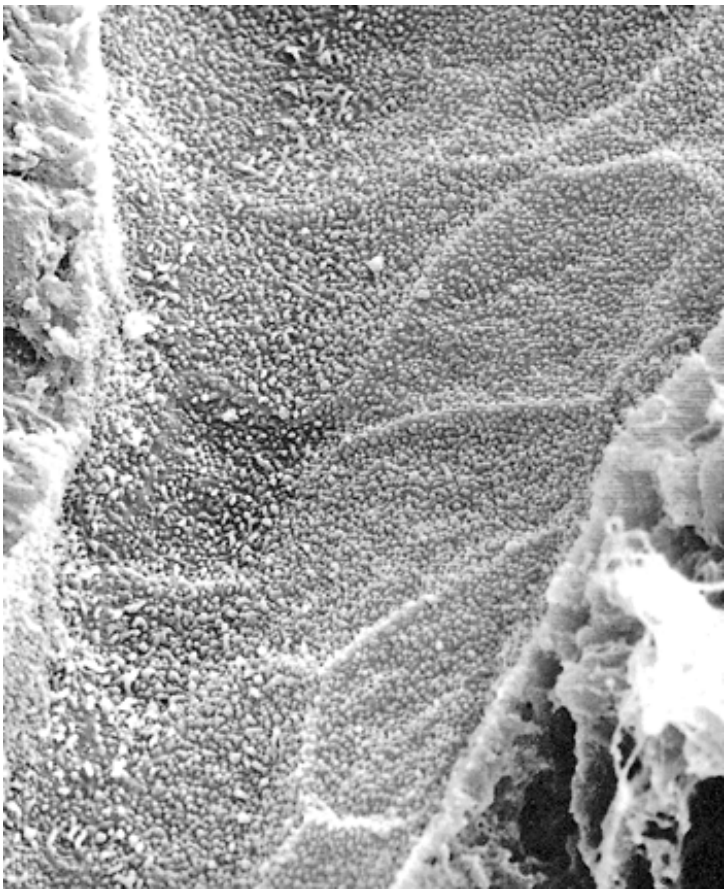

Figure 34.90 Scanning electron micrograph of the terminal IMCD. The entire luminal surface of the IMCD cells is covered with abundant short microvilli. There is an absence of cilia. (Original magnification Ã—12,500). Reprinted with permission from:
Clapp WL, Madsen KM, Verlander JW, Tisher CC. Morphologic heterogeneity along the rat inner medullary collecting duct. *Lab Invest* 1989;60:219â€“230.

The relative volume of the renal interstitium increases from the cortex to the tip of the papilla. The interstitial volume has been reported from 10 to 20% in the outer medulla to approximately 30 to 40% at the papillary tip in some species (557). This appreciable amount of interstitium in the medulla should not be mistaken for interstitial fibrosis by the pathologist. The medullary interstitium has a gelatinous appearance on light microscopy (Figure 34.92). The interstitial cells in the medulla include lymphocyte-like cells virtually identical to the ones

in the cortex, pericytes situated near the descending vasa recta, and prominent lipid-containing cells mainly localized to the inner medulla (548). The latter, the renomedullary interstitial cells, are often arranged in rows between the loop of Henle and the vasa recta, have irregular, long cytoplasmic processes, and contain lipid inclusions. These cells can be observed on 1-Âµm thick toluidine blue-stained sections of the inner medulla. The lipid droplets contain mainly triglycerides that are rich in unsaturated fatty acids, including arachidonic acid, phospholipids, and cholesterol (548). In addition to the synthesis of the extracellular matrix of the interstitium, the renomedullary interstitial cells are believed to contribute to the endocrine-like antihypertensive function of the renal medulla (558 ,559).

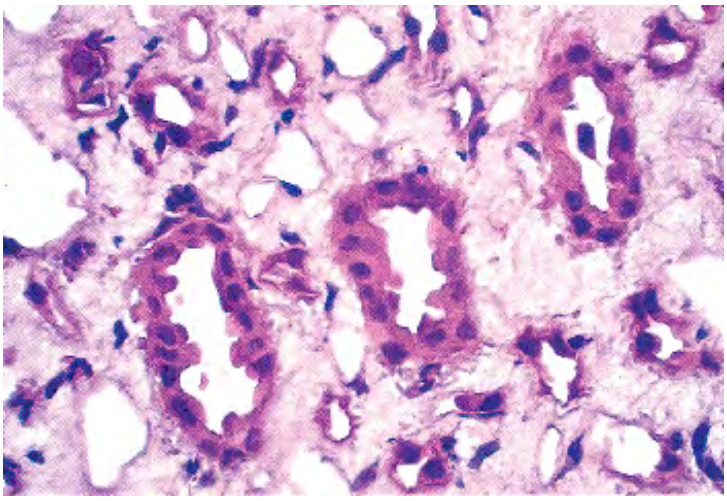

Figure 34.92 Renal biopsy specimen illustrating the inner medulla. Note the prominent amount of interstitium surrounding the tubules. (Original magnification Ã—500.)

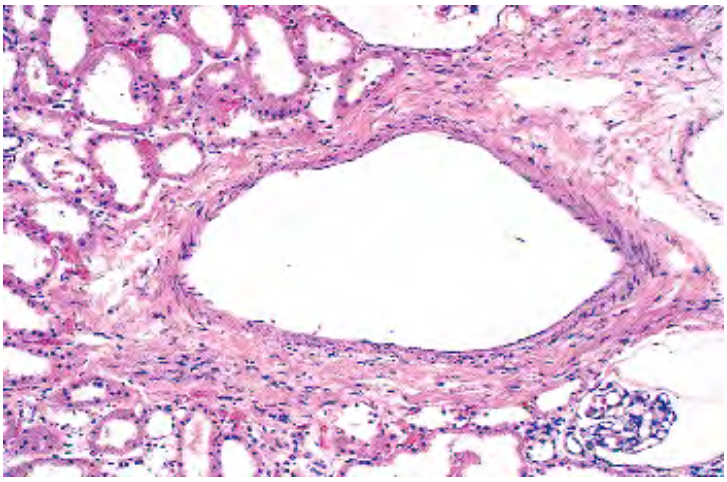

Figure 34.93 Micrograph of the corticomedullary junction illustrating an arcuate artery (original magnification Ã—125).

Vasculature

A detailed description of the renal vasculature is available (560). The segmental arteries, originating from the anterior and posterior

divisions of the main renal artery, divide to form the interlobar arteries, which course toward the cortex along the septa of Berlin between adjacent renal pyramids. At the corticomedullary junction, the interlobar arteries give rise to the arcuate arteries, which follow a gently curved course along the base of the pyramids parallel to the kidney surface (Figure 34.93). The interlobular arteries branch sharply from the arcuate arteries and ascend in the cortex in a radial fashion toward the renal surface. Because the renal lobules cannot be clearly distinguished, it has been recommended that the interlobular arteries be called cortical radial arteries (276 ,560).

Most afferent arterioles originate from the interlobular arteries, and each supplies a single glomerulus. The angle of origin of the afferent arterioles becomes less recurrent and more open as the interlobular arteries extend to the outer cortex (Figure 34.94) (561). The length of the afferent arterioles is variable; average values of 170 to 280 Âµm have been reported (Figure 34.95) (562 ,563). Some rare branches of the intrarenal arteries that do not terminate in glomeruli, the so-called aglomerular vessels, may result from degeneration of the connected glomeruli (561). Aglomerular arterioles near the corticomedullary junction have been observed to enter the medulla, and shunt arterioles between afferent and efferent arterioles have been reported (564 ,565 ,566).

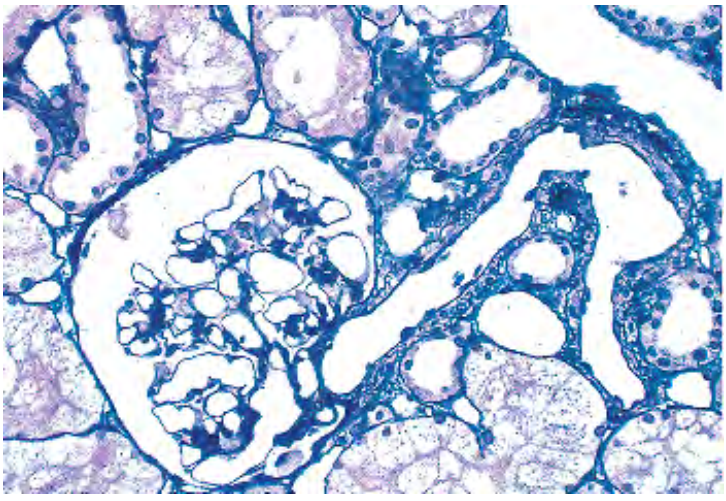

Figure 34.94 Juxtamedullary glomerulus with a connected hilar

arteriole. Note the recurrent angle of the arteriole. (Silver methenamine stain, original magnification Ã—250.)

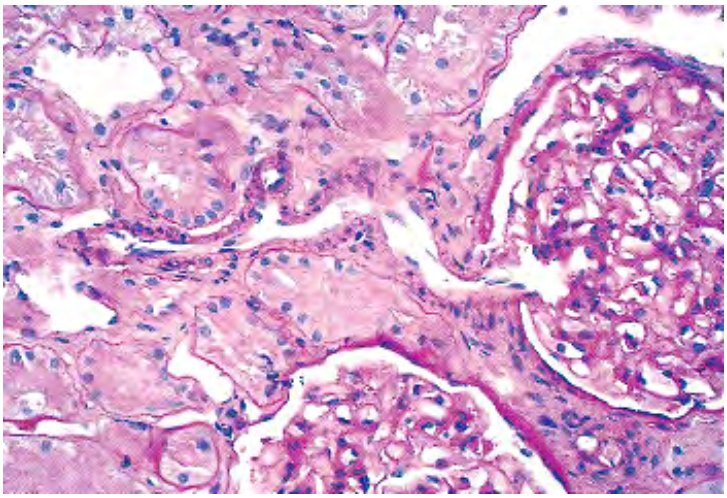

Figure 34.95 Micrograph depicting the transverse course of an afferent arteriole supplying a glomerulus. (PAS stain, original magnification Ã—250.)

The wall structure of the intrarenal arteries and the proximal portion of the afferent arterioles resembles that of blood vessels of the same size elsewhere in the body. The endothelium stains for factor VIIIâ€“related antigen (Figure 34.96) (567 ,568) and CD34 (Figure 34.97) (569 ,570), whereas the muscularis stains for smooth muscle actin (Figure 34.98) (571) and vimentin.

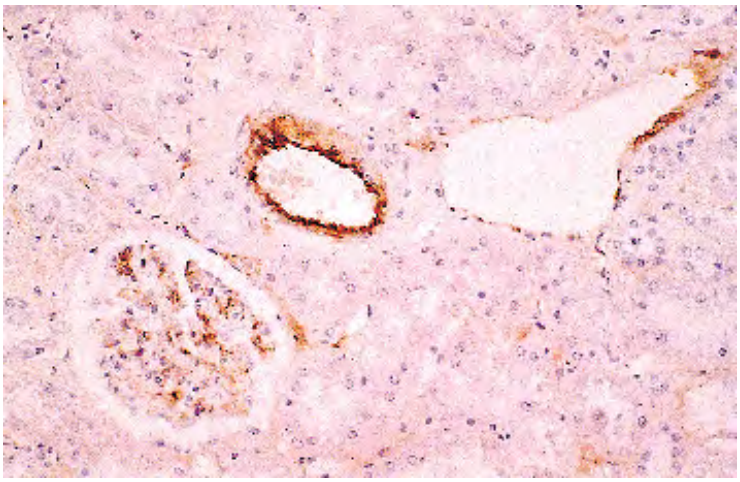

Figure 34.96 Factor VIII is produced by endothelium. The micrograph shows factor VIII immunoperoxidase staining of a medium-sized artery (*center*), vein (*right*), and glomerulus (*left*) (original magnification Ã—62).

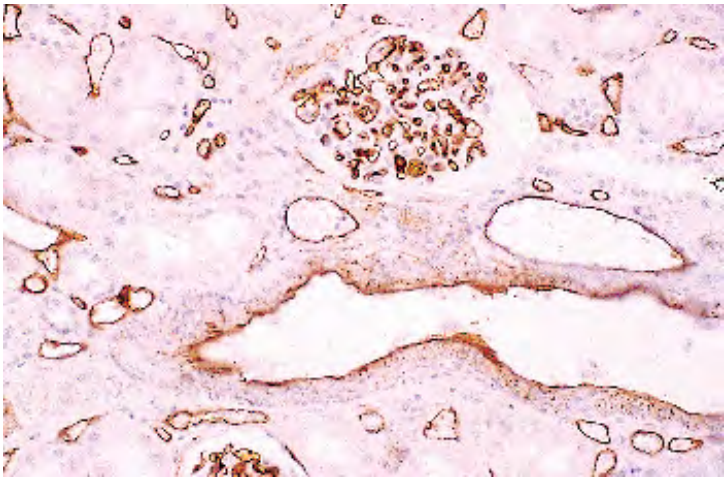

Figure 34.97 CD34 immunoperoxidase staining demonstrates a greater variety of vascular structures that label more intensely than with factor VIII. In the micrograph, arteries, veins, glomeruli, and peritubular capillaries are immunoreactive (original magnification Ã—62).

The efferent arterioles from the glomeruli branch to form a complex

postglomerular microcirculation (Figure 34.99). Although gradations exist, three basic types of efferent arterioles may be distinguished (572 ,573). The superficial or outer cortical efferent arterioles are fairly long and divide into extensive capillary networks that supply the convoluted tubules of the cortical labyrinth. These capillaries are readily identified by CD34 and smooth muscle actin staining (Figures 34.98 , 34.100 ,34.101). The midcortical efferent arterioles are variable in length and supply the cortical labyrinth and the straight tubules of the medullary rays. With the exception of the outer cortex, there is dissociation between the tubule segments and the efferent arterioles of their parent glomeruli. In the midcortex and inner cortex, tubule segments are supplied by capillaries of efferent arterioles from other glomeruli (574 ,575).

The efferent arterioles from juxtamedullary nephrons descend and supply the entire medulla. In contrast to the efferent arterioles of superficial and midcortical glomeruli (Figure 34.102), those from juxtamedullary glomeruli are larger in diameter, display more layers of smooth muscle cells, and have more endothelial cells on cross sections (274 ,560).

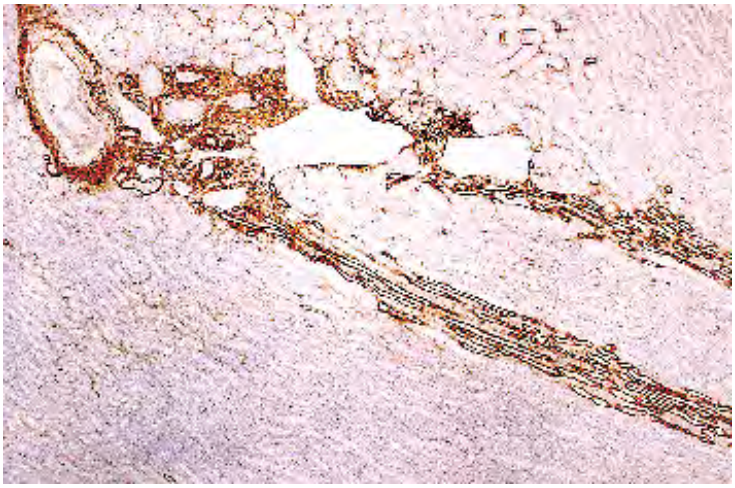

Figure 34.98 Smooth muscle actin immunoperoxidase stain illustrating a labeled large artery (*upper left*) and arterioles at the corticomedullary junction and two positive-stained columns of vasa

recta (*midright*) penetrating the medulla. Two venous profiles (*upper center*) have minimal muscularis. (Original magnification Ã—11.)

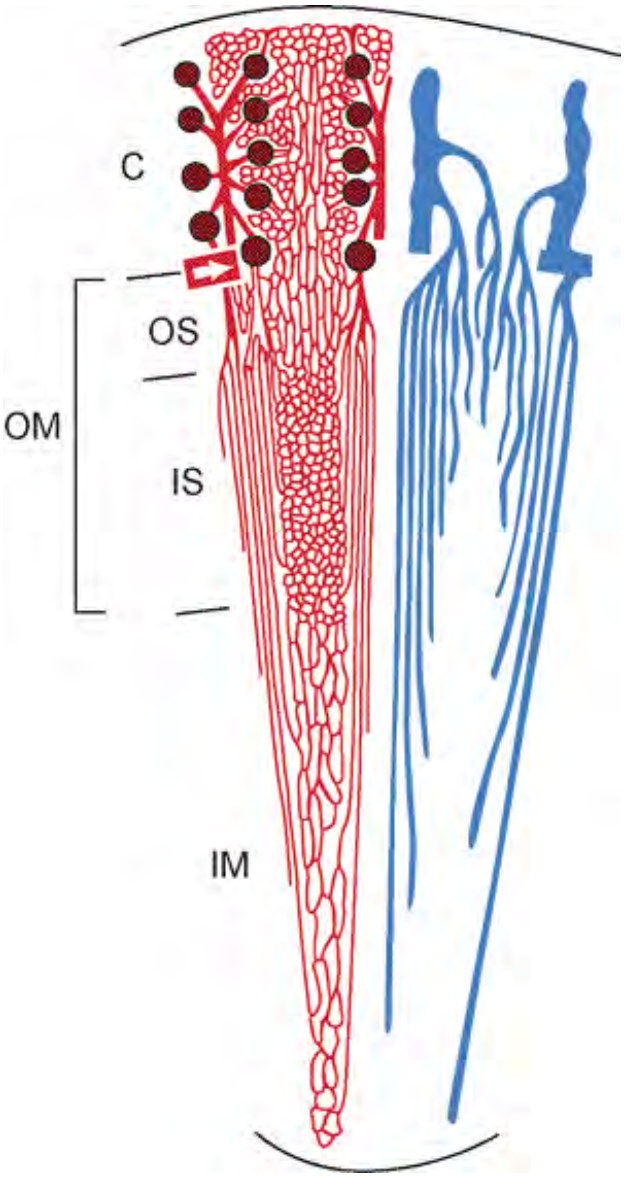

Figure 34.99 The renal microvasculature. The left side (red) illustrates the arterial vessels, glomeruli, and capillaries. An interlobular artery originates from an arcuate artery (*white arrow*) and gives rise to the afferent arterioles, which supply the glomeruli (dark brown). The efferent arterioles of the superficial and midcortical glomeruli supply the capillary plexuses of the cortical labyrinth and the

medullary rays. The efferent arterioles of the juxtamedullary glomeruli descend into the medulla and form the descending vasa recta, which supply the adjacent capillary plexuses. Note the prominence of the capillary plexus in the inner stripe of the outer medulla. The right side (blue), which may be superimposed on the left side, displays the venous system. The ascending vasa recta drain the medulla and empty into the arcuate and interlobular veins, which drain the cortex. The vasa recta from the inner medulla ascend within the vascular bundles, whereas most vasa recta from the inner stripe ascend between the bundles. Kriz W, Kaissling B. Structural organization of the mammalian kidney. In: Seldin DW, Giebisch D, eds. *The Kidney: Physiology and Pathophysiology* . 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:587â€“654.

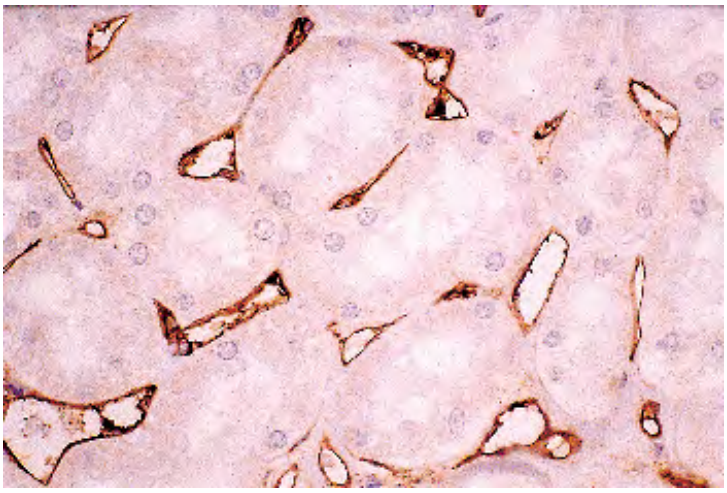

Figure 34.100 The extensive cortical peritubular capillary network is shown by endothelial labeling with CD34 antibody. (CD34 immunoperoxidase, original magnification Ã—120.)

In the outer stripe of the outer medulla, the efferent arterioles of juxtamedullary nephrons divide to form the descending vasa recta that descend in the vascular bundles but at intervals leave the bundles to

form capillary plexuses. The ascending (or venous) vasa recta drain the renal medulla. The ascending vasa recta from the inner medulla join the vascular bundles, whereas most from the inner stripe of the outer medulla ascend between the bundles (560). This architectural arrangement creates a functional separation of the blood flow to the outer and inner medulla. The close proximity of the arterial descending and venous ascending vasa recta within the vascular bundles permits effective countercurrent exchange (274 ,560). The ascending vasa recta at the corticomedullary junction empty into the arcuate and interlobular veins (Figure 34.98), which do form extensive anastomoses, in contrast to the arcuate arteries.

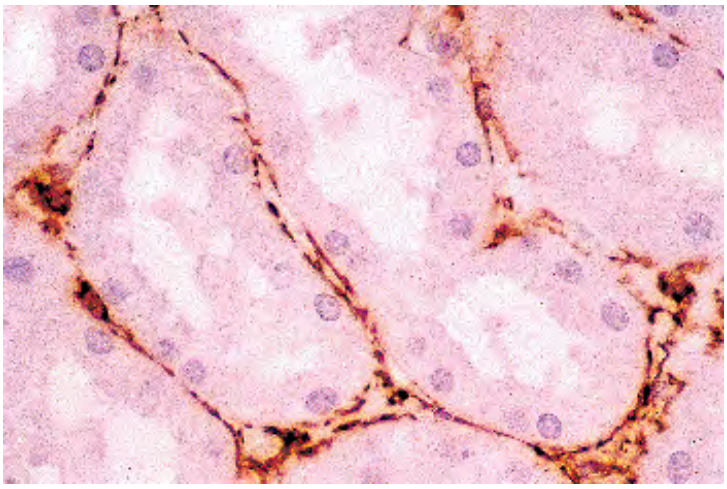

Figure 34.101 Smooth muscle actin expression complements and parallels the CD34 expression in documenting the cortical peritubular capillaries. (Smooth muscle actin immunoperoxidase, original magnification Ã—120.)

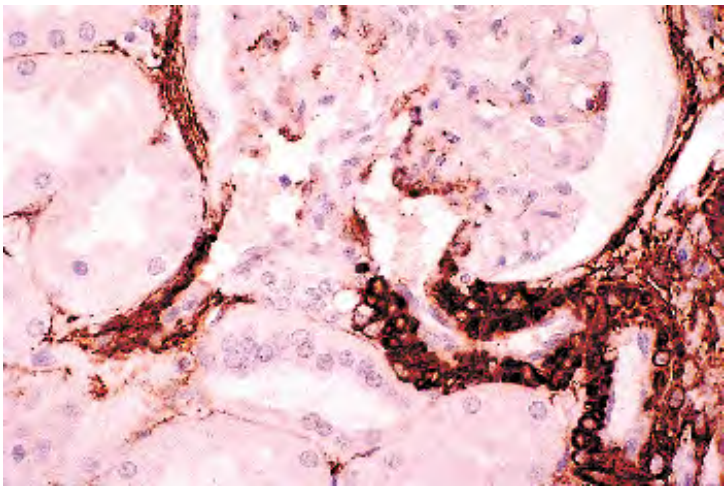

Figure 34.102 Smooth muscle actin immunoperoxidase of a superficial glomerulus delineating the more prominent smooth muscle investment of the afferent arteriole (*right*) compared with the efferent arteriole (*left*) (original magnification Ã—120).

The interlobular veins, which accompany the interlobular arteries, drain the cortex and empty into the arcuate veins. In sections the intrarenal veins have less musculature than comparably sized veins in other organs (Figure 34.98). The arcuate veins empty into the interlobar veins, which converge to form a single renal vein that exits at the hilus of the kidney.

Lymphatics

The lymphatic vessels of the kidney are embedded in the loose periarterial connective tissue in the cortex (Figure 34.103) (576 ,577 ,578). They are not prominent on routine histologic sections. The lymphatics originate as small vessels around the interlobular arteries and empty into arcuate and interlobar lymphatics, which finally drain into larger lymph vessels at the renal hilus. The interlobar and hilar lymphatics possess valves. Lymphatics are not believed to exist in the renal medulla (560 ,578). There is a less prominent subcapsular network of lymphatic vessels that appears to communicate with the major intrarenal lymphatics within the cortex (578). It has been

proposed that the periarterial spaces and the lymphatics may function as a unit to allow exchange with the venous system and serve as a route for the intrarenal distribution of hormones and inflammatory cells (579). Several markers of lymphatic endothelium are now available including: VEGFR-3 (receptor for VEGF-C, VEGF-D, lymphatic angiogenic factor), LYVE-1 (a CD44 homologous hyaluronate receptor), Prox-1 (lymphatic

vessel transcription factor), and podoplanin (a membrane mucoprotein) (580).

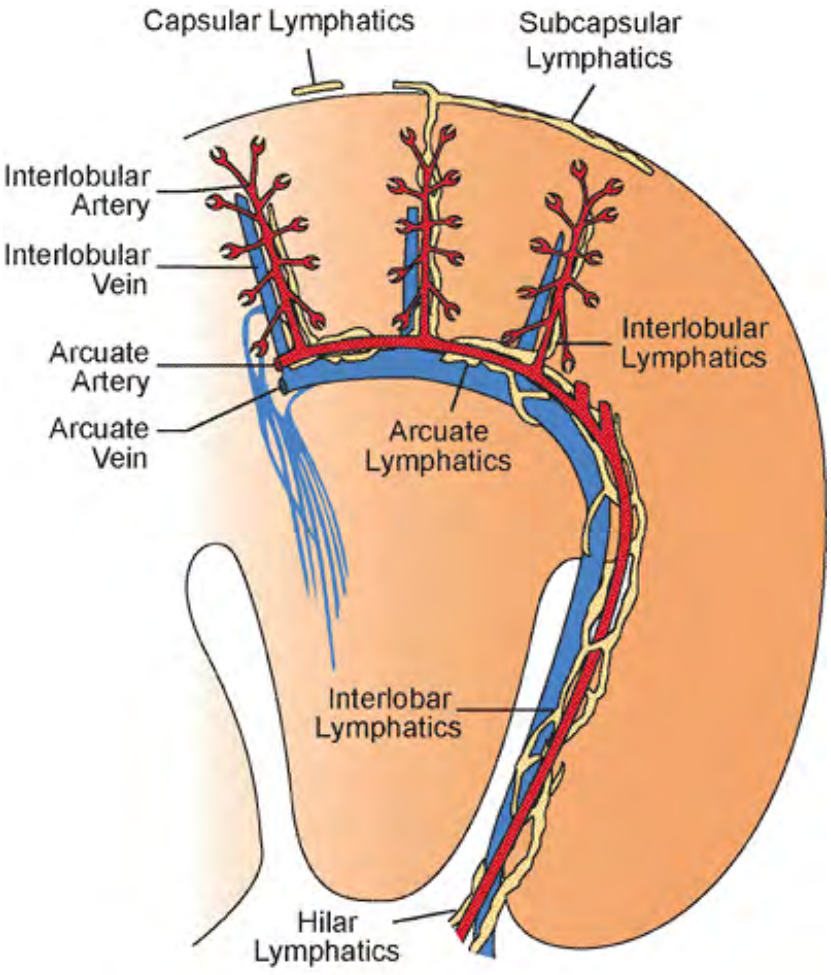

Figure 34.103 The lymphatic vessels of the kidney. The arteries (red), veins (blue), and lymphatics (yellow) are illustrated. The lymphatics

are primarily distributed in the cortex, although a subcapsular network is also present. Note the absence of the lymphatics in the medulla.

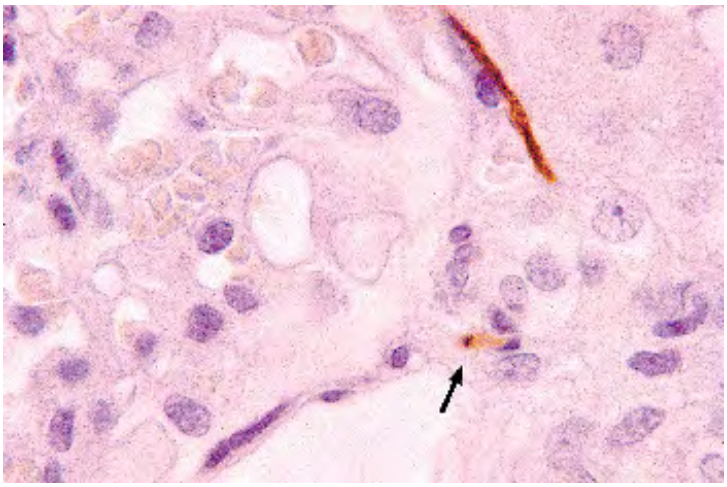

Figure 34.106 Two axons are demonstrated in this view of the vascular pole of a glomerulus (*center*). One axon has a longitudinal profile (*upper right*), and the other is observed in cross-section as a dot (*arrow*). (pNF immunoperoxidase, original magnification Ã—300.)

Nerves

The kidney is innervated by adrenergic fibers mainly derived from the celiac plexus (581). The nerve fibers generally accompany the arteries and arterioles in the cortex and outer medulla (582). Staining for myelin by S-100 (Figure 34.104) or for peripheral axons with antibodies against phosphoneurofilament (pNF) (Figure 34.105) demonstrates the nerve fibers (583 ,584 ,585 ,586). There is prominent innervation of the juxtaglomerular apparatus (Figure 34.106) (587). The efferent arterioles and the descending vasa recta are accompanied by nerve fibers as long as they contain a surrounding smooth muscle layer (588). Although the direct relationship of nerve terminals to tubules is somewhat controversial, autoradiographic studies have provided evidence for monoaminergic innervation of cortical tubules (589 ,590).

Acknowledgments

We are most grateful to Dr. Bruce Beckwith, whose figures and text from the previous edition of this book were in considerable measure retained. Dr. Beckwith has not only advanced our understanding of pediatric tumors, especially Wilms' tumor, but also provided insights into normal and abnormal kidney development. We also thank Roger Hoover of the University of Florida Biomedical Media Services and Ron Irby of the North Floridaâ€“South Georgia Veterans Health System for their expert and dedicated assistance with the figures.

Urinary Bladder, Ureter, and Renal Pelvis

Victor E. Reuter

Introduction

The urinary bladder is an epithelial-lined muscular viscus that has the ability to distend and accommodate up to 400 to 500 mL of urine without a change in intraluminal pressure. In addition, it is able to initiate and sustain a contraction until the organ is empty. Interestingly, micturition may be initiated or inhibited voluntarily despite the involuntary nature of the organ. The ureters are epithelial lined muscular tubes designed to transport urine from the kidneys to the urinary bladder with the aid of peristalsis. The renal pelvis represents the expanded proximal end of the ureter and serves to collect the urine excreted from the kidney and to transport it to the ureter proper.

Embryology

The cloaca is divided by the urorectal septum into a dorsal rectum and a ventral urogenital sinus (1,2). It is this urogenital sinus that will give rise to the majority of the urinary bladder; it is aided by the caudal migration of the cloacal membrane, which will close the

infraumbilical portion of the abdominal wall. The caudal portions of the mesonephric ducts become dilated and eventually fuse with the urogenital sinus in the midline dorsally, contributing to the formation of the bladder trigone. While these ducts contribute initially to the formation of the mucosa of the trigone, this is subsequently entirely replaced by endodermal epithelium of the urogenital sinus. The gradual absorption of the mesonephric ducts bring about the separate opening of the ureters into the urinary bladder in the area of the trigone. During embryologic development, the allantois regresses to completely form a thick, epithelial-lined tube, the urachus, which extends from the umbilicus to the apex (dome) of the bladder (1). Before or shortly after birth, the urachus involutes further becoming simply a fibrous cord. Pathologists commonly refer to this fibrous cord, which extends from the dome of the bladder to the umbilicus, as the urachal remnant, but it should be called the median umbilical ligament since â€œurachal remnantâ€• refers to remnants of the epithelial lining of the urachus that occasionally persist

within the median umbilical ligament (Figure 35.1). The epithelial lining of the urachus is urothelium, similar to that of the urinary bladder and ureter, but it frequently undergoes metaplastic change that is mostly of a glandular nature.

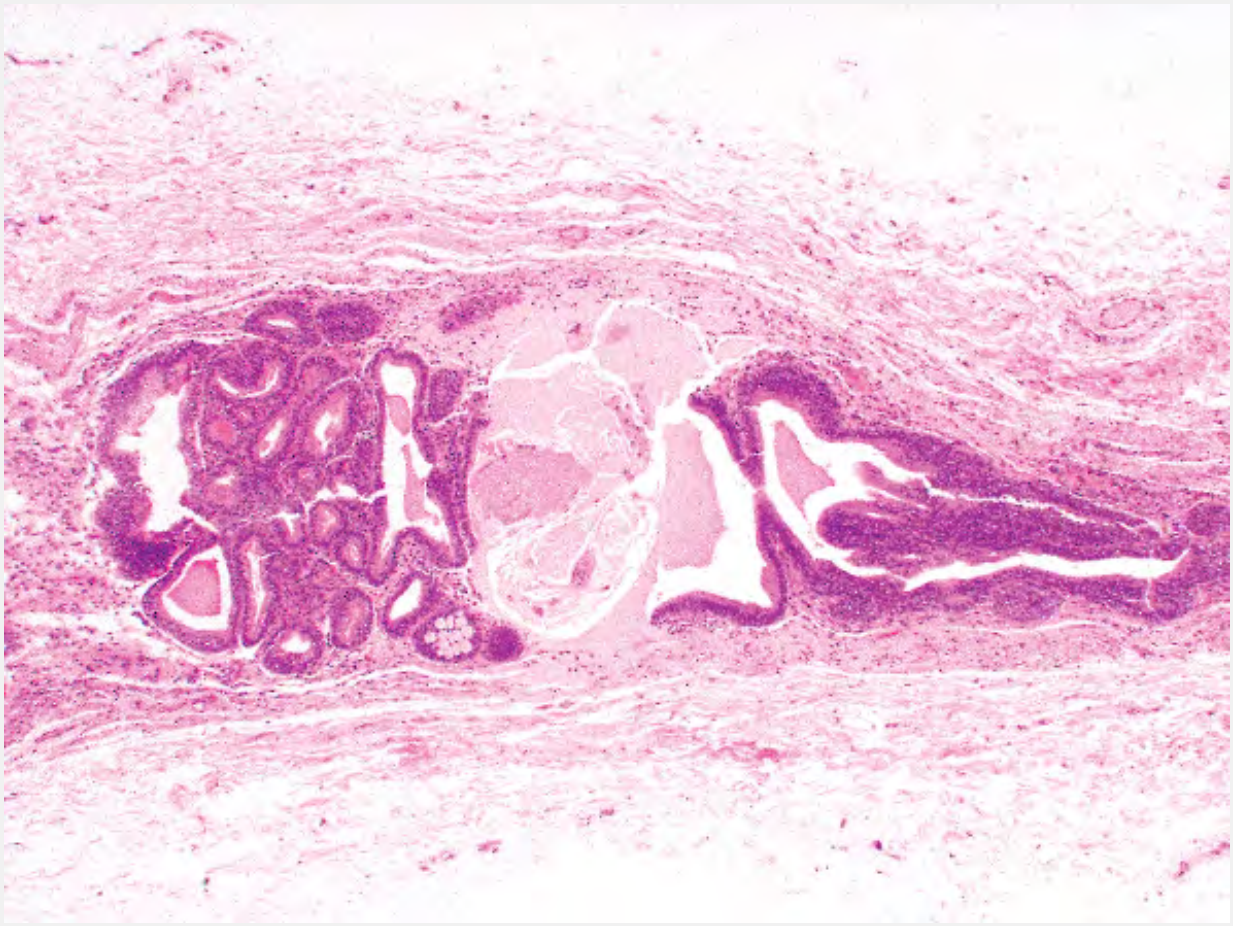

Figure 35.1 Urachal remnants within the median umbilical ligament.

The epithelium of the urinary bladder is endodermally derived from the cranial portion of the urogenital sinus in continuity with the allantois. The lamina propria, the muscularis propria, and the adventitia develop from the adjacent splanchnic mesenchyme. These facts are important in understanding the histogenesis and nomenclature of lesions arising from the epithelial surface, as well as the bladder wall. For example, glandular features within benign (cystitis glandularis, nephrogenic adenoma) and malignant (adenocarcinoma) urothelium is not due to mesodermal or

mÃ¼llerian rests within the trigone but come about through a process of metaplasia and are a reflection of histologic plasticity (multipotentiality) of the urothelium. Since the mesonephric ducts involute totally during embryologic development, it is wrong to refer to tumors with mixed epithelial and sarcomatoid features arising in the bladder epithelium as mesodermal mixed tumors. They are, in fact, â€œendodermal mixedâ€• tumors and are usually called sarcomatoid carcinomas (3). Very rarely, mÃ¼llerian rests may be identified in the wall of the bladder and ureters or in the surrounding soft tissues in the form of endometriosis, endocervicosis, or endosalpingiosis (so-called mÃ¼llerianosis) (4,5,6,7) (Figure 35.2).

The ureters develop by branching and elongation of the ureteric bud (metanephric diverticulum), which begins as a dorsal bud from the mesonephric duct (1,2). The stalk of the ureteric bud becomes the ureter, while the cranial end forms the renal pelvis, calyces, and collecting tubules. The epithelium of the ureter and renal pelvis, although histologically identical to that of the bladder, is of mesodermal derivation.

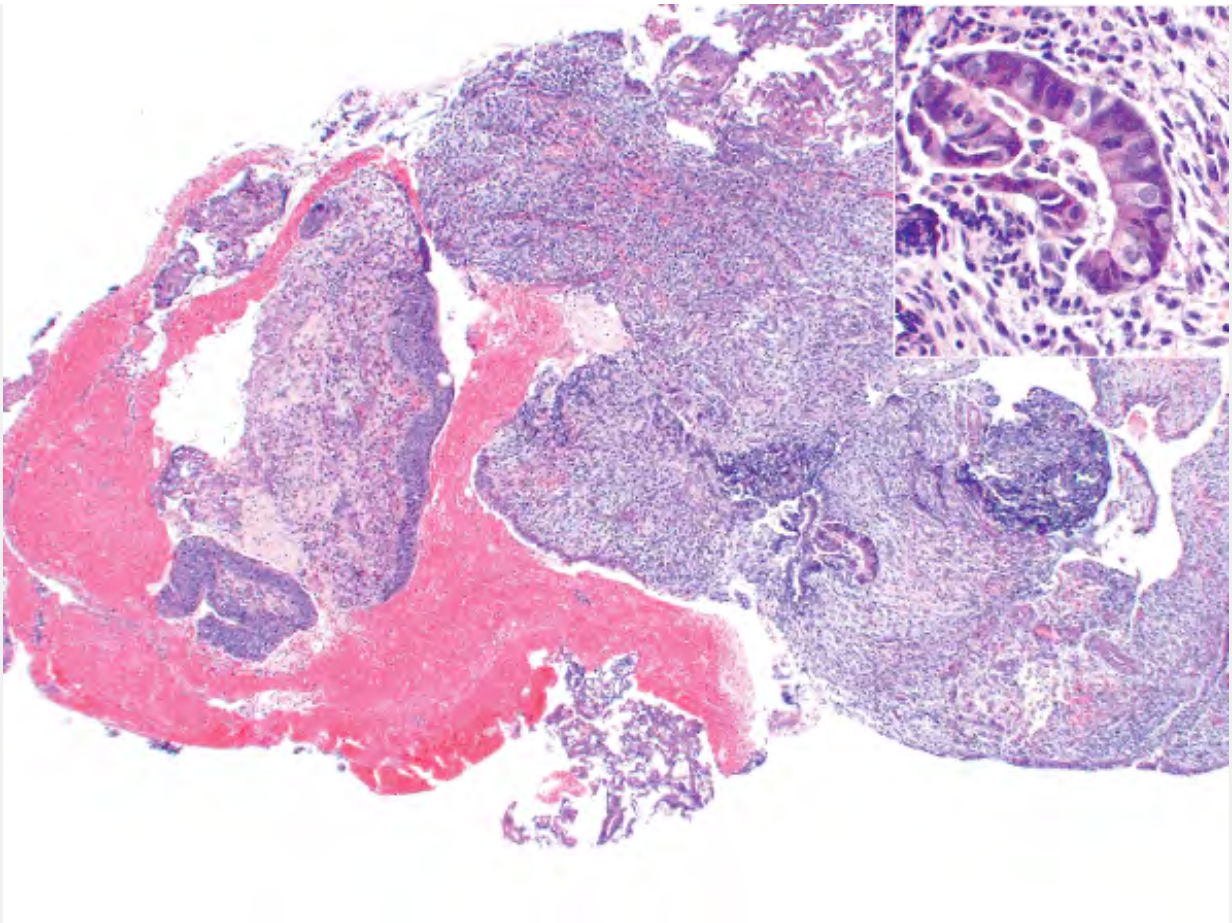

Figure 35.2 Endometriosis involving the ureteral wall. This female patient presented with hematuria and was thought to have a primary ureteral neoplasm. Insert shows an endometriotic gland at higher magnification.

Anatomic Considerations

Bladder

In the adult, the empty urinary bladder lies within the anteroinferior portion of the pelvis minor, inferior to the peritoneum. In infants and children, it is located in part within the abdomen, even when empty

(8). It begins to enter the pelvis major at about 6 years of age and will not be found entirely within the pelvis minor until after puberty. Nevertheless, in adults, as the bladder fills it will distend and ascend into the abdomen, at which time it may reach the level of the umbilicus.

The bladder lies relatively free within the fibrofatty tissues of the pelvis except in the area of the bladder neck, where it is firmly secured by the pubovesical ligaments in the female and the puboprostatic ligaments in the male (8,9). The relative freedom of the rest of the bladder permits expansion superiorly as the viscus fills with urine.

The empty bladder in an adult has the shape of a four-sided inverted pyramid and is enveloped by the vesical fascia (8). The superior surface faces superiorly and is covered by the pelvic parietal peritoneum (Figures 35.3,35.4). The posterior surface, also known as the base of the bladder, faces posteriorly and inferiorly. It is separated from the rectum by the uterine cervix and the proximal portions of the vagina in females and by the seminal vesicles and the ampulla of the vasa deferentia in males. These posterior anatomic relationships are very important clinically. Since the majority of vesicle neoplasms arise in the posterior wall adjacent to the ureteral orifices, invasive tumor may extend into adjacent soft tissue and organs (Figure 35.5A). The intimate relationship to the previously mentioned organs explains why hysterectomy and partial vaginectomy are commonly performed at the time of radial cystectomy in

women. Similarly, we know that perivesical and seminal vesicle involvement is a bad prognostic sign in bladder carcinoma in males (10,11,12), a reflection of high pathologic stage. It is important to note that seminal vesicles may contain carcinoma without invasion, and this occurs in cases of in situ urothelial carcinoma involving prostatic and ejaculatory ducts and extending into the seminal vesicle epithelium. The latter is a rare occurrence, but these patients

do not appear to have a similarly bad prognosis unless prostatic stromal invasion is present. The two inferolateral surfaces of the bladder face laterally, inferiorly, and anteriorly and are in contact with the fascia of the levator ani muscles. The most anterosuperior point of the bladder is known as the apex, and it is located at the point of contact of the superior surfaces and the two inferolateral surfaces. The apex (dome) marks the point of insertion of the median umbilical ligament and consequently is the area where urachal carcinomas are located (Figures 35.3,35.4).

Figure 35.3 Anatomical relationships of the urinary bladder in males.

Figure 35.4 Anatomical relationships of the urinary bladder in females.

The trigone is a complex anatomic structure located at the base of the bladder and extending to the posterior bladder neck. In the proximal and lateral aspects of the trigone, the ureters enter into the bladder (ureteral orifices) obliquely. The muscle underlying the mucosa in this region is a combination of smooth muscle of the longitudinal layer of the intramural ureter and detrusor muscle (13,14,15,16,17). The intramural ureter is surrounded by a fibromuscular sheath (Waldeyer's sheath) that is fused into the ureteral muscle. This fibromuscular tissue fans out in the area of the

trigone and mixes with the detrusor muscle, thus fixing the intramural ureter to the bladder. As the bladder distends, the surrounding musculature exerts pressure on the obliquely oriented intramural ureter, producing closure of the ureteral lumen and thus avoiding reflux of urine.

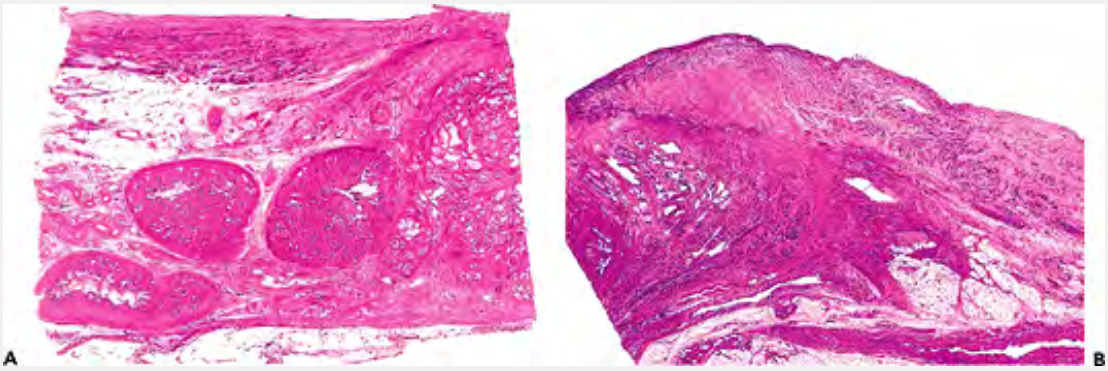

Figure 35.5 Bladder neck and distal trigone. A. The seminal vesicles are separated from the muscularis propria of the trigone by a scant amount of soft tissue. B. The muscularis propria merges with the prostate in the bladder neck area. The central (circular) fibers will predominate in this area and form the internal sphincter. The outer longitudinal layer contributes somewhat to the formation of the prostate musculature.

The most distal portion of the bladder is called the bladder neck, and it is marked by the area where the posterior and the inferolateral walls converge and open into the urethra. In the male, the bladder neck merges with the prostate gland, and one may occasionally observe several prostatic ducts present in this area. It is important to recognize the existence of these ducts since their involvement by carcinoma should not be mistaken with invasive carcinoma. The bladder neck is formed with contributions from the trigonal musculature (inner longitudinal ureteral muscle and Waldeyer's sheath), the detrusor musculature, and the urethral musculature (13,14,15,16,17,18). The internal sphincter is located in this general area, with major contributions from the middle circular layer of the detrusor muscle (Figure 35.5B).

The bladder bed (structures on which the bladder neck rests) is

formed posteriorly by the rectum in males and vagina in females (Figures 35.3 and 35.4). Anteriorly and laterally it is formed by the internal obturator and levator ani muscles, as well as the pubic bones. These structures may be involved in advanced tumors occupying the anterior, lateral, or bladder neck regions and render the patient inoperable.

The main arterial blood supply of the bladder comes from the inferior vesical arteries that branch from the internal iliacs (19,20). The umbilical arteries and its branches (the superior vesical arteries) also supply the bladder, as do the obturator and inferior gluteal arteries and, in females, the uterine and vaginal arteries. The veins of the urinary bladder drain into the internal iliac veins and form the vesical venous plexus. In the male, this plexus envelops the bladder base, prostate, and seminal vesicles and connects with the prostatic venous plexus. In females, it covers the bladder neck and urethra and communicates with the vaginal plexus. Lymphatic drainage is through the external and internal lymph nodes although drainage of portions of the bladder neck region may be through the sacral or common iliac nodes.

The urinary bladder is supplied by both sympathetic and parasympathetic nerves, which form the vesical nerve plexus (19,20). The former are derived from T_{11} through L_2 nerves and play no role in micturition. On the other hand, the parasympathetic nerves come from S_2 through S_4 and travel to the bladder via the pelvic nerve and inferior hypogastric plexus. These nerves are important to micturition since they contract the fibers of the muscularis propria, which in turn produces traction upon the bladder neck and opens the internal sphincter of the bladder. In fact, it is believed that micturition is initiated by voluntary relaxation of the perineal muscles and the striated muscle of the external sphincter located along the urethra. This action decreases urethral resistance and triggers contraction of the smooth muscle of the trigone and remaining bladder, closing the ureteral orifices and increasing the hydrostatic pressure within the viscus (9,21). These facts account for

the difficulty in starting micturition while whistling. The bladder also contains sensory nerves that travel along the pelvic and hypogastric nerves and account for the sensation of pain as the bladder becomes too distended.

Ureters

The ureters measure approximately 30.0 cm in length, equally divided between the abdomen (retroperitoneum) and pelvis (22,23,24,25,26,27). The abdominal ureter takes a vertical course downward and medially on the anterior surface of the psoas muscle, covered by adventitia that is in fact an extension of Gerota's fascia. The pelvic ureter can be subdivided into a longer parietal and a shorter intravesical portion. The parietal portion is intimately related to the peritoneum. It descends posterolaterally; and, as it approaches the bladder base, it becomes medially directed to reach the urinary bladder. The ureters enter the base of the bladder obliquely and empty into the bladder at the ureteral orifices. The distal parietal portion and the intravesical segments are enveloped in a fibromuscular sheath (Waldeyer's sheath), which aids in fixing the ureter to the bladder (see description of the trigone).

The ureteral blood supply is quite diverse (19,22). Depending on the anatomic level, it receives blood from branches of the renal, abdominal aortic, gonadal, hypogastric, vesical, and uterine arteries, which form a richly intercommunicating plexus of vessels surrounding the tube. Venous drainage is variable but tends to follow a pattern similar to the arterial distribution. Lymphatic drainage is also quite complex. The upper portions drain into the lateral aortic lymph nodes, the middle portion drains into the common iliac lymph nodes, and the inferior portion drains into either the common, external, or internal iliac lymph nodes.

Renal Pelvis

As previously mentioned, the renal pelvis has its origin in the cranial portion of the ureteric bud, together with the calyces and collecting ducts. The renal pelvis lies primarily within the renal hilum, a space formed medially when one draws a vertical plane through the medial aspects of the upper and lower poles of the kidney (Figure 35.6). Within the hilum is the renal sinus, a space within the medial and antral portion of the kidney occupied by the renal pelvis, renal vessels and nerves, renal calyces, and fat. The fibrous capsule that lines the kidney passes over the lips of the hilum and lines the renal sinus, becoming continuous with the renal calyces. Within the renal sinus, the renal pelvis divides into two and rarely three major calyces, which in turn divide into 7 to 14 minor calyces. Urine from the distal collecting ducts within the renal

medulla (ducts of Bellini) flows into the minor calyces at the tips of the renal papillae (area cribrosa) (Figures 35.6 and 35.7). The blood supply of the renal pelvis comes from branches of the renal arteries, and the venous drainage follows a similar distribution. Its lymphatic drainage is into the renal hilar lymph nodes.

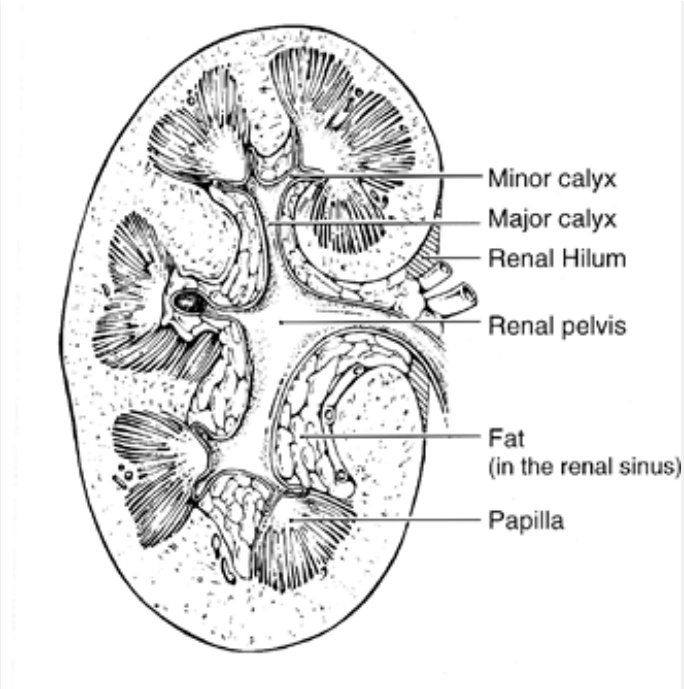

Figure 35.6 Anatomical relationships of the renal pelvis. Notice that the pelvis is mostly within the renal hilum (medial shaded area) and the renal sinus.

Microscopic Anatomy

The urinary bladder, ureter, and renal pelvis for the most part have a similar anatomic composition, the innermost layer being an epithelial lining and, extending outward, a lamina propria, smooth muscle (muscularis propria), and adventitia. The superior surface of the bladder comes in contact with parietal peritoneum and hence has a serosa. The anatomic landmarks are used clinically and pathologically to stage patients with urothelial cancer in order to choose therapy and estimate survival (Figure 35.8). For this reason, it is important to accurately identify them microscopically.

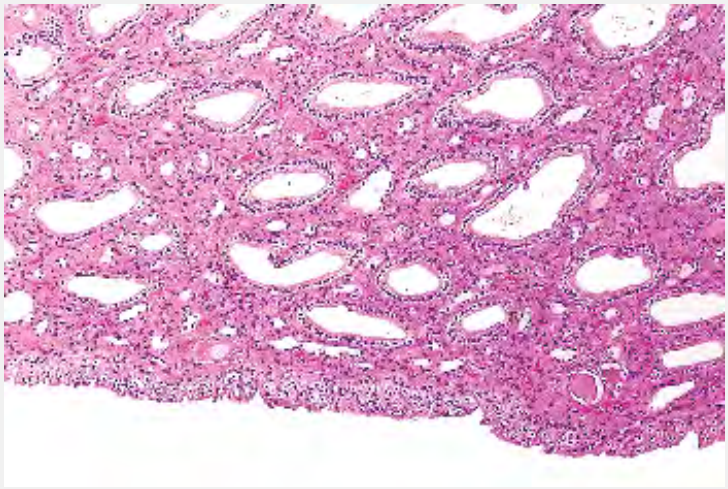

Figure 35.7 Renal papilla. Distal collecting ducts open into the urothelium covering the papillae.

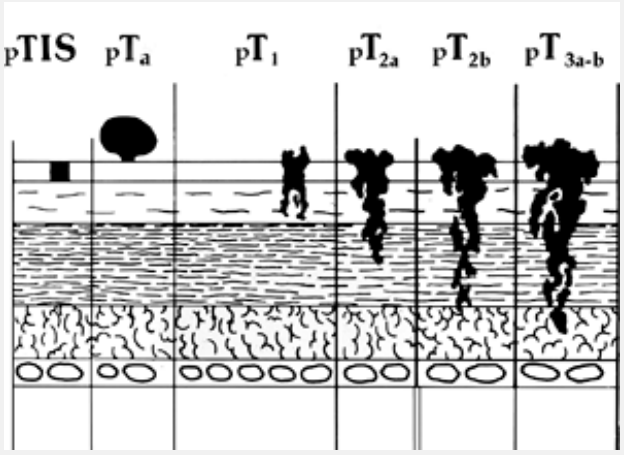

Figure 35.8 Pathologic staging of bladder cancer. This classification follows the recommendations of the American Joint Committee on Cancer (AJCC). In addition, prostatic stromal invasion is considered stage pT_4.

Urothelium

The urinary bladder, ureters, and renal pelvis are lined by so-called transitional epithelium. This name was coined because its histologic appearance was transitional between nonkeratinizing squamous and pseudostratified columnar. Many histologists and pathologists have suggested urothelium as a more appropriate term.

The thickness of the urothelium will vary according to the degree of distension and anatomical location. It may be only two or three cell layers thick along the minor calyces. In the contracted bladder, it is usually six to seven cells thick and in the ureter three to five cells thick. One can identify three regions: the superficial cells that are in contact with the urinary space, the intermediate cells, and the basal cells that lie on a basement membrane (28,29) (Figure 35.9). In the distended bladder, the urothelium

may be only two to three cells thick and flattened with their long axis horizontal to the basement membrane. In practice, the thickness of the urothelium is dependent not only in the degree of distension but also on the plane on which the tissue is cut. If the cut is tangential to the basement membrane, it is possible to generate an artificially thick mucosa. For these and other reasons, we feel that urothelial thickness is of marginal or no utility in the assessment of urothelial neoplasms.

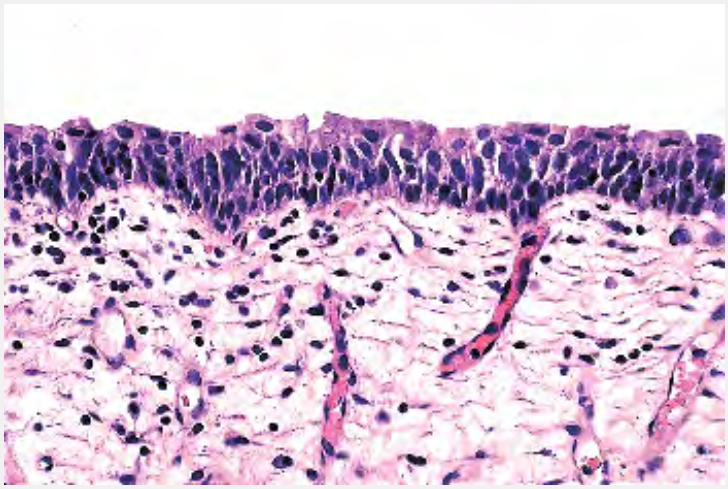

Figure 35.9 Normal urothelium. The mucosa may be up to seven cells thick in the bladder, but thickness will vary as a consequence of distension and other factors. The superficial (umbrella) cells have ample eosinophilic cytoplasm.

Figure 35.10 Urine cytology preparation stained with

monoclonal antibody CD-15. A large, binucleated umbrella cell expresses the antigen identified by this antibody, while other normal urothelial cells do not.

Superficial cells are in contact with the urinary space. They are large, elliptical cells that lie umbrella-like over the smaller intermediate cells (28,29,30,31). They may be binucleated and have abundant eosinophilic cytoplasm (Figure 35.10). In the distended bladder, they become flattened and barely discernible. While the presence of these cells is taken as a sign of normalcy of the urothelium, one must be aware that they may become detached due to superficial erosion during instrumentation or tissue processing in the prosecting area. Conversely, it is possible to see umbrella cells overlying frank carcinoma. In summary, the presence or absence of superficial cells cannot be used as a determining factor of malignancy.

Ultrastructural studies have shown the superficial urothelial cells to be quite unique. The luminal surface is lined by a cytoplasmic membrane that is three layers thick, having two electron-dense layers and a central lucent layer (Figure 35.11A). The two dense layers are said to be unequal thickness; for this reason, the membrane is known as the asymmetric unit membrane (AUM) (30,31,32,33,34). In reality, while the trilaminar arrangement of the cytoplasmic membrane can be readily observed, it is difficult to see the asymmetry of the dense layers. The membrane contains frequent invaginations, giving it a scalloped

appearance. The superficial (luminal) cytoplasm contains vesicles that are also lined by AUM (Figure 35.11B). During the process of distention, these invaginations and vesicles are incorporated into the surface membrane, thus increasing the surface area and maintaining the structural integrity of the urothelium.

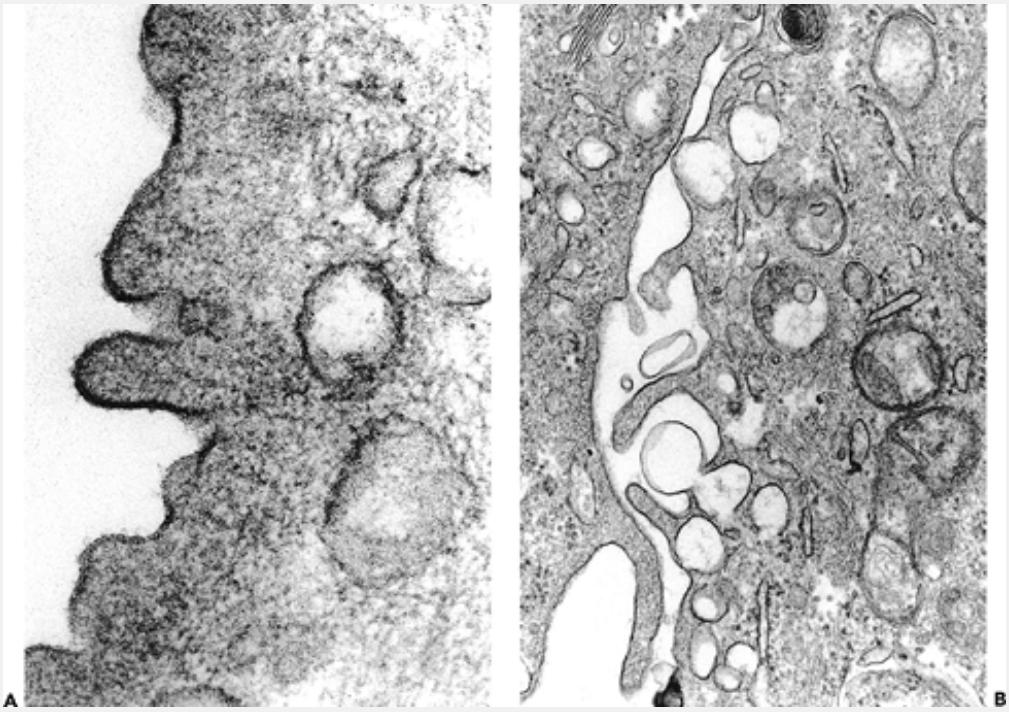

Figure 35.11 Ultrastructure of the urothelium. A. Detail of the luminal surface of a urothelial cell from a 1-year-old infant. The trilaminar cell membrane does not appear to be asymmetric (Ã—136,000). B. Vesicles communicating with the apical/lateral surface of a urothelial cell (Ã—54,000).

The intermediate cell layer may be up to five cells thick in the contracted bladder, where they are oriented with the long axis perpendicular to the basement membrane. The nuclei are oval and have finely stippled chromatin with absent or minute nucleoli. There is ample cytoplasm, which may be vacuolated. The cytoplasmic membranes are distinct, and these cells are attached to each other by desmosomes. In the distended state, this layer may be inconspicuous or only one cell thick and flattened. The basal layer is composed of cuboidal cells that are evident only in the contracted bladder and which lie on a thin but continuous basement membrane composed of a lamina lucida, lamina densa, and anchoring fibrils

(35). All normal urothelial cells may contain glycogen, but only the superficial cells are occasional mucicarminophilic.

Urothelial Variants and Benign Urothelial Proliferations

While the above microscopic and ultrastructural features describe normal urothelium, we know there are many benign morphologic variants. Koss studied 100 grossly normal bladders obtained postmortem (36). Of these, 93% had Brunn's nests, cystitis cystica, or squamous metaplasia.

The most common urothelial variant is the formation of Brunn's nests, which represent invaginations of the surface urothelium into the underlying lamina propria (Figure 35.12). In some cases these solid nests of benign-appearing urothelium may lose continuity with the surface. They become cystic due to accumulation of cellular debris or mucin, and the term *cystitis cystica* has been coined to describe this phenomenon. The lining epithelium of these small cysts is composed of one or several layers of flattened transitional or cuboidal epithelium. In some cases, the epithelial lining undergoes glandular metaplasia, giving rise to what is called cystitis glandularis (Figure 35.12). The cells become cuboidal or columnar and mucin secreting; some are transformed into goblet cells. These processes also occur in the renal pelvis and ureter, where they are called pyelitis or ureteritis cystica (or glandularis), respectively (Figure 35.13).

Brunn's nests, cystitis cystica, and cystitis glandularis represent a continuum of proliferative or reactive changes seen along the entire urothelial tract, and it is common to see all three in the same tissue sample (Figure 35.12). Most investigators believe that they occur as a result of local inflammatory insult (36,37,38). Nevertheless, these proliferative changes are seen in the urothelium of patients with no evidence of local inflammation, so that it is possible that they also

represent either normal histologic variants or the residual effects of old inflammatory processes (39,40). The high incidence of these proliferative changes in normal bladder suggests that they are not likely to be premalignant changes and that there is no cause-and-effect relationship between their presence and the appearance of bladder cancer. It is true that one or all of these changes are commonly present in biopsy specimens containing bladder cancer; but, the coexistence may be coincidental, or the cancer itself may be producing the local inflammatory insult that causes them. The fact that exceptional cases may occur in which carcinoma clearly arises within the epithelium of these reactive lesions does not alter this argument (41,42).

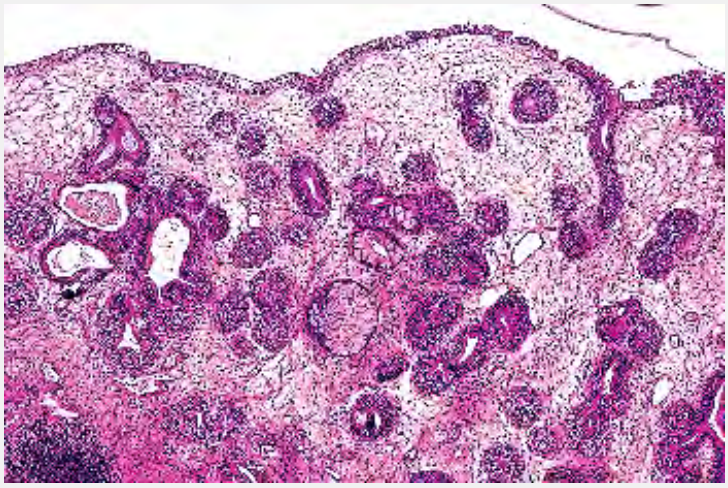

Figure 35.12 Bladder urothelium exhibiting proliferative changes, including Brunn's nests and cystitis glandularis.

Metaplasia refers to a change in morphology of one cell type into another that is considered aberrant for that location. Urothelium frequently undergoes either squamous or glandular metaplasia, presumably as a response to chronic inflammatory stimuli such as urinary tract infection, calculi, diverticula, or frequent catheterization

(37,40).

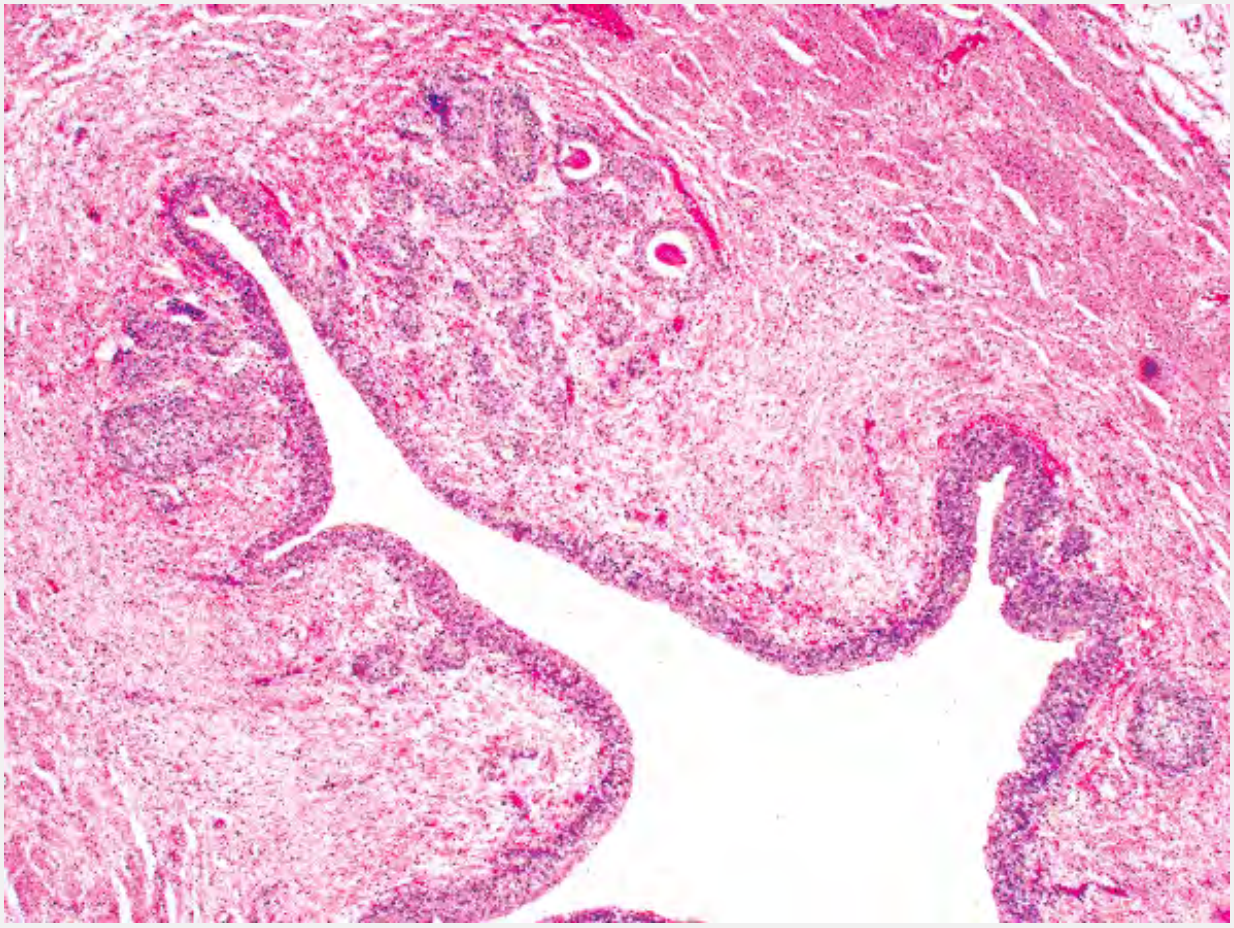

Figure 35.13 Brunn's nests involving a ureter. Notice that the nests are more numerous and irregularly oriented compared to what is commonly seen in the bladder.

Figure 35.14 Squamous epithelium in the trigone of a woman. In this setting squamous epithelium is so common that it is considered to be a normal urothelial variant.

Squamous epithelium in the area of the trigone is a common finding in women. It is characterized by abundant intracytoplasmic glycogen and lack of keratinization, making it histologically similar to vaginal or cervical squamous epithelium (Figure 35.14). In this particular setting, most of us believe that squamous epithelium should be regarded as a variant of urothelium rather than metaplasia. Squamous metaplasia may occur at other sites and at times may undergo keratinization and even exhibit parakeratosis and a granular layer. Squamous metaplasia is not preneoplastic per se, but patients with keratinizing squamous metaplasia must be monitored closely since some may progress to squamous carcinoma (43).

The most common site of glandular metaplasia of the urothelium is the bladder, in the form of cystitis glandularis. Nevertheless, it may also occur within surface urothelium elsewhere in the urinary tract, usually as a response to chronic inflammation or irritation and also in cases of bladder exstrophy (44,45). The epithelium is composed of

tall columnar cells with mucin-secreting goblet cells (Figure 35.15), strikingly similar to colonic or small intestinal epithelium in which one might identify even Paneth's cells. In this setting, we should use the term intestinal metaplasia. As with squamous metaplasia, glandular metaplasia is not of itself a precancerous lesion but may eventually undergo neoplastic transformation in exceptional cases (45). Patients should be monitored accordingly.

So-called nephrogenic adenoma is a distinct metaplastic lesion characterized by aggregates of cuboidal or hobnail cells with clear or eosinophilic cytoplasm and small discrete nuclei without prominent nucleoli (46). These cells line thin papillary fronds on the surface or form tubular structures within the lamina propria of the bladder (Figure 35.16). The tubules are often surrounded by a thickened and hyalinized basement membrane. Variable numbers of acute and chronic inflammatory cells are commonplace within the bladder wall.

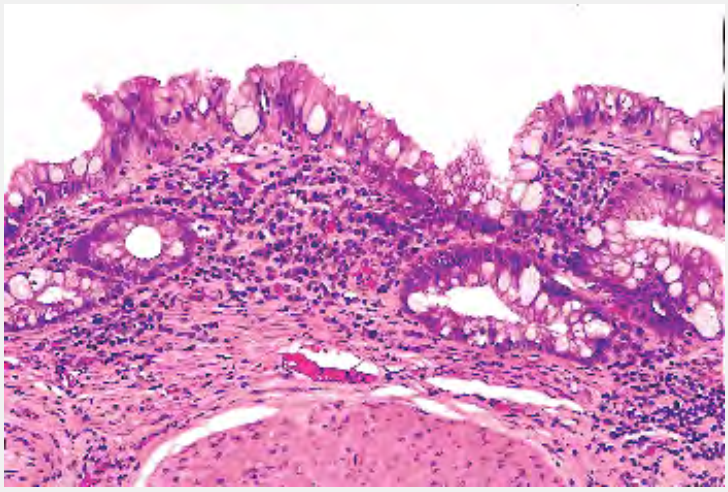

Figure 35.15 Intestinal metaplasia. The individual cells are morphologically identical to intestinal-type epithelium, even at the electron microscopic level.

Nephrogenic adenoma is thought to be secondary to an inflammatory

insult or local injury (46,47,48,49,50). It was originally described in the trigone and given its name because it was thought to arise from mesonephric rests. We now know that nephrogenic adenoma may occur anywhere in the urothelial tract, although it is most common in the bladder. It is important in that it may present as an exophytic mass mimicking carcinoma grossly and suggesting adenocarcinoma microscopically. The benign histologic appearance of the cells arranged in characteristic tubules surrounded by a prominent basement membrane should provide the correct diagnosis. A very interesting publication described nephrogenic adenomas of the bladder in patients who underwent renal transplantation (51). The authors demonstrated the adenomatous lesions and the donor kidneys were clonal, suggesting that they developed through a process of shedding of donor renal tubule cells followed by implantation and proliferation within

the bladder. While this is interesting, it is certainly not the usual mechanism by which they develop.

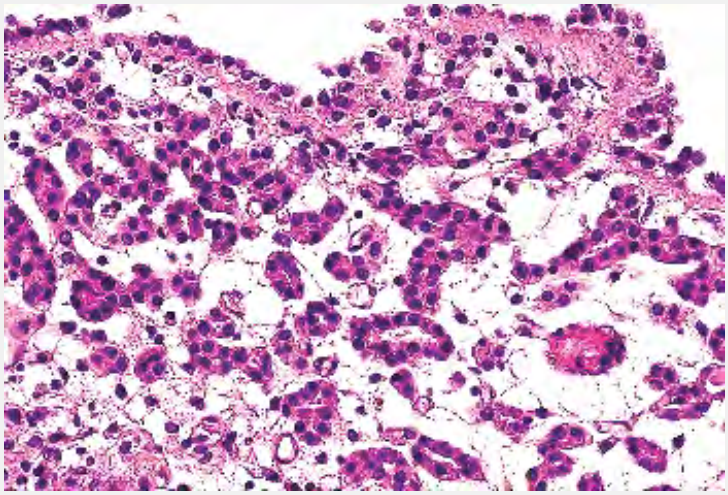

Figure 35.16 Nephrogenic adenoma. This proliferative urothelial lesion is characterized by aggregates of cuboidal cells with scant eosinophilic cytoplasm forming small tubules within the lamina

propria. It may exhibit an exophytic, papillary growth.

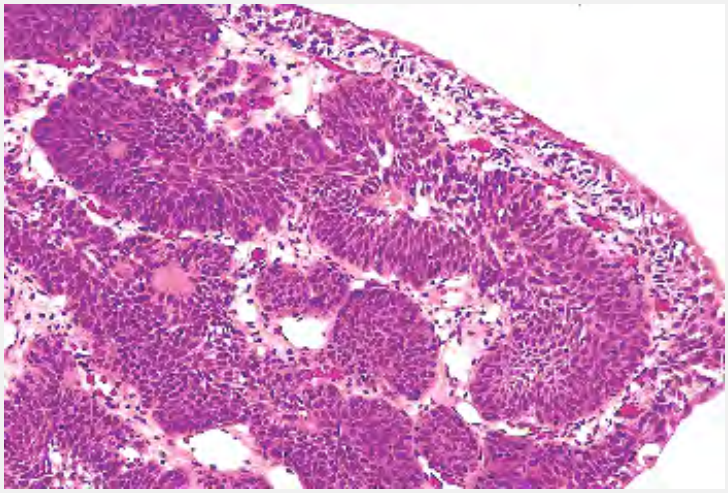

Figure 35.17 Inverted papilloma. This proliferative urothelial lesion is characterized by invaginated cords and nests of transitional epithelium within the lamina propria.

Inverted papillomas are relatively rare lesions that may occur anywhere along the urothelial tract and may be confused clinically and pathologically with transitional-cell carcinoma (52,53). In order of decreasing frequency, they occur in the bladder, renal pelvis, ureter, and urethra (54,55,56,57,58,59,60). Patients usually present with hematuria. Cystoscopically, the lesions are polypoid and either sessile or pedunculated. The mucosal surface is smooth or nodular and without villous or papillary fronds. Microscopically, the surface epithelium is compressed but otherwise unremarkable. It is undermined by invaginated cords and nests of transitional epithelium that occupy the lamina propria (Figure 35.17). The accumulation of these endophytic growths gives the lesion its characteristic polypoid gross appearance. The urothelial cells forming the cords are benign, exhibiting normal maturation and few mitoses. They are similar to

the cells of bladder papillomas, differing only in that the epithelial cords are endophytic and consequently more closely packed. Frequently the cells are oval or spindle-shaped. Epithelial nests may become centrally cystic, dilated, and even lined by cuboidal epithelium.

These cords of transitional epithelium in the lamina propria represent invagination, not invasion. As such, there are no fibrous reactive changes within the stroma. Although mitotic figures can be seen, they are rare, regular, and located at or near the basal layer of the epithelium. Inverted papillomas are discrete lesions and do not exhibit an infiltrative border (54,55). One must be careful not to confuse a nested type of urothelial carcinoma infiltrating the lamina propria with an inverted papilloma.

The etiology of inverted papilloma is unclear. Most investigators feel that, similar to other proliferative lesions such as Brunn's nests and cystitis cystica, they are a reactive, proliferative process secondary to a noxious insult. They are not premalignant, although in exceptional cases they have been associated with carcinoma (56,57,58). Given the rarity of this association, we consider it incidental.

Lamina Propria

The lamina propria lies between the mucosal basement membrane and the muscularis propria. It is composed of dense connective tissue containing a rich vascular network, lymphatic channels, sensory nerve endings, and a few elastic fibers (20,28,32). In the deeper aspects of the lamina propria, of the urinary bladder and ureter, the connective tissue is loose, allowing the formation of thick mucosal folds when the viscus is contracted (Figures 35.18,35.19). Its thickness varies with the degree of distention and is generally thinner in the areas of the trigone and bladder neck. In fact, in patients with urinary outflow obstruction (i.e., prostatic hyperplasia), the bladder neck may contain muscularis propria directly beneath the

mucosa, with the lamina propria being virtually indiscernible (Figure 35.5B). Lamina propria is also absent beneath the urothelium lining the renal papillae in the renal pelvis and is quite thin along the minor calyces (Figure 35.20).

In the midportion of the lamina propria of the bladder lie intermediate-sized arteries and veins. Wisps of smooth muscle are commonly found in the lamina propria and usually are associated with these vessels (61,62) (Figures 35.21A and 35.21B). These fascicles of smooth muscle are not connected to the muscularis propria; they appear as isolated bundles but may form a discontinuous thin layer of muscle. The anatomic relationship of these fibers to the overlying urothelium can be severely disrupted by inflammation or prior therapeutic intervention when they may be seen juxtaposed to the basement membrane (Figure 35.21C). Uncommonly, these muscle fibers may present as a continuous layer of muscle within the lamina propria, thus forming a true muscularis mucosae (62). In evaluating surgical and

biopsy material, every effort should be made to distinguish these superficial muscle fascicles from muscularis propria since a failure to do so will lead to errors in tumor staging and treatment. A pathologist should not sign out a biopsy as â€œtransitional cell carcinoma invading muscleâ€• because he/she is not giving useful information as to the depth of invasion. In fact, many urologists are unaware of the existence of a superficial muscle layer (muscularis mucosae) so that the above diagnosis will lead the urologist to treat the patient as a deeply invasive tumor (stage pT_2 or greater) when in fact the patient has superficially invasive disease (stage pT_1). Occasionally one may encounter fat within the

lamina propria and muscularis (63) (Figure 35.22). At this time, it is unclear whether this is due to the patient's body habitus, but its presence should not be misinterpreted by pathologists as evidence of perivesical fat.

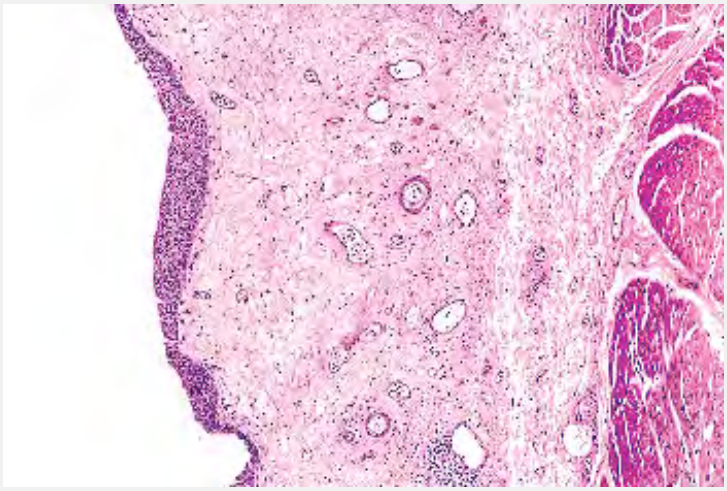

Figure 35.18 Lamina propria. It is composed of connective tissue, vascular structures, sensory nerves, and elastic fibers. Notice that the superficial connective tissue is denser than the deep portion.

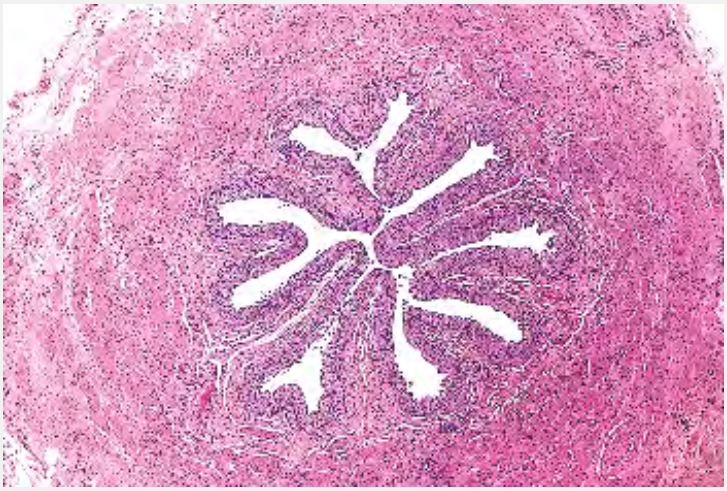

Figure 35.19 Cross section of mid-ureter. The elastic fibers and loose connective tissue within the lamina propria impart a festooned appearance to the urothelium. Notice that the different

layers of the muscularis propria are indiscernible.

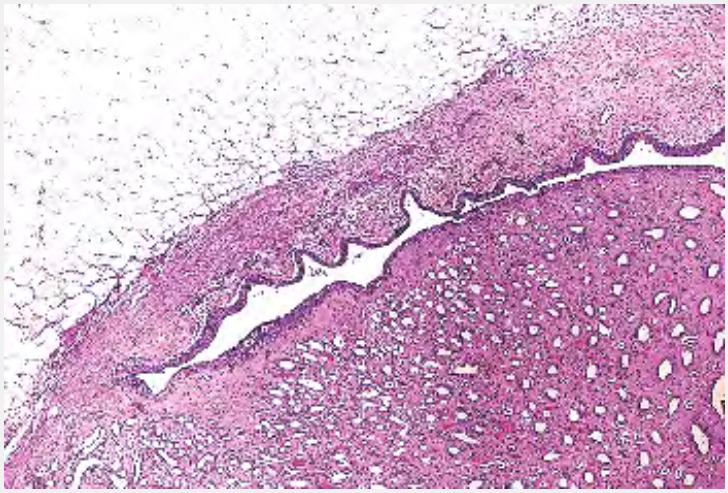

Figure 35.20 Junction of the renal papilla with the minor calyx. Notice the absence of the lamina propria along the papilla and a very thin lamina propria and muscularis propria along the minor calyx.

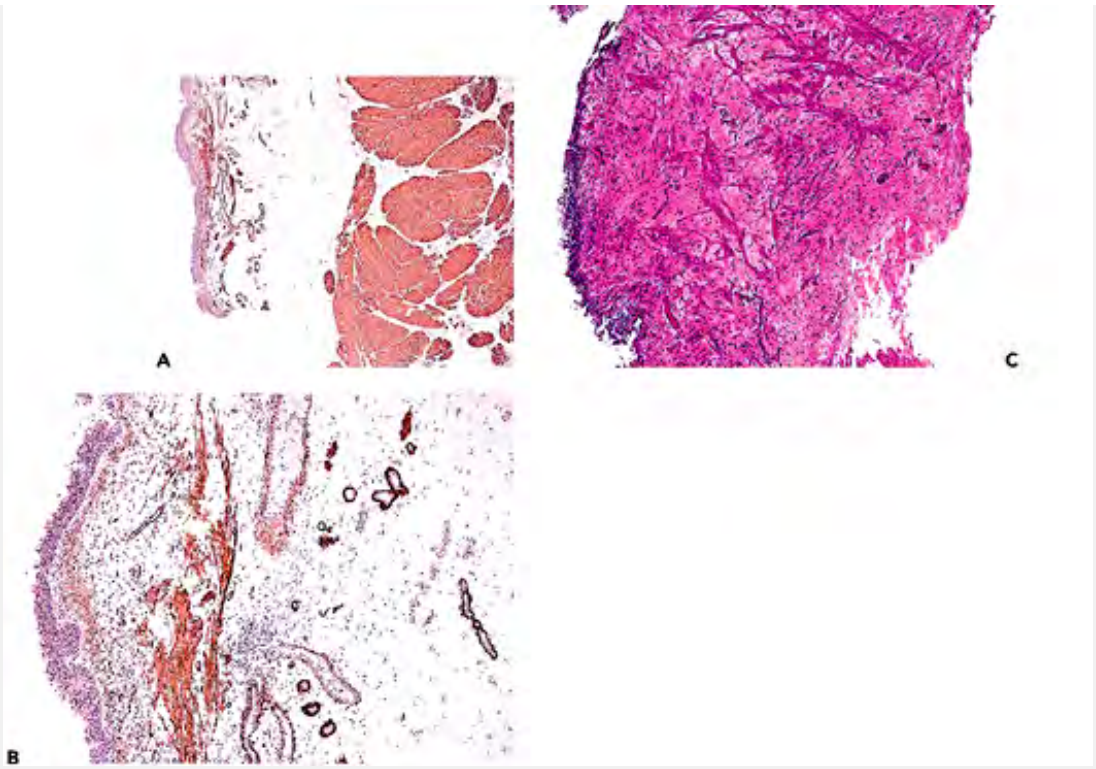

Figure 35.21 Lamina propria of the urinary bladder. A. and B. Discontinuous smooth muscle fascicles are adjacent to intermediate size vessels within the lamina propria (antiâ€“actin monoclonal antibody). C. Disorganized wisps of superficial smooth muscle lie directly beneath the urothelium at the site of a prior biopsy. (Transurethral resection biopsy [TURB] specimen.)

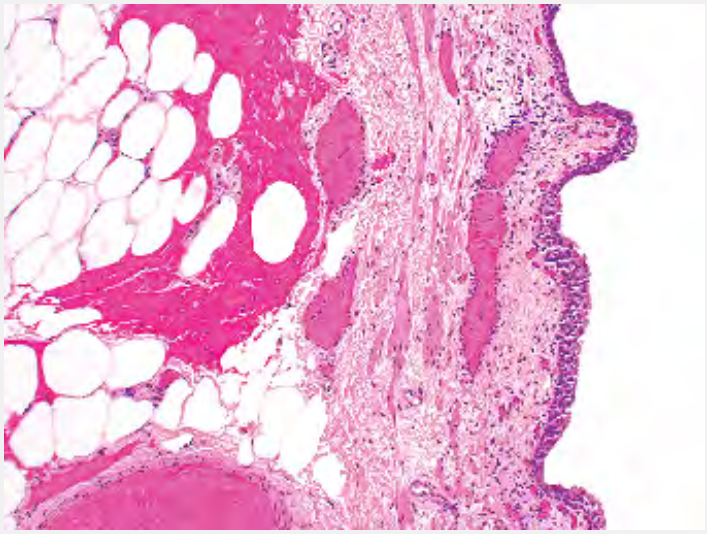

Figure 35.22 Mature adipose tissue within the lamina propria of the urinary bladder.

Pathologists are surprised to learn that, in terms of prognosis and treatment, urologists and urologic oncologists lump noninvasive (T_a) and superficially invasive (T_1) into a single category. It is my opinion that this is due greatly to the fact that we, as pathologists, do not agree as to what constitutes lamina propria invasion. There are many cases of pT_1 disease that are unequivocal, but there are an equal number in which invasion is, at best, questionable. Pathologists' interpretation in the latter group is inconsistent and not reproducible. While this confusion is partly due to the lack of orientation of transurethral biopsy specimens and to disruption of the normal histologic architecture by tumor or prior therapy, it is clear that better parameters are needed to make this distinction.

Muscularis Propria

The muscularis propria is said to be composed of three smooth muscle coats, inner and outer longitudinal layers, and a central

circular layer. In fact, these layers can only be identified consistently in the area of the bladder neck. In other areas, the longitudinal and circular layers mix freely and have no definite orientation. In the ureter, the muscularis propria is thicker distally, and the proximal portion contains only two layers (64). In the renal pelvis, the muscularis propria becomes thinner along the major and minor calyces, and no orientation of the muscle fibers is evident. No muscular fibers are evident between the urothelium and the renal medulla at the level of the renal papillae (Figures 35.7, 35.20). Within the renal sinus, the muscularis propria is surrounded by variable amounts of fat (Figures 35.6, 35.23). This fact is rarely mentioned by pathologists at the time of evaluating urothelial tumors arising in the renal pelvis. Many cases are signed out as â€œinvading renal hilar fatâ€• or â€œinvading perirenal fat,â€• when in fact the invasion is solely into the fat within the renal sinus. The significance of this finding remains to be determined (65).

In the contracted bladder, the muscle fibers are arranged in relatively coarse bundles that are separated from each other by moderate to abundant connective tissue containing blood vessels, lymphatics, and nerves. Mature adipose tissue may also be present. Very infrequently, one may see nests of paraganglia, usually associated with neural or vascular structures (Figure 35.24A). The cells are arranged in discrete nests or cords and have clear or granular cytoplasm with round or vesicular nuclei. They should not be confused with invasive carcinoma. Immunohistochemical stains for cytokeratins are negative but for chromogranin are positive (Figure 35.24B).

Similar to other layers, the thickness of the muscularis propria will vary from patient to patient, with age, and with the degree of distention (Figures 35.25Aâ€“B). In fact, Jequier and Rousseau (66) performed sonographic measurements of the bladder wall thickness in 410 urologically normal children and 10 adults. They found that the bladder wall thickness varied mostly with the state of bladder filling and only minimally with age and gender. The bladder wall had

a mean thickness of 2.76 mm when empty and 1.55 mm when distended.

For staging purposes, the muscularis propria has been divided into two segments, superficial and deep (T_{2a} and T_{2b}, respectively) (Figure 35.8). No anatomical landmarks can be used to make this distinction so it must be done by direct visualization on the light microscope. Prior transurethral resection will alter the anatomy of the site and mask normal landmarks, making proper staging difficultâ€”if not impossible.

Bladder diverticula are relatively common, yet their etiology remains controversial. Most investigators agree that they occur secondary to increased intravesical pressure as a

result of obstruction distal to the diverticulum (67,68,69). The obstruction brings about compensatory muscle hypertrophy and eventual mucosal herniation in areas of weakness. Others feel that at least some diverticula are a consequence of congenital defects in the bladder musculature, citing as evidence cases of diverticula in young patients without evidence of obstruction (69,70). The most common sites of diverticula are (a) adjacent to the ureteral orifices, (b) the bladder dome (probably related to an urachal remnant), and (c) the region of the internal urethral orifice. Grossly, one sees distortion of the external surface of the bladder. The diverticula may be widely patent but are usually narrow in symptomatic patients. The mucosa adjoining the diverticulum is usually hyperemic or ulcerated. There may be epithelial hyperplasia and hypertrophy of the muscularis propria. Very commonly, there is inflammation involving the lamina propria and muscularis. The wall of the diverticulum itself consists of urothelium and underlying connective tissue, similar to the bladder mucosa with lamina propria (Figure 35.26). Few, if any, muscle fascicles of the muscularis propia will be identified in the majority of cases of acquired diverticula, although muscularis mucosae may be present. The true â€œcongenitalâ€• diverticulum contains a thinned outer muscle layer. Infrequently, the epithelium lining the sac will

undergo squamous or glandular metaplasia due to local irritation associated with urine stasis, infection, or stone. In these cases, it is not unusual for the diverticular wall to become extensively fibrotic.

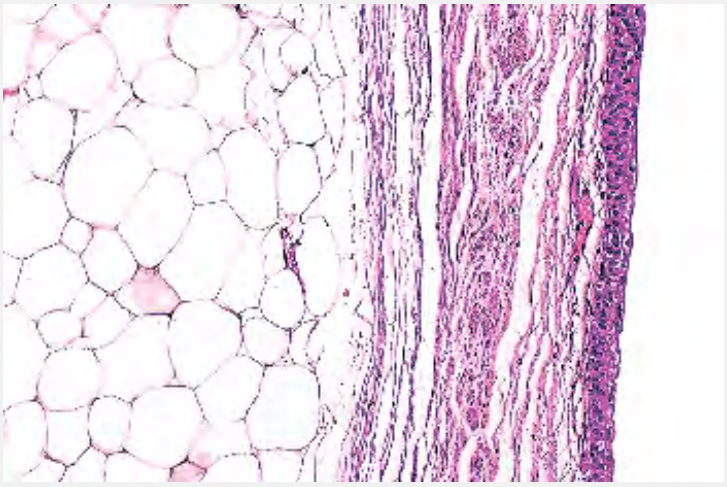

Figure 35.23 Urothelial wall along the minor calices. Thin layers of lamina propria and muscularis propria are surrounded by fat within the renal sinus.

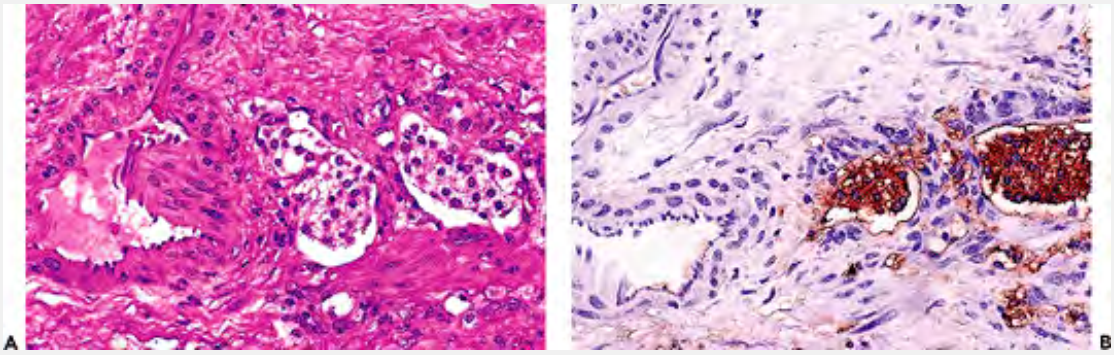

Figure 35.24 Nests of paraganglia within the bladder wall. A. The cells are small, have vesicular nuclei and clear cytoplasm,

and are seen adjacent to neural or vascular structures. They should not be confused with invasive carcinoma. B. Immunostain for chromogranin A can clarify the issue.

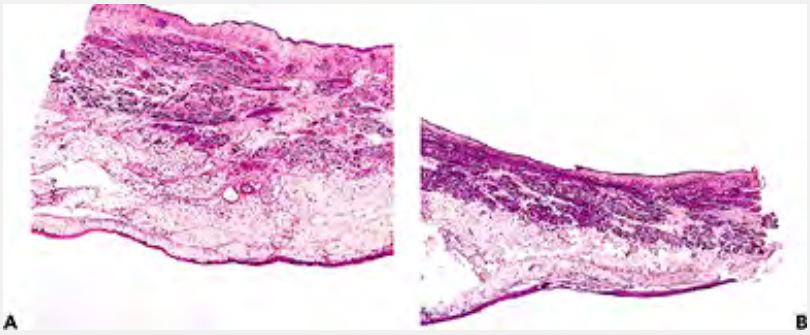

Figure 35.25 Full thickness section of the bladder. A. Notice the irregular thickness of the lamina propria. The three layers of muscle comprising the muscularis propria cannot be clearly defined. In contradistinction to the muscularis propria of the gut, there are ample amounts of soft tissue between muscle bundles in the bladder. B. Cross section of distended bladder. The overall thickness of the viscus is diminished as compared to the contracted bladder. Both the lamina propria and muscularis propria become more compact.

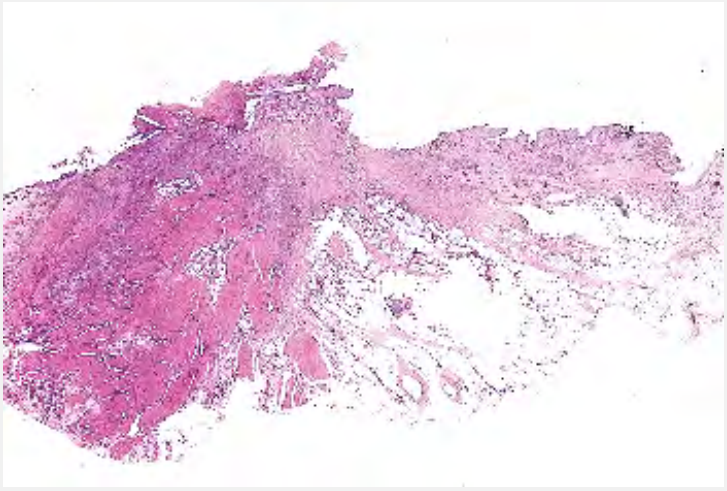

Figure 35.26 Bladder diverticulum. To the left is inflamed but anatomically normal bladder wall, while in the center and to the right one sees total absence of the muscularis propria. Perivesical soft tissue comes in contact with the inflamed, fibrotic, and thickened lamina propria.

Major complications of bladder diverticula include infection, lithiasis, and carcinoma. It is believed that 2 to 7% of patients with bladder diverticula will develop an associated neoplasm, presumed secondary to the chronic inflammatory stimuli mentioned above (71,72). Ureteral diverticula are rare and are asymptomatic if uncomplicated (73). They are not seen in the renal pelvis.

Prostate

John E. McNeal

Embryology and Development of the Prostate

The prostate appears in early embryonic development as a condensation of mesenchyme along the course of the pelvic urethra. By 9 weeks of embryonic life, a number of features that are characteristic of adult contour and location are evident (Figure 36.1). The mesenchymal condensation is most dense along the posterior (rectal) aspect of the urethra and distal (apical) to its midpoint. This is the only region where highly condensed mesenchyme is in immediate contact with urethral lining epithelium, and only here is the urethra lined by a tall columnar epithelium (1). Between its midpoint and the bladder neck, the proximal urethral segment shows a sharp anterior angulation. However, the strip of highly condensed mesenchyme continues directly proximally to a dome-shaped base, leaving a gap between condensed prostatic mesenchyme and proximal urethra.

The ejaculatory ducts penetrate the mesenchyme toward the future verumontanum, which is located at the urethral midpoint. This is wolffian duct tissue, but its stroma is indistinguishable from the remaining prostatic mesenchyme, which is mainly derived from

the urogenital sinus (2). However, that portion of the mesenchyme that surrounds the ejaculatory ducts and expands proximally to occupy nearly the entire prostate base is distinguishable in the adult as the central zone, which is probably also derived from the wolffian duct, as are the seminal vesicles (1). In this concept, the prostate is of dual embryonic derivation.

At about 10 weeks, epithelial buds begin to branch, mainly posteriorly and laterally from the posterior and lateral walls of the distal urethral segment into the condensed mesenchyme. Recent computer reconstructions of serially sectioned specimens have shown that the branching pattern that is established initially is identical to that described for the adult later in this chapter (3).

This developmental program is activated by androgen secreted by the fetal testes. However, the eventual size of the neonatal prostateâ€”less than 1 cm in diameterâ€”is predetermined by the stroma as a programmed number of stromal cell divisions, after which the stroma ceases to have further inductive influence on the branching duct system.

Figure 36.1 Embryonic prostate, age 9 weeks, in the sagittal plane of the pelvis. Urethra (narrow central lumen) is angulated to the right at the midpoint, where the ejaculatory duct approaches from above left. A vertical strip of highly condensed prostate mesenchyme contacts the posterior urethral wall only distal to the ejaculatory ducts. The prostate is flanked by the rectum (*left*) and pubis (*right*). Duct buds have not yet formed.

Postnatally the prostate grows at a slow rate, reaching less than 2 cm in diameter by the time of puberty. During this period, the ducts and acini are lined by epithelium, which undergoes little change from the neonatal period. Gland spaces are lined by cells that are crowded with multilayered dark nuclei (Figure 36.2). There is a superficial resemblance to adult postinflammatory atrophy, but the histologic features are quite different.

The pubertal growth acceleration and maturation of the prostate gland appears not to be complete until at least 20 years of age. The average prostate by this time measures about 4.5 cm in width, 3.5 to 4.0 cm in length, and 3 cm in thickness. In most men over 50 years of age, there is focal resumption of growth as benign nodular hyperplasia (BPH). This process increases the thickness of the gland prominently and affects its length the least; in massive BPH, however, the prostate becomes nearly spherical, with a diameter of 6 cm or more. Dissections show that BPH represents enlargement of only a single tiny region of the gland. In fact, the normal mass of the glandular portion of the prostate after subtraction of the BPH-prone region remains at nearly constant mean volume until 70 years of age or more. However, the range about the mean increases in men more than 50 years of age, suggesting that the normal non-BPH glandular prostate may continue enlarging into old age rather than undergoing atrophy.

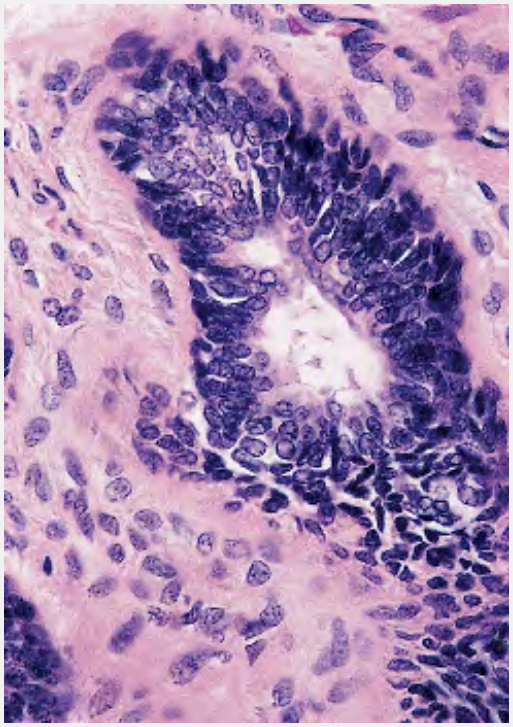

Figure 36.2 Prepubertal prostatic duct lined by epithelium with multiple layers of nuclei and showing no cytoplasmic differentiation.

General Relationships: The Glandular Prostate

The human prostate gland is a composite organ, made up of several glandular and nonglandular components. These different tissues are tightly fused together within a common capsule so that gross dissections are difficult and unreliable. Anatomic features are best demonstrated by examination of cut sections in carefully selected planes (4,5). The nonglandular tissue of the prostate is concentrated anteromedially and is responsible for much of the anterior convexity of the organ. The contour of the glandular prostate approximates a disk with lateral wings that fold anteriorly to partially encircle the nonglandular tissue. There are four distinct glandular regions, each of which arises from a different segment of the prostatic urethra.

The urethra is a primary reference point for describing anatomic relationships. These relationships are best visualized in a sagittal plane of section (Figure 36.3). The prostatic urethra is divided into proximal and distal segments of approximately equal length by an abrupt anterior angulation of its posterior wall at the midpoint between the prostate apex and bladder neck (1,6). The angle of deviation is roughly 35 degrees, but it is quite variable and is greater in men with nodular hyperplasia. The base of the verumontanum protrudes from the posterior urethral wall at the point of angulation. The verumontanum bulges into the urethral lumen along its posterior wall for about half the length of the distal segment and tapers distally to form the crista urethralis.

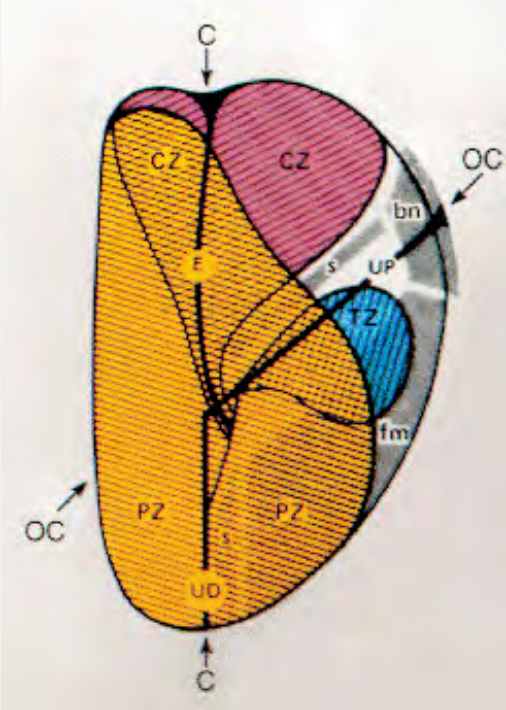

Figure 36.3 Sagittal diagram of distal prostatic urethral segment (*UD*), proximal urethral segment (*UP*), and ejaculatory ducts (*E*) showing their relationships to a sagittal section of the anteromedial nonglandular tissues [bladder neck (*bn*), anterior fibromuscular stroma (*fm*), preprostatic sphincter (*s*), distal striated sphincter (*s*)]. These structures are shown in relation to a three-dimensional representation of the glandular prostate [central zone (*CZ*), peripheral zone (*PZ*), transition zone (*TZ*)]. Coronal plane (*C*) of Figure 36.4 and oblique coronal plane (*OC*) of Figure 36.5 are indicated by arrows.

The distal urethral segment receives the ejaculatory ducts and the ducts of about 95% of the glandular prostate; it is, therefore, the only segment that is primarily involved in ejaculatory function. The ejaculatory ducts extend proximally from the verumontanum to the

base of the prostate, following a course that is nearly a direct extension of the long axis of the distal urethral segment, although usually offset a few millimeters posteriorly.

A coronal plane of section along the course of the ejaculatory ducts and distal urethral segment provides the best demonstration of the anatomic relationships between the two major regions of the glandular prostate (7) (Figure 36.4). The peripheral zone comprises about 65% of the mass of the normal glandular prostate. Its ducts exit from the posterolateral recesses of the urethral wall along a double row extending from the base of the verumontanum to the prostate apex. The ducts extend mainly laterally in the coronal plane, with major branches that curve anteriorly and minor branches that curve posteriorly (Figure 36.4). The central zone comprises about 30% of the glandular prostate mass. Its ducts arise in a small focus on the convexity of the verumontanum and immediately surrounding the ejaculatory duct orifices. The ducts branch directly toward the base of the prostate along the course of the ejaculatory ducts, fanning out mainly in the coronal plane to form a conical structure that is flattened in the anteroposterior dimension. The base of the cone comprises almost the entire base of the prostate. The most lateral central zone ducts run parallel to the most proximal peripheral zone ducts, separated only by a narrow band of stroma.

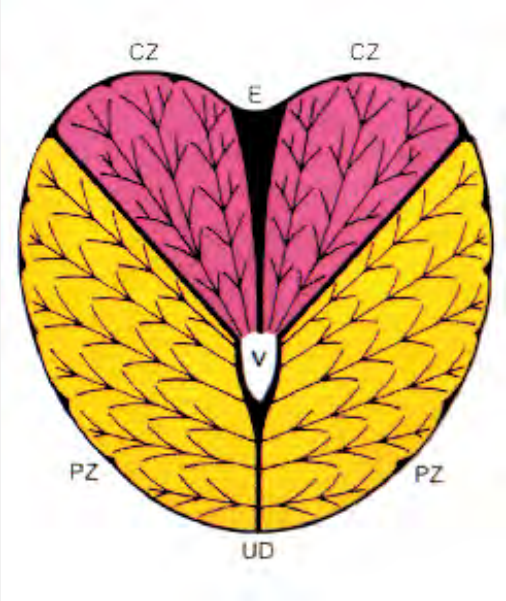

Figure 36.4 Coronal section diagram of prostate showing location of central zone (*CZ*) and peripheral zone (*PZ*) in relation to the distal urethral segment (*UD*), verumontanum (*V*), and ejaculatory ducts (*E*). The branching pattern of prostatic ducts is indicated; subsidiary ducts provide uniform density of acini along entire main duct course.

The proximal segment of the prostatic urethra is best visualized in an oblique coronal-plane section running along its long axis from the base of the verumontanum to the bladder neck (Figure 36.5). Normally, the proximal urethral segment is related to only about 5% of the prostatic glandular tissue, and almost all of this is represented by the transition zone (8). This zone consists of two independent small lobes whose ducts leave the posterolateral recesses

of the urethral wall at a single point, just proximal to the point of urethral angulation and at the lower border of the preprostatic sphincter. The sphincter is a sleeve of smooth muscle fibers

surrounding the proximal urethral segment (6,8) (Figure 36.6). The main ducts of the transition zone extend laterally around the distal border of the sphincter and curve sharply anteriorly, arborizing toward the bladder neck immediately external to the preprostatic sphincter. Main duct branches fan out laterally and ventrally toward the apex but not dorsally above the plane of the urethra. The most medial ducts and acini of the transition zone curve medially to penetrate into the sphincter (Figure 36.6).

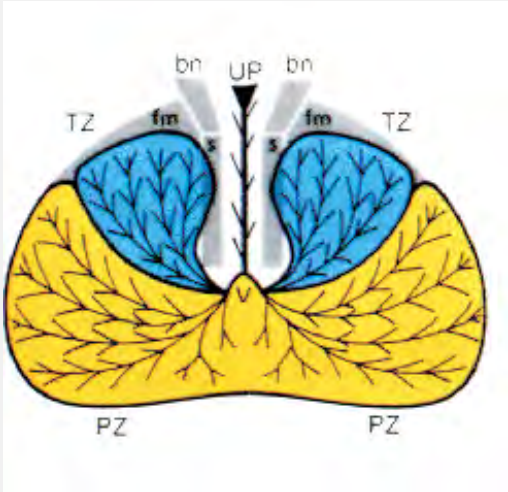

Figure 36.5 Oblique coronal section diagram of prostate showing location of peripheral zone (*PZ*) and transition zone (*TZ*) in relation to proximal urethral segment (*UP*), verumontanum (*V*), preprostatic sphincter (*s*), bladder neck (*bn*), anterior fibromuscular stroma (*fm*), and periurethral region with periurethral glands. Branching pattern of prostatic ducts is indicated: the medial transition zone ducts penetrate into the sphincter.

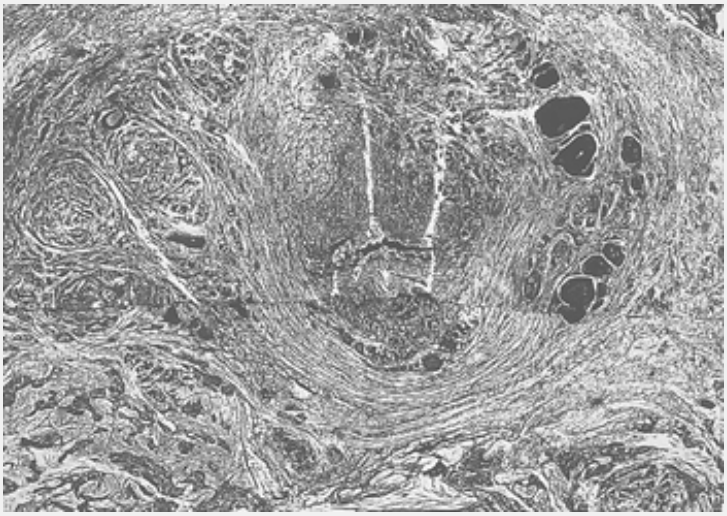

Figure 36.6 Preprostatic sphincter in section transverse to long axis of proximal urethral segment. The sphincter is most compact dorsal to the urethra (*below*) and separates periurethral tissue (*dark central area*) from central zone glands (*bottom, right,* and *left*). Laterally, transition zone glands are embedded in the sphincter. They show cystic change (*right*) and nodule formation (*left*).

The periurethral gland region is only a fraction of the size of the transition zone. It consists of tiny ducts and abortive acinar systems scattered along the length of the proximal urethral segment and arborizing exclusively inside the confines of the preprostatic sphincter. These glands lie within the longitudinal periurethral smooth muscle stroma.

The peripheral zone is the most susceptible region to inflammation (7) and is the site of origin of most carcinomas (9). Some cancers arise in the transition zone, and mosttumors found incidentally at transurethral resection (TUR) represent this site of origin (10,11).

The transition zone and periurethral region are the exclusive sites of origin of BPH (8). Most cases consist almost entirely of

transition zone enlargement, so-called lateral lobe hyperplasia. Benign nodular hyperplasia in the periurethral region seldom attains significant mass, except as the occasional midline dorsal nodule at the bladder neck that protrudes into the bladder lumen. The above anatomic descriptions have gained acceptance over the past 10 years, replacing a number of previous anatomic models that suffered from less accurate descriptions of morphologic detail (12,13).

General Relationships: Nonglandular Tissue

The nonglandular tissues of the prostate are the preprostatic sphincter, striated sphincter, anterior fibromuscular stroma, and prostatic capsule. The nerves and vascular supply are also included in this section.

The preprostatic sphincter consists of precisely parallel, compact ring fibers forming a cylinder whose proximal end abuts against the detrusor muscle surrounding the urethra at the bladder neck. The coarsely interwoven, somewhat randomly arranged smooth muscle bundles of the detrusor contrast sharply with the uniform arrangement of the sphincter fibers, but there is no boundary between the two structures.

The preprostatic sphincter is thought to function during ejaculation to prevent retrograde flow of seminal fluid from the distal urethral segment. It also may have resting tone that maintains closure of the proximal urethral segment (6). Dorsal to the urethra, the sphincter is compact, but laterally its fibers spread apart and mingle with the small ducts and acini of the medial transition zone (Figure 36.6) (8). Anterior and ventral to the urethra, its fibers do not form identifiable complete rings but blend with the tissue of the anterior fibromuscular stroma. The anterior fibromuscular stroma is an apron of tissue that extends downward from the

bladder neck over the anteromedial surface of the prostate, narrowing to join the urethra at the prostate apex (8) (Figures 36.3, 36.7). Its

lateral margins blend with the prostate capsule along the line where the capsule covers the most anteriorly projecting border of the peripheral zone (Figure 36.5). Its deep surface is in contact with the preprostatic sphincter and transition zone proximally and with the striated sphincter distally. It is composed of large compact bundles of smooth muscle cells that are similar to those of the bladder neck and blend with them at its proximal extent. The smooth muscle fibers are more random in orientation than those of the bladder neck, but they tend to be aligned more or less vertically. They are often separated by bands of dense fibrous tissue.

Figure 36.7 Texture of anterior fibromuscular stroma in an

area with little fibrous component. Muscle bundles are coarse and interwoven (trichrome stain).

The anterior fibromuscular stroma is distinguished from the capsule of the prostate by its thickness, its coarse interwoven muscle bundles, and its rough external surface. Microscopically its external aspect shows interdigitation of the muscle bundles along its surface with the adipose tissue of the space of Retzius.

Between the verumontanum and the prostate apex, there is a striated sphincter of small, uniform, compactly arranged striated muscle fibers. It is best developed near the apex and is continuous with the external sphincter below the prostate apex (6,14). The sphincter is incomplete posterolaterally, where its semicircular fibers anchor into the anterior glandular tissue of the peripheral zone rather than encircling the posterior aspect of the urethra. Its degree of development and precise anatomic relationships are variable between prostates. Near the apex in some prostates, individual striated fibers may penetrate deeply into the glandular tissue of the peripheral zone. Consequently, most of the length of the prostatic urethra is provided with sphincteric muscle. The distal striated sphincter is incomplete posteriorly, and the proximal smooth muscle sphincter is probably incomplete anteriorly.

The prostatic capsule envelopes most of the external surface of the prostate, and the terminal acini of the central zone and peripheral zone abut on the capsule. The terminal acini of the transition zone abut on the anterior fibromuscular stroma, and the periurethral glands never reach the prostate surface (8,11). At the prostate apex, there is a defect in the capsule anteriorly and anterolaterally. Here the most distal fibers of the anterior fibromuscular stroma and the striated sphincter together often mingle with the prostatic glandular tissue anterolateral to the urethra, and the relative extent of these three tissue components may vary considerably between prostates. Hence, if carcinoma at

the prostate apex invades anteriorly, it may occasionally be difficult to determine whether it has invaded beyond the boundary of the gland. However, around most of the circumference of the apex, the capsule is complete up to the border of the periurethral stroma, where the urethra penetrates the prostate surface. Even with extensive BPH, a thin compressed rim of peripheral zone tissue enclosed by capsule usually still forms the apical prostate boundary except anterior and anterolateral to the urethra.

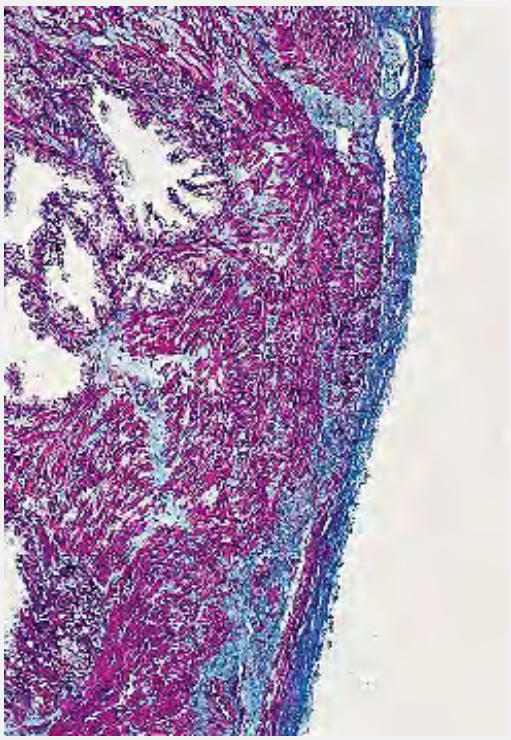

Figure 36.8 The prostate capsule consists of a layer of mainly transverse smooth muscle bundles (red), which is of variable thickness and blends with periacinar smooth muscle bundles at the capsule's poorly defined inner aspect (*left*). Collagen fibers (blue) are always present and usually concentrated in a thin compact membrane at the external capsular border (*right*) (trichrome stain).

The capsule of the prostate ideally consists of an inner layer of smooth muscle fibers, mainly oriented transversely, and an outer collagenous membrane. However, the relative and absolute amounts of fibrous and muscle tissue and their arrangement vary considerably from area to area (Figure 36.8) (15,16). At the inner capsular border, transverse smooth muscle blends with periacinar smooth muscle, and clear separation between them cannot be identified either microscopically or by gross dissection. The distance from terminal acinus to prostate surface is variable even between different regions within a single prostate, and the proportion and arrangement of collagenous tissue is inconstant except for the most superficial layer, which appears to form a thin continuous collagenous membrane over the prostate surface. Consequently, except for its external surface, the prostate capsule cannot be regarded as a well-defined anatomic structure with constant features. In contrast to the kidney, there is no inner membrane surface that can be stripped in evaluating capsule penetration by prostatic carcinoma; there are no reliable landmarks for determining the depth of capsule invasion. However, it has been proposed that only complete penetration with perforation through the capsule surface may be related to prognosis in prostatic carcinoma (16,17). Hence, penetration of cancer into the capsule without perforation is not of clinical importance.

Over the medial half of the posterior (rectal) surface of the prostate, the thickness of the capsule is increased by its fusion to Denonvilliers' fascia (Figures 36.9,36.10). This is a thin, compact collagenous membrane whose smooth posterior surface rests directly against the muscle of the rectal wall (18). The capsule is typically fused to the inner aspect of the fascia, obliterating any trace of its original surface except for occasional remnants of an interposed adipose layer that embryonically covered the anterior aspect of the fascia. In the adult, there remain only scattered

microscopic islands of fat, usually forming a layer that is only one adipose cell thick.

Smooth muscle fibers are found to a variable extent in Denonvilliers' fascia, but they usually course vertically, in contrast to the predominant transverse muscle fibers of the adherent capsule. In some prostates, the smooth muscle of Denonvilliers' fascia is gathered into a thick, flattened vertical band at the midline, where it easily may be mistaken in a radical prostatectomy specimen for muscle of the rectal wall. This is an important distinction because carcinoma invading such a longitudinal muscle bundle may still be confined within the prostate and should not be considered to have invaded the rectum. Wherever the capsule and fascia are fused, it is the surface of the fascia rather than the capsule surface that presents a barrier to the spread of carcinoma.

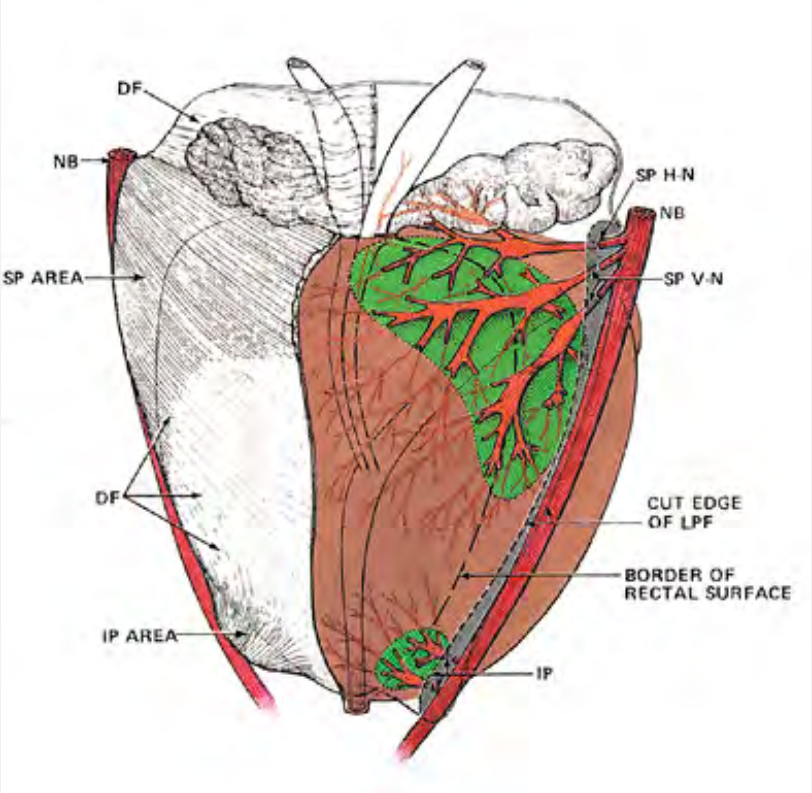

Figure 36.9 Distribution of nerve branches to the prostate, right posterolateral view. Nerves within the neurovascular bundle (*NB*) (red) branch to supply the prostate (brown) in a large superior pedicle (*SP*) at the prostate base and a small inferior pedicle (*IP*) at the prostate apex. Nerve branches (orange) leave the lateral pelvic fascia (not shown) to travel in Denonvilliers' fascia (*DF*), which has been cut away from the right half of the prostate. Nerve branches from the superior pedicle fan out over a large pedicle area. A small horizontal subdivision (*H-N*) crosses the base to midline; a large vertical subdivision (*V-N*) fans out extensively over the prostate surface as far distally as midprostate. Branches continue their course within the prostate after penetration into the capsule within a large nerve penetration area (green). A small inferior pedicle has a limited ramification and nerve penetration area (green). (LPF, lateral pelvic fascia)

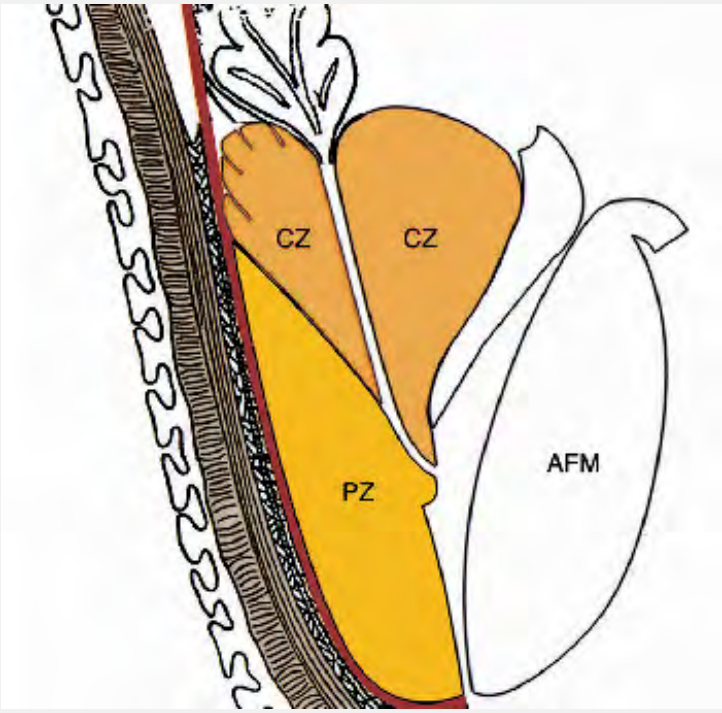

Figure 36.10 Relationships of Denonvilliers' fascia (narrow red band) to sagittal plane of prostate (yellow and orange; *right*) and to rectal smooth muscle (brown; *left*). (*CZ,* central zone; *PZ,* peripheral zone; *AFM,* anterior fibromuscular fascia)

Superiorly, Denonvilliers' fascia extends above the prostate to cover the posterior surface of the seminal vesicles, but it is only loosely adherent to them (Figure 36.9,36.10). Laterally, the fascia leaves the posterior capsule where the prostate surface begins to deviate anteriorly, and it continues in a coronal plane to anchor against the pelvic sidewalls. So the prostate and seminal vesicles are suspended along the anterior aspect of this fascial membrane as the uterus is suspended from the broad ligament in the female. This can be demonstrated in the radical prostatectomy specimen after surgery for carcinoma. If the specimen is picked up at the right and left superior margins, its posterior aspect is a smooth-surfaced triangular membrane whose apex coincides with the prostate apex and whose base is a transverse line above the seminal vesicles. Any surgical defect in the fascia potentially compromises the complete resection of the tumor because tears in the fascia tend to extend through the adherent capsule and into the gland.

Where Denonvilliers' fascia separates from the prostate capsule posterolaterally, the space between them is filled with adipose tissue in a thick layer between the anterior aspect of the fascia and the posterolateral capsular surface of the prostate. The autonomic nerves, from the pelvic plexus

to the seminal vesicles, prostate, and corpora cavernosa of the penis, travel in this fatty layer. The nerves, along with the blood vessels to the prostate, originate from the paired neurovascular bundles that course vertically along the pelvic sidewalls just anterior to the junction of Denonvilliers' fascia with the pelvis

(Figure 36.9) (19). Most of the nerve branches to the prostate leave the neurovascular bundle at a single level just above the prostate base and course medially as the superior pedicle. These nerve branches fan out to penetrate the superior pedicle insertion area of the capsule, which is centered at the lateral aspect of the prostate base posteriorly (19,20). The insertion area does not usually extend far onto the rectal surface but extends toward the prostate apex as far as the midprostate. Some nerve trunks travel medially across the prostate base, sending branches into the central zone, but the majority of nerve branches fan out distally and penetrate the capsule at an oblique angle.

Most examples of capsule penetration by cancer represent tumor extension through the capsule along perineural spaces (20). Because of the oblique retrograde nerve pathway toward the prostate base, perforation though the full capsule thickness most commonly occurs near or even above the superior border of the cancer within the gland. Because of the boundaries of the superior pedicle insertion area plus the additional thickness of Denonvilliers' fascia overlying the capsule posteromedially, penetration of cancer directly through the rectal surface of the prostate is uncommon.

Before supplying the corpora cavernosa, nerve branches leave the neurovascular bundle at the prostate apex in the very small inferior pedicle and penetrate the capsule directly in a small apical insertion area located laterally and posterolaterally (20). Here the distance from neurovascular bundle to prostate capsule is narrowed to only a few millimeters. The prostate apex is the most common location for positive surgical margins at radical prostatectomy. This may result from capsule penetration along inferior pedicle nerves by cancers that are located near the apex, but it most commonly results from inadvertent surgical incision into the prostate. In this area, the surgeon is most concerned to stay close to the prostate capsule in order to spare the nerves involved in erectile function (21,22).

Arterial branches follow the nerve branches from the neurovascular bundle; they spread over the prostate surface and penetrate the capsule to extend directly inward toward the distal urethral segment between the radiating duct systems of the central and peripheral zones (23,24). A major arterial branch enters the prostate at each side of the bladder neck and runs toward the verumontanum parallel to the course of the proximal urethral segment. It supplies the periurethral region and medial transition zone. Transurethral resection regularly obliterates this arterial branch and all the tissue supplied by it (23).

Architectural Patterns of the Glandular Prostate

The biologic role of the prostate calls for the slow accumulation and occasional rapid expulsion of small volumes of fluid. These requirements are optimally met by a muscular organ having a large storage capacity and low secretory capacity. In such an organ, the different morphology of ducts and acini found in organs of high secretory capacity, such as the pancreas, would appear to be of limited value. Accordingly, the prostatic ducts are morphologically identical to the acini except for their geometry, and both appear to function as distensible secretory reservoirs. Within each prostate zone, the entire ductâ€“acinar system, except for the main ducts near the urethra, is lined by columnar secretory cells of identical appearance between ducts and acini. Immunohistochemical staining for prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP) shows uniform granular staining of all ductal and acinar cells (Figure 36.11). In view of these considerations, there is probably no functional ductâ€“acinar distinction in the prostate, and it is unlikely that there is any morphologic or biologic distinction between carcinomas of ductal versus acinar origin.

Except for the main transition zone ducts, which terminate at the anterior fibromuscular stroma, the main ducts of the prostate originate at the urethra and terminate near the capsule (4,7,8) (Figures 36.4,36.5). Because ducts and acini within each zone have comparable caliber, spacing,

and histologic appearance, ducts, ductules, and acini cannot reliably be distinguished microscopically except in sections cut along the ductal long axis. Hence, abnormalities of architectural pattern are identified in routine sections mainly by deviations from normal size and spacing of glandular units.

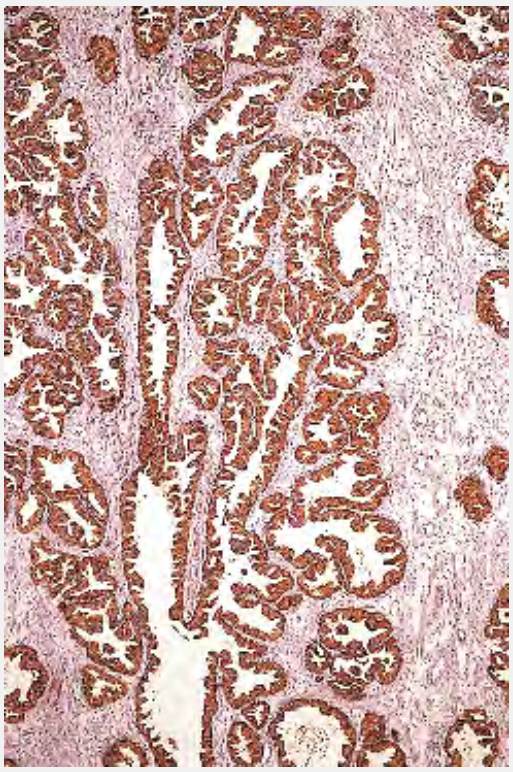

Figure 36.11 Ducts and acini of peripheral zone, immunostained with anti-PSA and showing uniform distribution of protein throughout the cytoplasm of all ducts and acini.

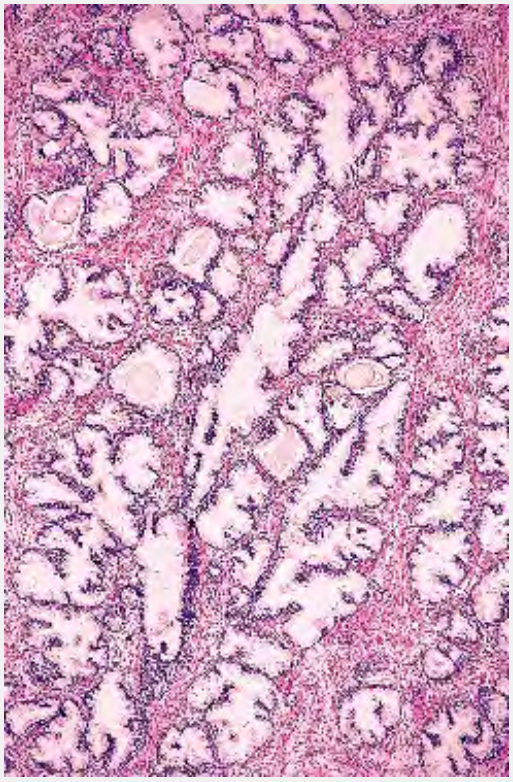

Figure 36.12 Subsidiary duct and branches in peripheral zone, terminating in small rounded acini with undulating borders. Ducts and acini have similar calibers and histologic appearances.

The main excretory duct orifices of the peripheral zone arise from the urethral wall about every 2 mm along a double lateral line extending the full 1.5 cm length of the distal urethral segment. A cluster of three or four subsidiary ducts arise about every 2 mm along the course of each main excretory duct from urethra to capsule. They branch at angles of about 15 degrees and extend only a short distance, rebranching and giving rise to groups of acini (Figure 36.12). Hence, acini tend to be distributed with nearly uniform density along the course of the main duct between urethra and capsule, except that no acini are found immediately

adjacent to the urethra. Conversely, beneath the capsule all glands are acinar. The architecture in the transition zone is similar to the peripheral zone. However, there is more extensive arborization because the main ducts arise from the urethra in a small focus.

The duct origins of the transition zone and periurethral glands from the proximal urethral segment represent a proximal continuation of the double lateral line of the peripheral zone duct origins along the distal urethral segment. However, periurethral ducts also originate anteriorly and posteriorly. This accounts for the presentation of periurethral gland BPH as a dorsal midline bladder neck mass, whereas the lateral locations of transition zone BPH masses reflect the constant location of their main ducts (8).

In the peripheral zone and transition zone, ducts and acini are usually 0.15 to 0.3 mm in diameter and have simple rounded contours that are not perfectly circular because of prominent undulations of the epithelial border (5,7). The undulations mainly reflect the presence of corrugations of the wall, which presumably allow expansion of the lumina as secretory reservoirs. An important criterion for the diagnosis of many highly differentiated prostatic carcinomas is their tendency toward precisely round or oval glandular contours (25,26), reflecting a loss of reservoir function.

Central zone ducts and acini are distinctively larger than those of the peripheral zone and transition zone and may be up to 0.6 mm in diameter or larger (Figure 36.13). Unlike the peripheral zone, both ducts and acini of the central zone become progressively larger toward the capsule at the prostate base, where they often exceed 1 mm in diameter. There is also a gradient of increasing density of acini toward the base. Both of these gradients reflect the great expansion of central zone cross-sectional area from a small focus on the verumontanum to almost the entire prostate base. Near the urethra, the central zone ducts have few branches

and lack distinctive histologic features. Hence, they may not be recognizable in transverse planes of section near the base of the verumontanum. Acini are clustered into lobules around a central subsidiary duct,

which is distinguishable from the acini in cross section only by its central location. Ducts and acini are polygonal in contour. Many of the corrugations in their walls are exaggerated into distinctive intraluminal ridges with stromal cores, which partially subdivide acini.

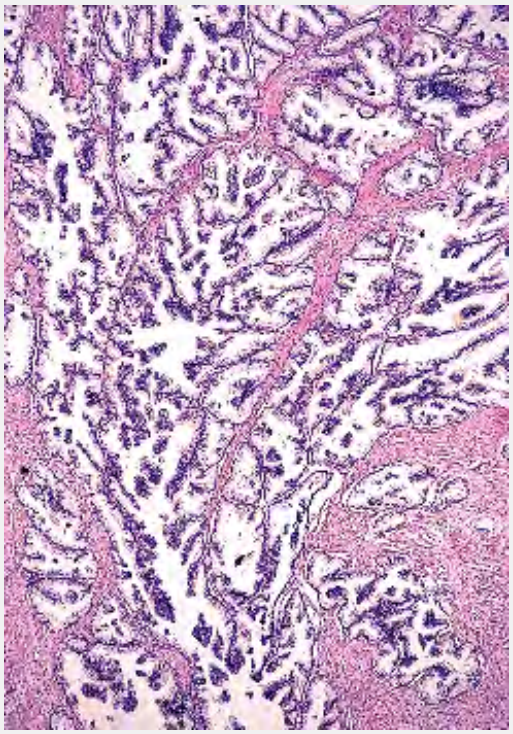

Figure 36.13 Subsidiary ducts and acini in the central zone form a compact lobule with flattened gland borders and prominent intraluminal ridges.

Glandular subdivisions within a given duct branch in the central

zone are separated by narrow bands of distinctively compact smooth muscle fibers, whereas broader bands separate different branches. The normal overall ratio of epithelium to stroma here (lumens excluded) is roughly 2:1. The epithelial to stromal ratio of the peripheral zone and transition zone is close to 1:1. In the peripheral zone, the more abundant stroma is loosely woven, with randomly arranged muscle bundles separated by indistinct spaces containing loose, finely fibrillar collagenous tissue. Between the glandular spaces in a given duct branch, stroma is as abundant as between different branches.

There is an abrupt contrast in stromal morphology that delineates the boundary between central zone and peripheral zone and a similar contrast between peripheral zone and transition zone (11) (Figures 36.14,36.15,36.16). The transition zone stroma is composed of compact interlacing smooth muscle bundles (Figures 36.14, 36.16). This stromal density contrasts sharply with the adjacent loose peripheral zone stroma, but it blends with the stromas of the preprostatic sphincter and anterior fibromuscular stroma. Stromal distinctions are less evident in older prostates and may be obliterated by disease (27,28).

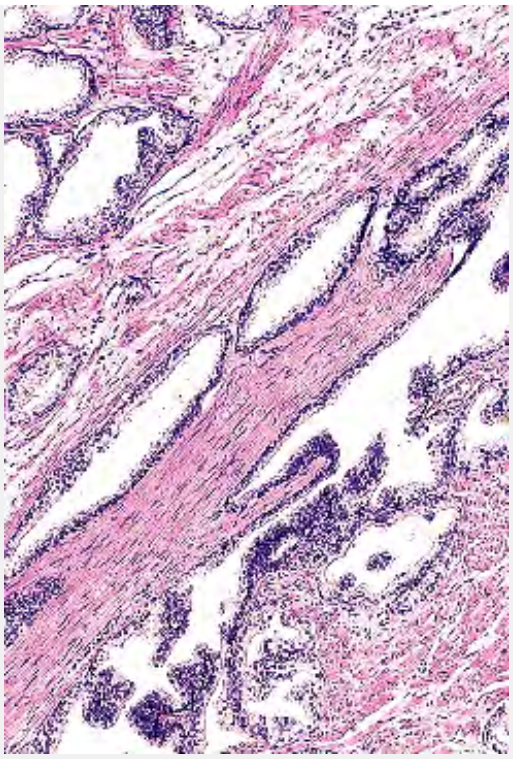

Figure 36.14 Border between the peripheral zone (*above*) and transition zone shows contrast in stromal texture and a band of smooth muscle at the zone boundary. Glandular histology is similar between zones.

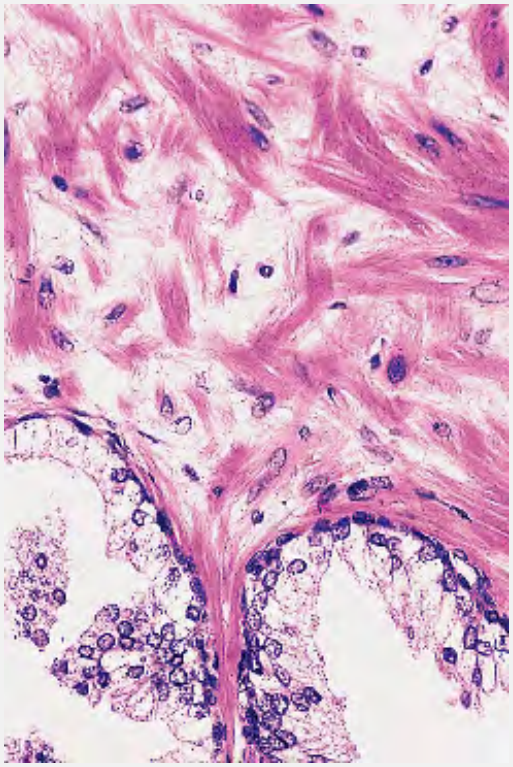

Figure 36.15 Peripheral zone acini set in loosely woven fibromuscular stroma. Secretory cells are more regular than in central zone, with smaller basal nuclei and pale cytoplasm. Basal cells are visible.

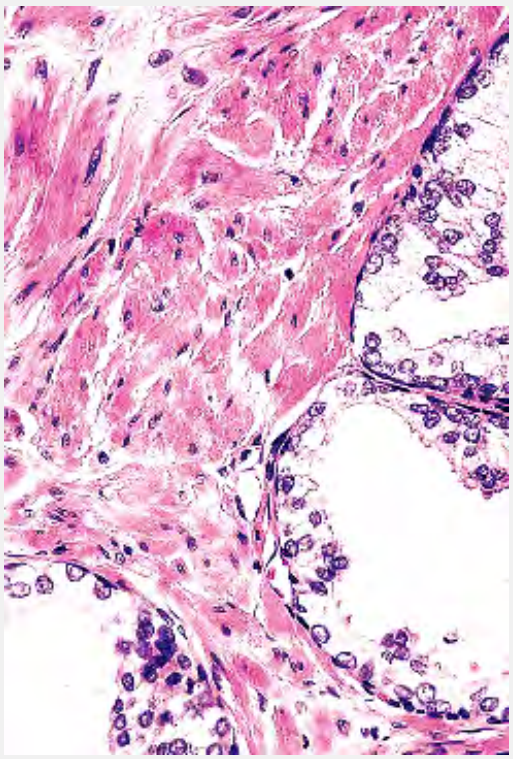

Figure 36.16 Transition zone acini set in a compact stroma composed of interlacing, coarse, smooth muscle bundles. Acinar histology is identical to that in the peripheral zone. Basal cells are visible.

Cytologic Features of the Glandular Prostate

As with other glandular organs, the secretory cells throughout the prostate are separated from the basement membrane and stroma by a layer of basal cells. These cells are markedly elongated and flattened parallel to the basement membrane and have slender, filiform dark nuclei and usually little or no discernible cytoplasm (29) (Figures 36.15,36.16). They are typically quite

inconspicuous; and, in routine preparations, the basal cell envelope may appear incomplete or even absent around individual ducts or acini. However, immunohistochemical staining for basal cellâ€“specific keratin or for p63 antibody shows the envelope to be complete, even where no basal cells are identified with routine stains (30). These stains are consistently negative in the cells of invasive malignant glands (31) because basal cells are absent.

Basal cells are not myoepithelial cells analogous to those of the breast because, by electron microscopy, they do not contain muscle filaments (29). Logically, myoepithelial cells would appear to be functionally superfluous in a muscular organ (29). Basal cells have been found to be the proliferative compartment of the prostate epithelium, normally dividing and maturing into secretory cells (32,33,34). Using immunostaining for proliferating cell nuclear antigen as a marker for cycling cells, roughly 1% of basal cells and 0.1% of secretory cells were labeled in each zone, and there was no difference between ducts and acini. Eighty-three percent of all labeled cells were basal cells, even though they comprised only 30% of the total epithelial cell population (34).

In all zones of the prostate, the epithelium contains a small population of isolated, randomly scattered endocrineâ€“paracrine cells (35) that are rich in serotonin-containing granules and contain neuron-specific enolase. Subpopulations of these cells also contain a variety of peptide hormones, such as somatostatin, calcitonin, and bombesin. They rest on the basal cell layer between secretory cells but do not typically appear to extend to the lumen or may send a narrow apical extension to the lumen. They often have laterally spreading dendritic processes. They are not reliably identifiable microscopically except with immunohistochemical and other special stains. Their specific role in prostate biology is unknown, but they presumably have paracrine function, perhaps in response to neural stimulation. Like similar cells in the lung and other organs, they occasionally give rise to small cell carcinomas, which do not contain PSA or PAP

(36). Not infrequently, however, small cell carcinoma arises as a variant morphologic pattern within adenocarcinomas that elsewhere contain PSA and PAP; peptide hormones are found only in the small cell component (36). Hence, the status of these cells as an independent lineage is doubtful in the prostate.

The secretory cells of the prostate contribute a wide variety of products to the seminal plasma. PSA and PAP are produced by the secretory cells of the ducts and acini of all zones. Pepsinogen II (37) and tissue plasminogen activator (38) are normally produced only in the ducts and acini of the central zone. Lactoferrin is also exclusively a secretory product of the central zone, except in areas of inflammation where both the cells and secretions anywhere in the prostate may produce this substance (39). Lectin staining for cell membrane carbohydrates also shows significant differences between the two zones (40). It has been suggested that the central zone may be specialized for the production of enzymes whose substrates are secreted by the peripheral zone (38), but probable substrates have not been identified. In fact, no secretory product has so far been identified that is produced exclusively by the peripheral zone or transition zone.

The cytoplasm of the normal secretory cell in all zones is similar in appearance and is dominated by the universal abundance of uniform small clear secretory vacuoles. Vacuoles in peripheral zone and transition zone cytoplasm are packed at nearly maximum density (41), whereas, in the central zone, a more abundant dense cytoplasm is associated with a somewhat wider vacuole spacing and lower vacuole density. Because the secretory vacuoles appear empty by routine microscopy, peripheral zone and transition zone cells are pale to clear, and central zone cells are typically somewhat darker.

However, the appearance of normal cell cytoplasm on tissue sections is strongly influenced by staining technique and by the type of fixative used. In the peripheral zone and transition zone,

light hematoxylin and eosin (H&E) staining after formalin fixation shows that normal cells are â€œclear cellsâ€• in which a faint network of pale-staining cytoplasmic partitions between vacuoles can be visualized with careful scrutiny under high magnification (Figure 36.17). Only an occasional cell shows complete outlines that define numerous intact vacuoles, but immunostaining with PSA or PAP on the same tissue sharply outlines all the cytoplasmic vacuolar partitions and shows no evidence of protein within the vacuoles. Denser H&E staining not only darkens the partitions but also enhances diffuse staining throughout the cytoplasm, which obscures both the clear cell appearance and the visualization of the vacuoles.

The contents of the apparently empty vacuoles consist partly of lipid, as judged by interpretation of fat stains on fresh frozen sections, but there is also a nonlipid component. With H&E staining after fixation in glutaraldehyde or the commercial fixative Ultrim (American Histology Reagent Co., Stockton, CA), the clear vacuoles are replaced by brightly staining red granules. The nature of the stained product is probably related to spermine, a low-molecular weight alkaline substance. Using these alternate fixatives, immunostaining for protein such as PSA or PAP is still negative within vacuole lumens.

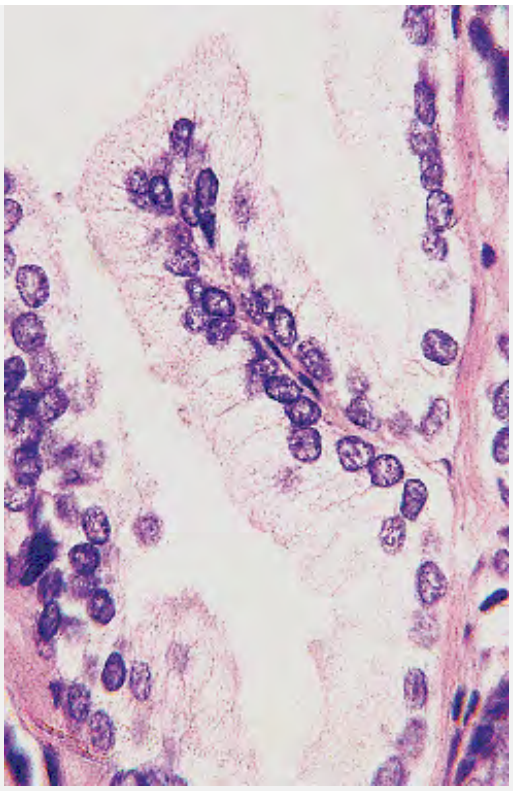

Figure 36.17 Peripheral zone epithelium showing clear cells in which cytoplasm is barely discernible as composed of a sheet of small empty vacuoles with delicate pale partitions.

Vacuoles are usually reduced or absent in the cytoplasm in dysplasia (prostatic intraepithelial neoplasia) (41) (Figure 36.3) and in most invasive carcinomas of Gleason's grade 3 or higher. In Gleason's grades 1 and 2 cancer, as well as some areas in grade 3 cancer, cytoplasmic vacuoles are retained, and these tumors have been referred to as clear cell carcinomas.

The secretory lining of peripheral zone glands conveys an orderly appearance, with a single layer of columnar cells having basally oriented nuclei. In most glands, however, the epithelial row shows considerable random variation between neighboring cells in the

ratio of cell height to width and in apparent cell volume. Nuclear location also varies from the basal cell aspect to the mid-portion of the cell. The luminal cell border is consequently often uneven, and its roughness is accentuated by frequent cells whose luminal aspect is irregular and frayed. Prostate-specific antigen stain shows a reticular pattern diffusely throughout the cytoplasm (Figure 36.18).

These deviations from uniformity and the resulting slightly untidy pattern of the normal epithelial strip appear intimately related to secretory function. Cytokeratin immunostaining of secretory cells shows that the cytoskeleton does not extend as far as the luminal aspect of each cell (Figure 36.19); it usually terminates somewhat above the midportion of the cell level in a sharp transverse line whose level from cell to cell defines a more uniform thickness of

the epithelial row than the full thickness that is stained by H&E. All of the cell contents toward the lumen from this transverse line appear to represent an isolated apocrine secretion compartment having diminished or absent cytoskeleton. As much as one-third of the total height of some cells may belong to this apocrine compartment. Lumenward from the terminal line of the keratin cytoskeleton, neighboring cells may lose their lateral adhesion and are sometimes separated by a narrow cleft. The indistinct luminal aspect of some cells appears to represent disintegration of this apical portion of the cell in situ. Release of contents of apocrine secretion into the lumen by fragmentation while still attached to the cell is the characteristic mode of peripheral zone and transition zone secretions; release of intact apocrine sacs from the underlying cell is rarely seen.

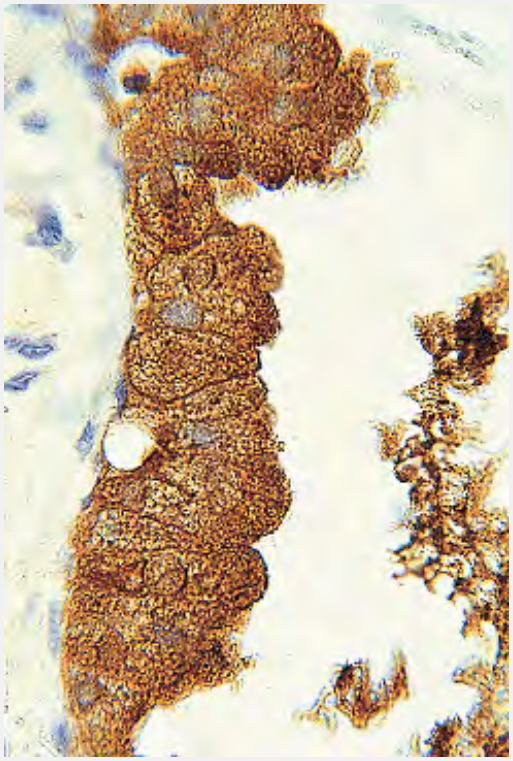

Figure 36.18 Peripheral zone epithelium immunostained with anti-PSA. Protein is concentrated in a reticulated pattern that spares vacuole lumens and accentuates portions of vacuole partitions.

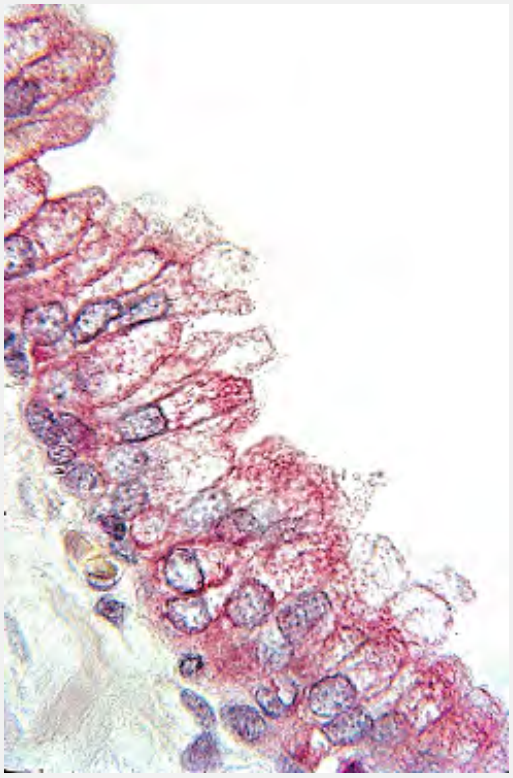

Figure 36.19 Peripheral zone epithelium immunostained with antibody to secretory cell cytokeratin. Normal epithelial cells appear quite variable in size and shape, and some nuclei are displaced from cell base. Cytokeratin is accentuated toward luminal border, but at lower right and upper middle, clusters of cells have attached apocrine compartments lumenward, which have no cytokeratin staining and accentuate the irregularity of luminal epithelial border.

The morphologic appearance of normal peripheral zone epithelium is closely mimicked by only that minority of clear cell well-differentiated carcinomas that retain abundant cytoplasmic clear vacuoles, often Gleason's grades 1 and 2 (25,26). However, these malignant cells usually differ from normal peripheral zone in having a sharply defined luminal plasma membrane that lies at the

same height between epithelial cells and traces an even transverse line around the gland perimeter (Figure 36.20). Thus, the fragmenting apocrine compartment is usually absent; and, correspondingly, the cytoskeleton as visualized by keratin immunostaining the entire cytoplasm. Also, these malignant clear cells are of more nearly equal dimensions and contours than their benign counterparts, and nuclei are more strictly localized at the cell base. In dysplasia and in most grade 3 carcinomas, secretory vacuoles are much reduced or absent; cell cytoplasm is correspondingly dark (41).

Figure 36.20 Clear cell carcinoma immunostained with antibody to secretory cell cytokeratin shows stronger cytokeratin accentuation at a luminal epithelial border, which is more even than in Figure 36.19, and lacks the apocrine secretory compartment. Cells are larger and more uniform

than in Figure 36.19, with more basally located nuclei.

Central zone epithelium, by contrast, shows an accentuation of the mild disorder of cell arrangement of the peripheral zone/transition zone (Figure 36.21). Here the epithelium is variably thickened by prominent cell crowding. Nuclei, which are usually larger than in the peripheral zone, are often displaced further from the cell base than in the peripheral zone and may give the illusion of stratification in more crowded areas. Cell height is often quite variable, and because the luminal cell border usually is intact rather than disintegrating, irregular protrusion of cell apices into the lumen is prominent. Apocrine secretion in the central zone may be identical to that in the peripheral zone, but often it is characterized by intact spherical sacs in the gland lumen, containing no vacuoles, and staining more densely than the parent cell. They tend to remain intact after secretion as dense luminal spheres (Figure 36.21).

The dark cytoplasm, thickened variable epithelium, and complex architecture in the central zone may be misinterpreted as atypical hyperplasia or dysplasia on needle

biopsies. However, the distinctive histologic features plus the absence of nuclear size variability, hyperchromasia, and loss of polarity rule against dysplasia. The central zone is not often sampled by needle biopsies because its maximum extent is mainly restricted close to the prostate base.

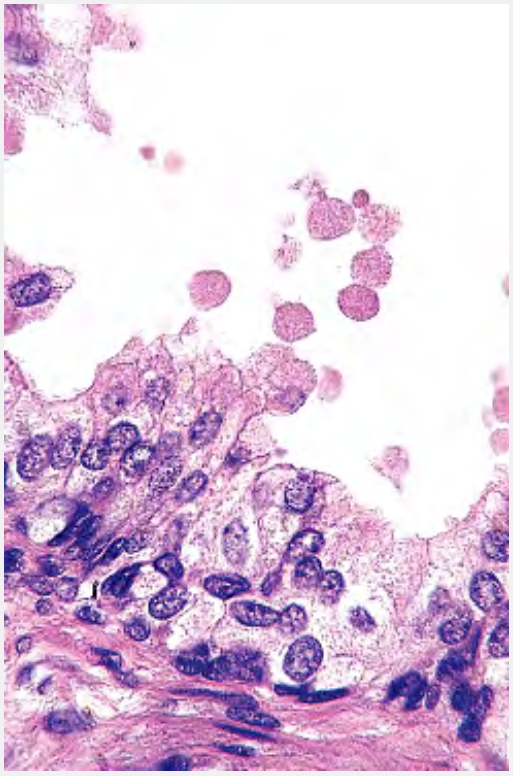

Figure 36.21 Central zone epithelium with dark cytoplasmic staining in an area of active apocrine secretion. Clear vacuoles are absent from apocrine secretion. Nuclei appear crowded and disordered, lying at different levels.

Unique specialized secretory structures called lacunae are also common in the central zone (39). These are tiny round lumens that appear to lie entirely within the epithelial cell layer, isolated from the main ductâ€“acinar lumen system (Figures 36.22,36.23). A complete layer of flattened epithelial cells is seen to surround each lacuna, but these lacunar cells have no apparent contact with stroma. They only abut onto surrounding secretory cells. Lacunae are a specialized apparatus for lactoferrin production and storage, as demonstrated by immunohistochemical staining.

The central zone appears to represent a separate glandular organ

within the prostate capsule. Aside from its unique morphologic features, its ducts arise from the urethra separately from the double lateral line of the remainder of the prostate. In addition, its ducts are in close anatomic proximity to the ejaculatory ducts and seminal vesicles. It has been suggested that the central zone may arise embryonically as an intrusion of wolffian duct stroma around the ejaculatory ducts into an organ that is otherwise of urogenital sinus origin (7). Pepsinogen II (37) and lactoferrin (39) are secreted by both the central zone and seminal vesicles but are not found under normal conditions in the peripheral or transition zones.

Figure 36.22 Central zone with dense muscle bundles, dark basal cells, and opaque cytoplasm.

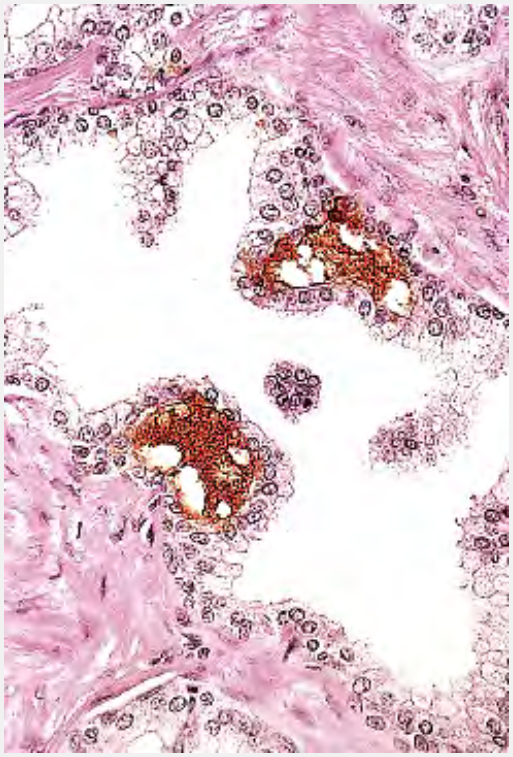

Figure 36.23 Central zone gland immunostained with anti-lactoferrin. Lacunae on both sides of the lumen are densely stained, but cell cytoplasm is negative.

Deviations from Normal Histology

Beyond the age of 30 years, many prostates begin to show a variety of focal deviations from normal morphology (4,7,27,28). Their prevalence, extent, and severity progressively increase with age so that most prostates by the seventh decade of life are quite heterogeneous in histologic composition. Although these deviant histologic patterns seldom have clinical significance, their distinction from adenocarcinoma or BPH is sometimes difficult.

Early morphologic studies concluded that focal atrophy in the prostate was a manifestation of aging and was seen as early as 40

years of age. In fact, focal atrophy in the prostate is often the consequence of previous inflammation rather than aging (4,7). The number and extent of atrophic foci tend to be greater in older men, but their histologic appearance is identical to that of isolated foci found as early as 30 years of age. The histologic features are identical to those produced by chronic bacterial prostatitis, but no etiologic agent has been identified in the vast majority of cases, most of which appear to be asymptomatic.

Postinflammatory atrophy is an extremely common lesion and is mainly a disease of the peripheral zone, where its distribution is sharply segmental along the ramifications of a duct branch (4,7). It is characterized by a marked shrinkage of ducts and acini with periglandular fibrosis and variable distortion of architecture (Figures 36.24,36.25).

Glandular units may be drawn together into clusters or spread out into a pattern suggesting invasive carcinoma. In addition to the presence of tiny distorted glands, the resemblance to cancer is further increased by the fact that nuclei may remain relatively large with occasional small nucleoli.

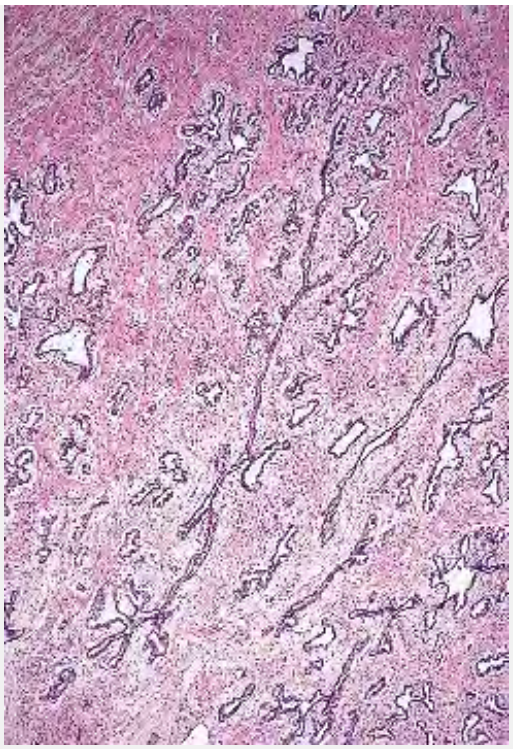

Figure 36.24 Focus of postinflammatory atrophy in peripheral zone. Ductâ€“acinar architecture is apparent but distorted by marked gland shrinkage, with reduced luminal area and periglandular fibrosis.

In contrast to carcinoma, cell cytoplasm is usually much reduced in volume, and evidence of the original ductâ€“acinar architecture often can be detected. Furthermore, there is usually residual inflammation, with scattered round cells in the adjacent stroma. Finally, there is sometimes an admixture of glands showing the earlier active phase of the process, with prominent periductal and periacinar chronic inflammatory infiltrate and less prominent gland shrinkage.

Cystic atrophy is another common focal lesion that is typically found in the peripheral zone and is segmental in distribution. The markedly enlarged acini with flattened epithelium and the

segmental distribution suggest an obstructive cause (Figure 36.26). However, obstruction is not typically demonstrable, and the stroma between glands is usually attenuated rather than compressed by luminal expansion. This suggests that stromal atrophy may be the main pathogenetic event.

The histologic hallmark of BPH is the expansile nodule, produced by the budding and branching of newly formed ductâ€“acinar structures (Figure 36.27), by the focal proliferation of stroma, or by a combination of both elements (4,5,8,42). It mainly affects the transition zone, with occasional contribution from the periurethral region. Individual BPH nodules rarely become larger than 1.6 cm in greatest diameter; and, in any prostate, median nodule diameter is almost always less than 8 mm. An exception is produced in massive BPH by secondary nodule enlargement due to cystic dilatation of component glands.

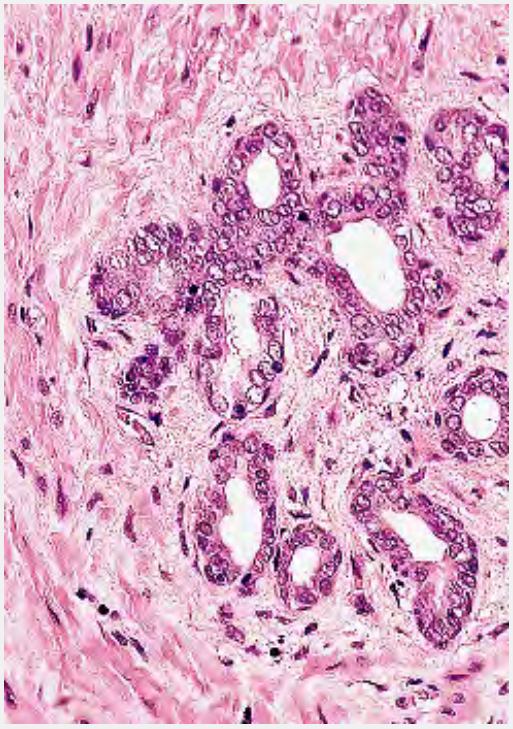

Figure 36.25 Tiny distorted glands of postinflammatory

atrophy. Irregular contours and large nuclei mimic carcinoma; however, cytoplasm is scant, and there are periglandular collagenous rings.

Figure 36.26 Cystic atrophy in the peripheral zone.

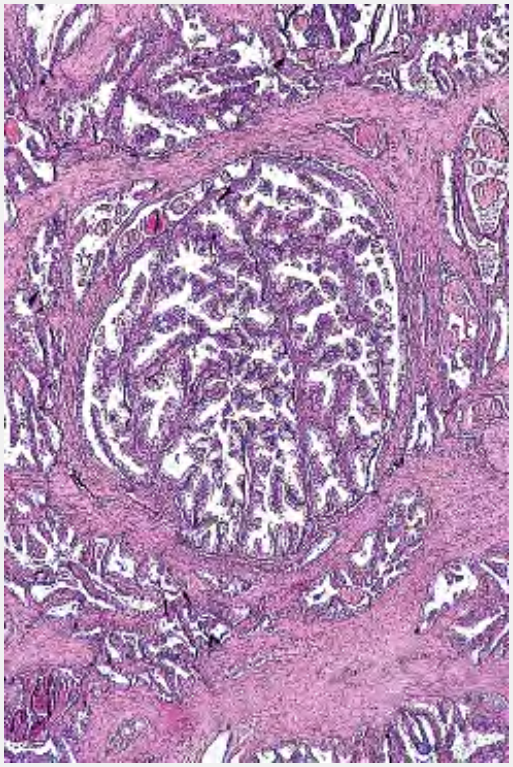

Figure 36.27 Very small, gland-rich benign nodular hyperplasia nodule arising from dense stroma.

Grossly BPH is usually recognized as a globular mass replacing each transition zone and composed of numerous individual nodules embedded within a diffusely hyperplastic transition zone tissue (Figure 36.28). Only the nodular component is recognizable histologically as a deviation from normal pattern; internodular tissue, even when increased in amount, is not distinguishable microscopically from normal transition zone.

The enlargement of transition zone BPH produces a characteristic progressive deformity of overall prostate contour (Figure 36.29). The tissue lateral and posterior to the prostatic urethra (central zone and peripheral zone) is relatively unyielding, and expansion

is directed anteriorly and toward the apex at the selective expense of stretching and thinning of the anterior fibromuscular stroma. This produces a predominant increase in the thickness (anteroposterior dimension) of the gland. The anterolateral wings of the peripheral zone where they taper to join the anterior fibromuscular stroma (Figure 36.5) are compressed and thinned concomitant with increase of overall prostate width, but posterior and lateral peripheral zones are not significantly thinned except in massive BPH.

The central zone is the least compressed region, but it is pulled forward over the BPH mass, accompanied by characteristic lengthening of the proximal urethral segment. As the urethra lengthens, its angulation at the midpoint increases, sometimes approaching 90 degrees (Figure 36.29). Increased angulation produces a more globular anteroapical compartment, which accommodates a larger BPH mass. The mucosa of the lateral urethral walls is compressed between the two opposed transition zone masses, and its surface area is stretched to a larger expanse as the transition zone masses expand (Figure 36.30).

Figure 36.28 Small BPH nodule with increase of epithelial to stromal ratio to roughly 2:1 and surrounded by normal transition zone with epithelial to stromal ratio far below 1.

Basal cell hyperplasia is most often seen as a secondary change in BPH nodules or inflammatory foci (33). The basal cells of ducts and acini become rounded with oval nuclei, and they form a multilayered lining that stains for

basal cellâ€“specific cytokeratin (Figure 36.31). There is typically a single luminal row of columnar secretory cells that stain positive for PSA.

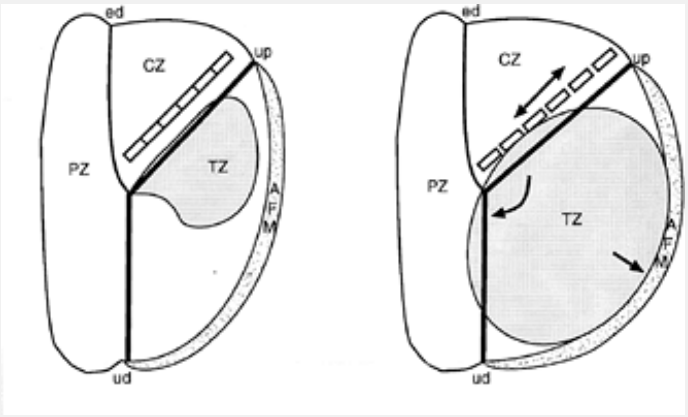

Figure 36.29 Sagittal diagrams of prostate showing main features of deformity produced by transition zone BPH. Transition zone (*TZ*) is bounded by the distal urethral segment (*ud*), proximal urethral segment (*up*), and anterior fibromuscular stroma (*FM*) (see Figure 36.3). Only the last leg of this triangular compartment yields easily to the pressure of transition zone expansion. Increased angulation and lengthening of urethra produce a more spherical compartment with increased capacity. *Arrows* indicate main features of deformity. (*CZ*, central zone; *PZ*, peripheral zone; *ed*, ejaculatory duct)

Figure 36.30 Model of prostate with severe BPH seen in three-quarter frontal view. The transition zone mass on far side (blue) shows growth mainly anteriorly and toward the apex. BPH mass has been removed on the near side, showing concavity in the peripheral zone caused mainly by stretching and thinning of the anterolateral margin. The urethra shows prominent increased angulation, with anterior stretching of lateral walls between BPH masses.

In BPH, basal cell hyperplasia is common at the margin of nodule infarcts, where presumably it represents a reaction to ischemia. Consistent with this proposal is the finding of smooth muscle atrophy and replacement by fibroblastic stroma in these areas. Much more commonly, basal cell hyperplasia is found in BPH nodules without frank infarction, but the almost invariable presence of fibroblastic stroma and smooth muscle atrophy suggest that ischemia may be etiologic here also. Gland shrinkage also usually accompanies these foci and may suggest a superficial resemblance to carcinoma.

Dysplasia is a type of morphologic change seen in any prostate zone and characterized by focal enlargement of individual cells in an area with rounded dark nuclei showing changes characteristic of adenocarcinoma and occasionally showing features intermediate between cancer, dysplasia ducts, and acini (Figures 36.32,36.33).

Evaluation of Radical Prostatectomy Specimens

Normal morphologic features can be difficult to evaluate in the age group in which radical prostatectomy is usually performed. Landmarks are often obscured or distorted by retrogressive changes with aging or inflammation, whereas some prostates retain the normal appearance of the third decade of life, and some show increased glandular epithelial activity with or without atypia. Not infrequently, the morphologic appearance of any zone seems unrelated to the changes in other zones. Difficulties of interpretation are compounded when all sections are cut in the same plane

rather than different planes designed for optimum visualization of each zone.

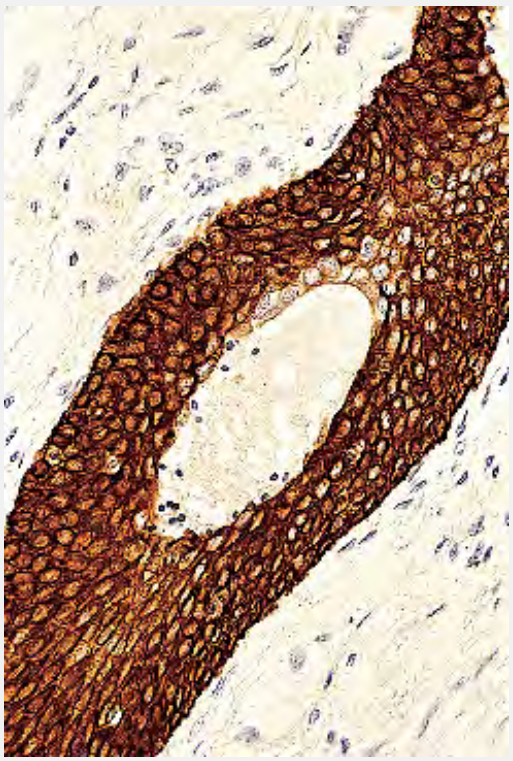

Figure 36.31 Prostatic duct with basal cell hyperplasia immunostained with antibody to basal cellâ€“specific cytokeratin. Basal cells create multiple layers, but a single luminal layer is secretory and remains unstained.

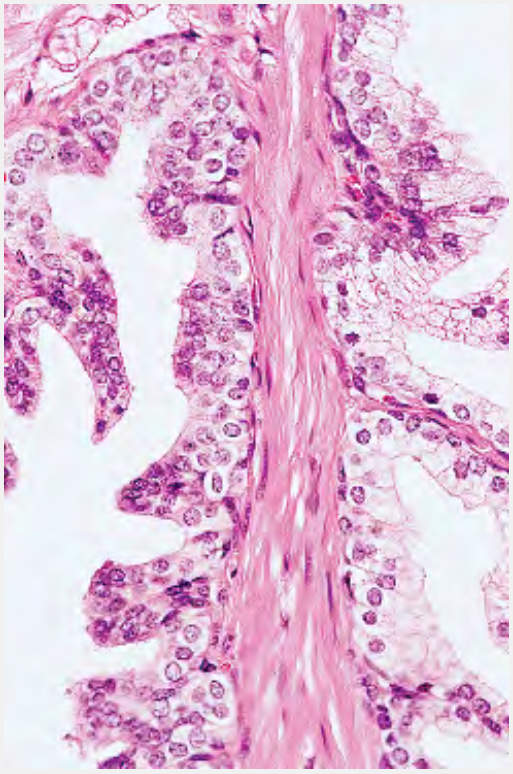

Figure 36.32 Central zone with right half normal and left half showing mild dysplasia.

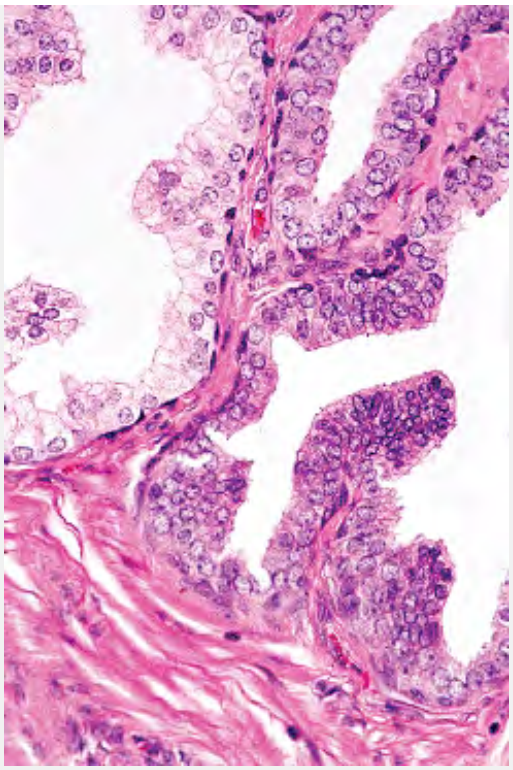

Figure 36.33 Central zone with left half showing mild dysplasia and right half showing severe dysplasia.

Transverse planes of section, perpendicular to the rectal surface are the most common type of routine prostate sectioning, partly because they are the easiest to cut. They are also nearly parallel to the plane of many ultrasound and magnetic resonance images. They show much the same relationships as the oblique coronal planes except that the urethra is never seen along its long axis. It is important to review the expected appearance of transverse planes at different levels because of the considerable differences encountered.

Transverse sections distal to the base of the verumontanum demonstrate the transition zone at most levels of section toward the apex in most men over 50 years of age, even when there are few nodules to signify BPH (8,42). Diffuse transition zone

enlargement accompanying nodule development is nearly universal with age, and expansion is mainly anterior and toward the apex. The boundary between the transition zone and peripheral zone is often visualized more clearly by ultrasound imaging than by histologic study. Microscopically the difference in texture of the stroma between the two zones is the most important evidence for the location of the boundary between them, but it may not be apparent at all points.

The boundary of the transition zone with the peripheral zone seldom extends closer than 1.0 cm to the posterior (rectal) prostate surface. If there has been a previous TUR, the resection cavity usually extends mainly anteriorly from the posterior urethral wall. Significantly, the TUR often spares the lateral portion of the transition zone, sometimes with residual nodules, and the transition zone boundary remains intact.

Proximal to the base of the verumontanum, only one or two sections still show a transition zone unless there is a large mass of BPH tissue. The ejaculatory ducts now appear on these proximal sections, with the utricle between them. The dorsal, compact transverse portion of the preprostatic sphincter may be seen just anterior to the ejaculatory ducts. The sphincter and urethral lumen progress more anteriorly at each level of section cephalad until they reach the anterior tissue border at the bladder neck.

The bladder neck lies a variable number of sections below (apical to) the highest transverse section cut at the prostate base (Figure 36.34). The central zone may not be apparent histologically until the bladder neck level of section or higher. It usually appears suddenly between two transverse levels of section separated by only 3 mm. This is because the central zone is an inverted flared cone whose apical region near the verumontanum consists predominantly of main duct branches that cannot be readily distinguished from those of other zones. At the transverse level where it is first recognizable, the anterior portion of the central

zone may lie directly above the area occupied by the transition zone in the section just one level below, and the transition zone is usually no longer visible. The central zone has a more distinctive histologic appearance in sections toward the base because of the rather abrupt increase in size and number of branches. The most basal section is usually almost entirely composed of central zone and consists mostly of acini that are distinctively large, polygonal, and closely packed (14).

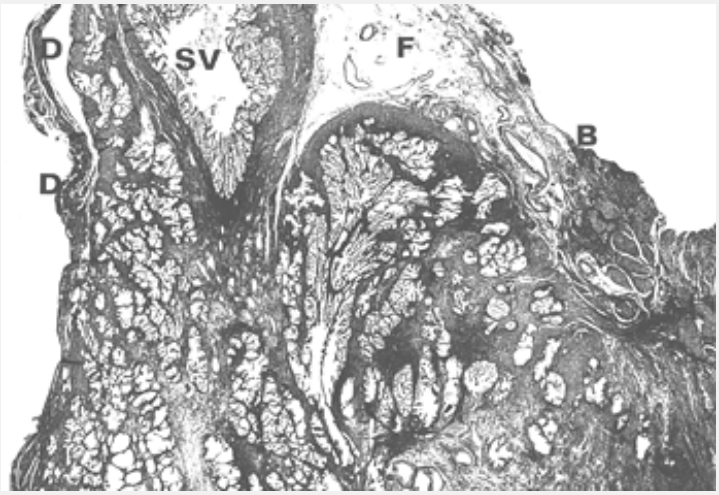

Figure 36.34 Parasagittal section of prostate base located almost at midline. Bladder neck smooth muscle above the level of bladder neck lumen is seen as a small dark patch (*B*) at far right. A layer of fat (*F*) covers the dome-shaped surface of the anterior central zone (*top center*). All glandular tissue within is central zone. One main duct (*center*) is seen in profile as it flares out toward the base, generating elaborate acinar structures. Behind the seminal vesicle (*SV*), the posterior central zone extends more celaphad as a narrow plate. Denonvilliers' fascia (*D*) is not adherent behind the seminal vesicles but blends with the capsule below.

As the seminal vesicles leave the prostate base, they extend laterally along its basal surface (Figure 36.9). Often there is no capsule between the two organs, at least for the medial centimeter or more of the seminal vesicle. The degree of fusion between the two muscular walls is variable between prostates, but there is frequently no boundary whatever between the two organs medially, and only one millimeter of common muscular wall may separate the most basal central zone gland lumen from the seminal vesicle lumen.

The origin of the ejaculatory ducts at the junction of seminal vesicles and vas deferens is surrounded by central zone glandular tissue and usually situated so that about two-thirds of the central zone mass is anterior to the ejaculatory ducts. However, it is quite common for the ejaculatory ducts to be situated more posteriorly; occasionally they enter the prostate on the rectal surface and entirely posterior to the central zone.

The most basal transverse section of prostate usually has some bladder neck muscular wall at its anterior extent (Figure 36.34). Behind this muscle is a strip of fat that lies between the seminal vesicles and the bladder and rests on top of the most anterior aspect of the central zone. That portion of the central zone anterior to the ejaculatory ducts usually terminates at a lower level than the posterior portion, and the latter extends further cephalad as a thin plate between seminal vesicles and Denonvilliers' fascia (Figure 36.35). The strip of fat contains the large nerve trunks extending medially from the autonomic ganglia of the superior pedicle, which is situated lateral to the central zone at this level. When cancer penetrates the capsule at the prostate base, it is often seen within the fatty strip between bladder neck and central zone. Less often, it is associated with the nerves and ganglia of the superior pedicle lateral to the gland. Occasionally cancer extends above the prostate base posteriorly within the layers of Denonvillier's fascia. In large cancers, these

three routes of extensionâ€”anteriorly, laterally, and posteriorlyâ€”often fuse with cancer in the seminal vesicle to produce a confluent mass of tumor above the prostate base.

Figure 36.35 High power of central zone showing vertical course of ducts. (*SV,* seminal vesicle; *F,* fat)

Figure 36.36 Apex of prostate seen grossly after 6-mm thick apical block has been subsectioned parasagittally at 3-mm

intervals. Orientation of sections and localization of lesions are easily demonstrated, and cuts through the capsule are nearly perpendicular to the apical surface.

At the apex of the prostate, sections should be taken as serial parasagittal subsections of a 6-mm thick block (Figure 36.36). This procedural modification sacrifices the transverse sectioning of the last level, which would lie 3 mm above the apex. However, it creates the advantage of showing the apical prostate tissue in planes that are more nearly perpendicular to the apical capsule surfaces, so that penetration of cancer can be more easily evaluated. In this area, where positive surgical margins are relatively common and capsule layers may be indistinct, such an advantage is important. Anterior to the urethra and for a narrow span anterolaterally, there is no capsule but only the distal end of the anterior fibromuscular stroma. Here there is a variable admixture of glands, striated muscle, and smooth muscle, and evaluation of capsule penetration is difficult. This is an area where adequate surgical resection is particularly difficult, and a positive margin may occasionally be created by transection of a small anterior cancer that was incidental, whereas the clinically detected cancer was elsewhere and has been successfully removed.

Considerations in Transurethral Resection and Needle Biopsy Specimens

Tissue distortion by heat coagulation near the edges of TUR chips can create important diagnostic problems that occasionally may be insurmountable. Basal cell hyperplasia,

adenomatous hyperplasia, inflammatory atrophy, and fragments of BPH nodules with small glands may be indistinguishable from

carcinoma. Loss of nuclear detail occurs to a greater depth into the chip than obvious cell distortion. Hence, small foci of cancer may be more difficult to diagnose because of the artifactual absence of nucleoli. Gleason has indicated that the identification of occasional nucleoli larger than 1 Âµm in diameter is an important criterion for distinguishing well-differentiated cancer from adenosis (26).

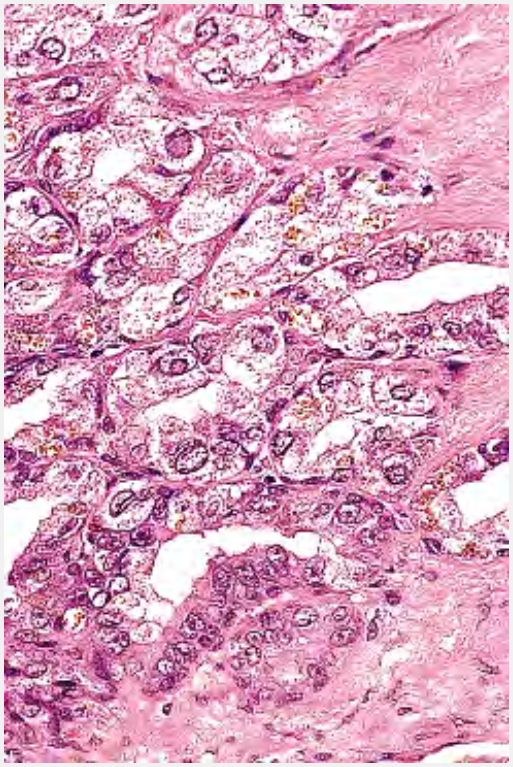

Figure 36.37 Benign tubular invaginations from the wall of the intraprostatic seminal vesicle showing architectural and cytologic features that suggest carcinoma. Note the characteristic yellow-brown cytoplasmic granules.

The same problems are seen in needle biopsies, where the artifact is presumably due to compression rather than heat. The presence of artifact is usually limited to loss of nuclear detail and is more

subtle because areas of severe tissue distortion are not often represented.

The regions of the prostate sampled by TUR and by needle biopsy tend to be quite different. Most needle biopsies represent peripheral zone tissue. Unless a special effort is made, the needle seldom reaches the central zone or the more anterior portions of the transition zone.

In the majority of cases, TUR specimens consist of transition zone tissue, urethral and periurethral tissues, bladder neck fragments, and anterior fibromuscular stroma (42). The preprostatic sphincter is always present but usually not identifiable. Occasionally, fragments of the proximal end of the striated sphincter are present. Our study of radical prostatectomy specimens post-TUR has shown that the resection usually does not extend beyond the transition zone boundary into the central or peripheral zones, and usually not all the transition zone tissue has been removed (42).

Occasionally, peripheral zone or central zone tissue may be sampled at TUR. Central zone fragments show distinctive architectural and cytologic features described above. They are not infrequently accompanied by fragments of ejaculatory duct, intraprostatic vas deferens, and/or seminal vesicle. The tiny tubular outgrowths from the walls of these structures may be misinterpreted as adenocarcinoma when seen in tangential sections that do not reveal the main lumen (Figure 36.37). This impression may be further encouraged by the frequent presence of enlarged dark nuclei of bizarre contour. The presence of golden brown cytoplasmic granules, which may be few and inconspicuous, helps to establish the true diagnosis. Uniform negative staining for PSA and PAP are confirmatory.

Acknowledgment

Dr. McNeal, the author of this chapter, passed away in November

2005. Dr. Ronald Cohen, who worked closely with Dr. McNeal for 10 years and is most familiar with Dr. McNeal's work, was asked to proofread and answer questions associated with this chapter. Dr. Cohen is Associate Professor on the Faculty of Medicine at University of Western Australia as well as Director of Pathology at Uropath both in Perth, Western Australia.

Testis and Excretory Duct System

Thomas D. Trainer

Introduction

The adult testes are paired organs that lie within the scrotum suspended by the spermatic cord (Figure 37.1). The average weight of each is 15 to 19 g, the right usually being 10% heavier than the left (1). The scrotal covering layers are skin, dartos muscle and Colles' fascia, an external spermatic fascia, and the parietal layer of the tunica vaginalis (Figure 37.2). The dartos muscle, of the nonstriated type, is closely attached to the overlying skin but glides freely over the underlying loose fascial layer.

Supporting Structures

The supporting structures of the testis consist of a tough capsule (the tunica) and a number of fibrous septa that extend from the inner surface of the tunica into the parenchyma and divide the testis into approximately 250 lobules, or compartments. The posterior portion of the testis not covered by the capsule is called the mediastinum, which contains blood vessels, nerves,

lymphatics, and the extratesticular portion of the rete testis. The capsule has three distinctive layers: the outer serosa, or tunica vaginalis; the thick, collagenous tunica albuginea; and the inner tunica vasculosa. The tunica vaginalis consists of a flattened layer of mesothelial cells overlying a well-developed basement membrane. It forms a sac with two components; a visceral portion covering the testis and head of the epididymis and a parietal portion, formed as the lining reflects posteriorly and superiorly at the mediastinum and epididymis and then covers the internal spermatic fascia. Infrequently, transitional or squamous metaplasia of the surface epithelium may be present (2). The tunica albuginea is composed of a layer of collagen fibers, within which are embedded fibroblasts, myocytes, mast cells, nerve

fibers, and nerve endings resembling Meissner's corpuscles. The myocytes, found primarily in the posterior aspect of the testis, undergo regular contractions and cause a transient increase in intratesticular pressure. The tunica vasculosa, a loose connective tissue layer containing blood vessels and lymphatics, sends septa into the testicular parenchyma to form the individual lobules. Blood vessels passing through the tunica do so in an oblique plane, which may or may not have some significance with respect to blood flow within the testis. It is well known that the pulse pressure in the testicular parenchyma is extraordinarily low. The tunica varies greatly in thickness with age, averaging 300 Âµg at birth, 400 to 450 Âµg in young adults, and 900 to 950 Âµg in men over 65 years of age (3).

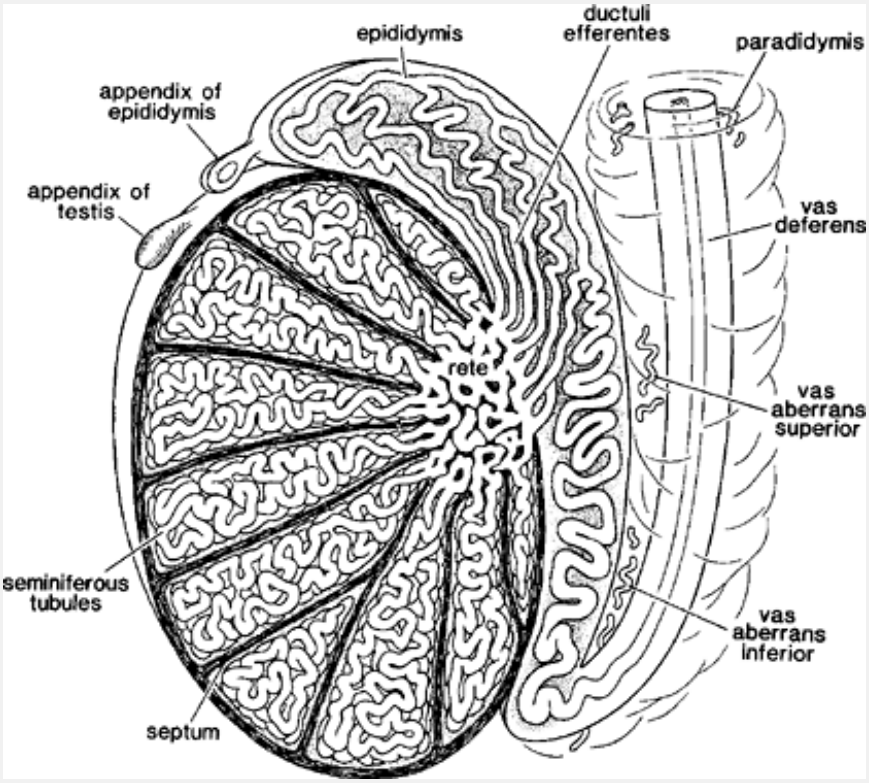

Figure 37.1 Diagrammatic view of testis, epididymis, and portion of ductus (vas) deferens.

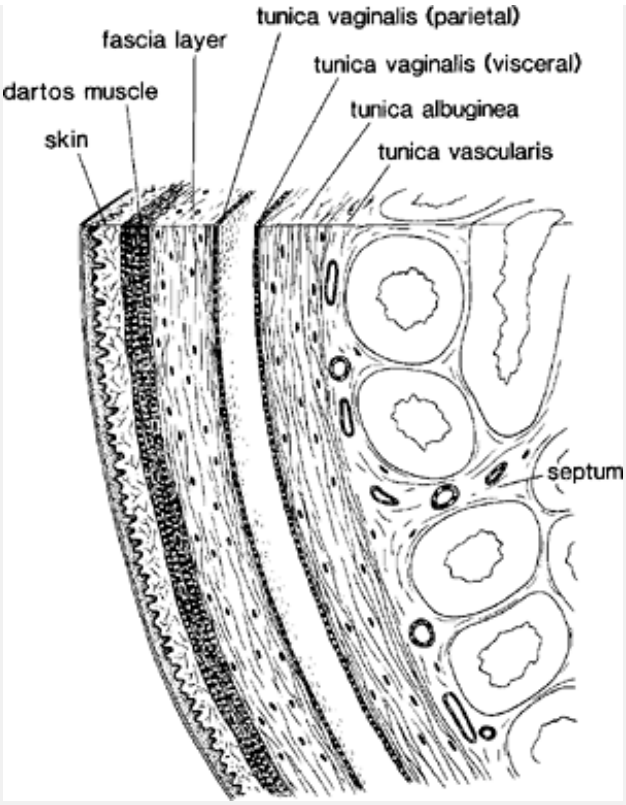

Figure 37.2 Scrotal covering layers and capsule of testis.

Seminiferous Tubules

Each lobule of the testis contains one to four seminiferous tubules (Figure 37.1). The individual tubule is a highly convoluted, closed loop structure, with numerous communications between the arms of the loop but without any blind endings or branches. Each arm of the loop empties into the septal portion of the rete testis, although infrequently seminiferous tubules may empty directly into the mediastinal rete. The total length of seminiferous tubules in each testis has been estimated between 299 and 981 m, with an average around 540 m (4). The average tubule diameter in young adults is 180 Âµm (Â± 30). The usual open testicular biopsy may encompass tubules from up to five lobules along with portions of

the intervening septa. It is important not to interpret the latter as foci of interstitial fibrosis. The seminiferous tubules are composed of germ cells in varying stages of differentiation and Sertoli cells. Each tubule has a distinctive basement membrane and a thin lamina propria (Figure 37.3).

Figure 37.3 A cross-sectional view of seminiferous tubule and interstitium. Germ cell maturation is variable around the tubule, a normal finding.

Sertoli Cells

Sertoli cells play important and very different roles in the fetal and adult testes, and these divergent roles are reflected in their proliferative activity, cell protein markers, and the nature of cellular intermediate filaments at these periods of the cell's life span. Adult Sertoli cells are nondividing cells. Their number is important since they have the capacity to nurture only a fixed number of germ cells. Genetic, hormonal, and environmental factors appear to play significant roles in determining the final

number of Sertoli cells in the adult testis (5). These tall, irregular, columnar cells, with their bases attached to the underlying basal lamina, have an abundant but relatively inconspicuous cytoplasm and an ill-defined cytoplasmic membrane on light microscopic examination. The cells send intricate cytoplasmic extensions around the germ cell elements and continuously alter their contours to accommodate the changing size and shape of the germ cells that they cradle. Adult Sertoli cell nuclei have round to slightly irregularly shapes, with a highly folded nuclear membrane, a homogeneous chromatin distribution, and a prominent, round nucleolus (Figure 37.4). These features are in sharp contast to those of the prepubertal and fetal Sertoli cells, which have an oval or elongated nucleus, a smoothly contoured nuclear membrane, and an inconspicuous nucleolus (Figure 37.15). The Sertoli cell nuclei represent about 10% of the nuclei in a normal adult tubule cross section. They are located toward the basal side of the tubule and lie just central to the nuclei of the spermatogonia and preleptotene spermatocytes. The cytoplasm may contain lipid vacuoles and/or granular eosinophilic material. Much of the phagocytosed material represents remnants of the residual bodies of the spermatid or degenerated earlier germ cell forms. Adult Sertoli cells contain vimentin as intermediate filaments, whereas embryonic and prepubertal Sertoli cells also contain cytokeratins 8 and 18 (6). The transient appearance of cytokeratins is of interest in view of the report of a malignant Sertoli cell tumor containing both cytokeratins and vimentin (7). Low-molecular weight cytokeratins also may be identified in some of the Sertoli cells of atrophic tubules of the adult testis (8), in Sertoli cells of tubules containing in situ germ cell neoplasia (9), and in Sertoli cells of the contralateral testis of patients with germ cell neoplasms. These Sertoli cells have an immature morphological appearance and appear to be part of the testicular dysgenesis syndrome described recently (10). Adult Sertoli cells, unlike fetal or prepubertal Sertoli cells, express androgen receptors within their

nuclei but, at the same time, have lost their expression of cytoplasmic anti-mÃ¼llerian hormone (5,11). A wide variety of other molecules are produced by the Sertoli cells, including inhibin/activin, insulin-like growth factor, platelet-derived growth factor, transforming growth factor, interleukins 1 and 6, and neurofilament proteins (12,13). Still unclear is whether or not the fetal Sertoli cell produces a substance or employs some other mechanism that serves to eventually bring the fetal germ cell into mitotic arrest. Those germ cells that fail to reach the fetal testis or the female germ cells in the ovary do not appear to be exposed to this undefined Sertoli cell product and consequently become arrested in the early phase of the first meiotic division (14,15). Present in the cytoplasm are the crystalloids of Charcot-BÃ¶ttcher (16). These bundles of filamentous structures, located primarily in the basal portion of mature Sertoli cells, are best seen by ultrastructural examination but occasionally are large enough to be seen by light microscopic studies (Figure 37.5). Ultrastructurally, they appear to merge with vimentin-labeled intermediate filaments, both of which are increased in the cryptorchid testes and the Sertoli cellâ€“only syndrome (9).

At puberty, a tight junction complex forms between adjacent Sertoli cells, dividing the seminiferous tubule into

basal and adluminal compartments; the former contains spermatogonia and preleptotene spermatocytes, and the latter holds the remaining primary spermatocytes, secondary spermatocytes, and spermatids. A transient, intermediate compartment is formed by adjacent Sertoli cells as germ cells move from the basal compartment to the adluminal compartment. A tight junction complex forms behind the germ cells to seal off the intercellular space, thereby ensuring the integrity of the Sertoli cell barrier (17). This junction forms the major blood-testis barrier, preventing access of bloodborne constituents to the germ cells in the adluminal compartment except through the Sertoli cell

cytoplasm. Still unclear is the mechanism that serves to promote the movement of germ cells from the basal compartment to the adluminal compartment.

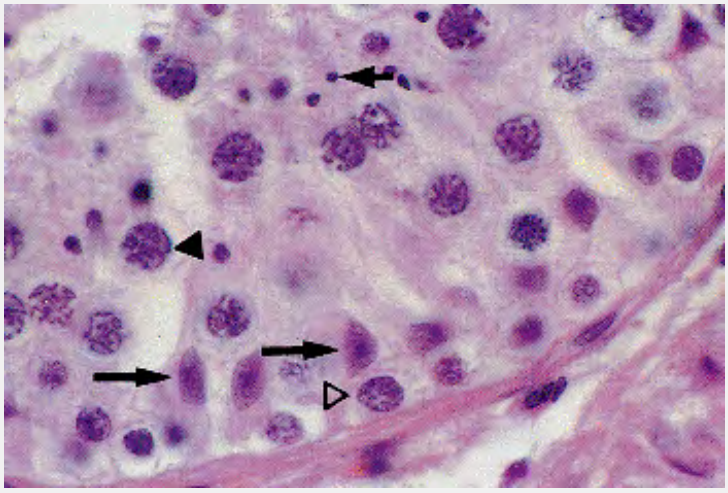

Figure 37.4 Seminiferous tubule with Sertoli cells (long arrows), spermatogonia (Î”), primary spermatocytes (â–²), and spermatids (short arrow).

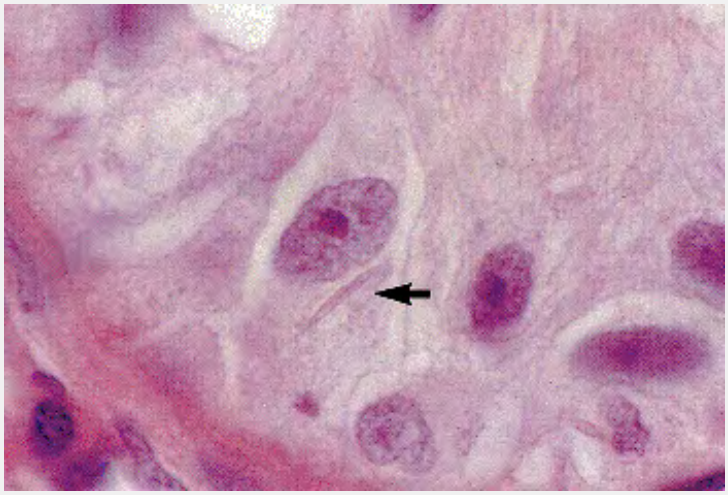

Figure 37.5 Sertoli cell with intracytoplasmic Charcot-BÃ¶ttcher crystalloids (arrow) from a patient with germ cell aplasia. Note the prominent nucleolus and slightly wrinkled nuclear membrane.

Other cell connections between adjacent Sertoli cells include gap junctions, desmosomes (rarely), and ectoplasm specialization sites (18). Intercellular junctionlike structures are present between Sertoli cells and germ cells, presumably serving as the conduit by which the Sertoli cell plays a role in the regulation of spermatogenesis.

Germ Cells

Germ cells are derived from tissues in the posterior wall of the yolk sac and migrate in early embryonic life to the gonadal ridge (19). Deviations in this migration route account for the appearance in abnormal locations of tumors derived from these cells (Figure 37.6). The germ cell elements comprise the bulk of the cells seen in the adult seminiferous tubule (Figures 37.3,37.4). Maturation in humans covers a period of 70 Â± 4 days (20), with no evidence that this time requirement is altered by age or pathologic states. The undifferentiated spermatogonia lie in the basal compartment and undergo proliferation and renewal. Some of them become committed to the process of spermatogensis and give rise to primary spermatocytes, heralding the first meiotic division of spermatogenesis. The earliest of the primary spermatocytes, the preleptotene forms, are also located in the basal compartment. The preleptotene spermatocytes are then moved by an unknown signal into the adluminal compartment, where they sequentially become leptotene, zygotene, pachytene, and diplotene primary spermatocytes, this phase of the cycle involving a period of 24 days (21). After this relatively long period of gametogenesis, the first meiotic division occurs with the formation of secondary

spermatocytes. These cells have an extremely short half-life and soon undergo the second meiotic division to form haploid spermatids, which are then converted into spermatozoa through a series of complex steps of metamorphosis (Figure 37.7).

Until spermatozoa are formed, all progeny of a spermatogonium committed to going through the meiotic process are connected together by a narrow cytoplasmic bridge that permits sharing of cytoplasmic organelles and allow for simultaneous maturation of interconnected cells. Of interest is the lack of these intercellular connections in seminomas and intratubular germ cell neoplasm but their occasional presence in spermatocytic seminomas (22). A failure of cell separation, a form of dysmaturation, is reflected in the tubular lumen and seminal fluid by the presence of multinucleated spermatids or multiheaded spermatozoa. In the late spermatid phase, excess cytoplasm is discarded by the spermatid and is phagocytosed by the enveloping Sertoli cells. The sloughing of germ cells into the seminiferous tubule lumen and the presence of immature and abnormal forms observed in patients with varicocele and other pathologic states suggest a failure of Sertoli cell regulation of this maturation process. One must take care to separate this pathologic sloughing process from the artifactual

sloughing that frequently occurs in open biopsy specimens (Figure 37.8).

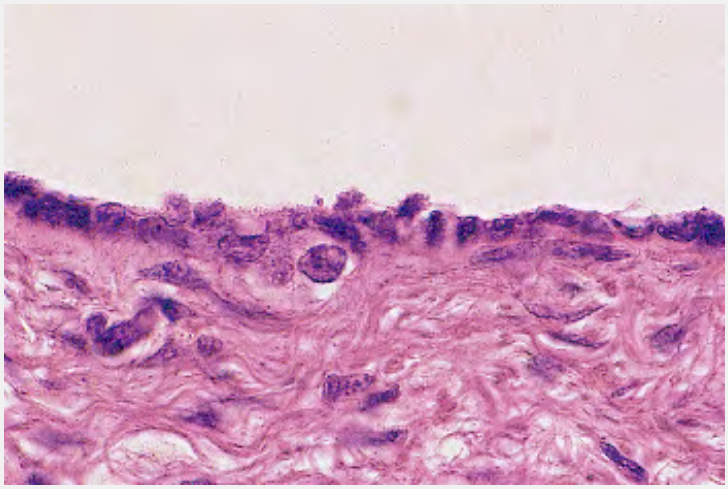

Figure 37.6 Germ cells located immediately beneath the mesothelial lining cells of the process vaginalis of a 16-week fetus.

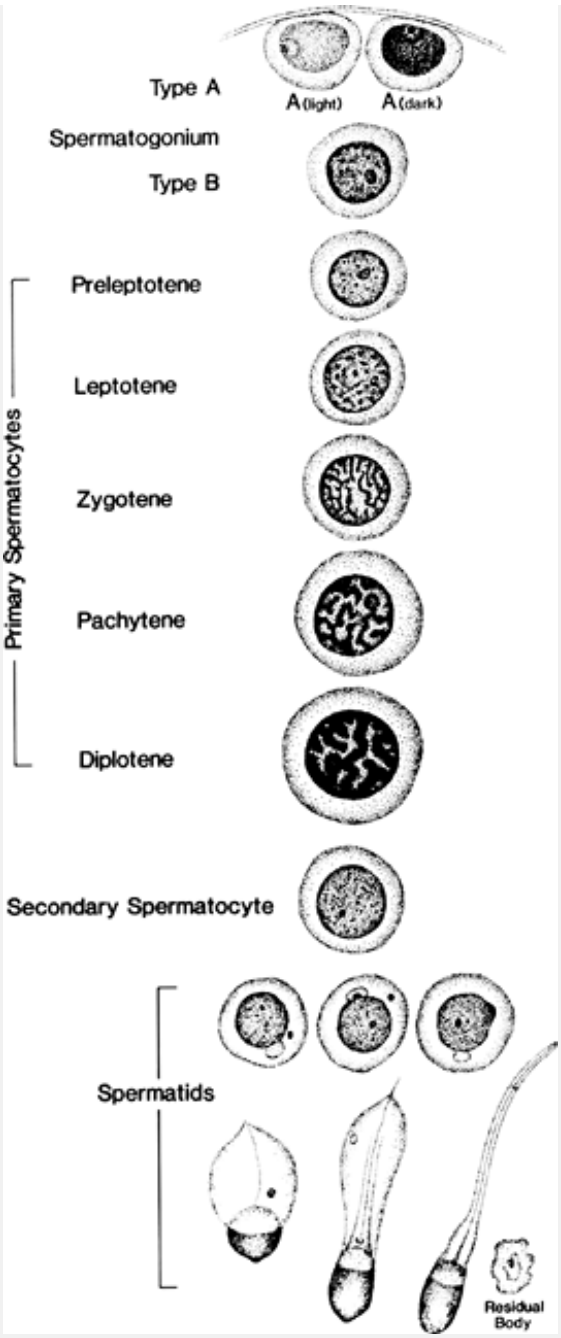

Figure 37.7 Steps in spermatogenesis.

Maturation of germ cells proceeds in an ordered, nonrandom fashion along the length of the seminiferous tubule. Groups of evolving germ cells of one level of development tend to be found

in association with developing germ cells of another level of development at any point along the tubule. Clermont (23) described 14 cell association patterns in the rat testis and 6 such cell associations in humans. In the rat, a given cross section of seminiferous tubule shows only one cell association around the circumference of the tubule, whereas in humans up to three cell associations may be seen in a tubule cross section. Initially this arrangement of cell clusters was considered to form an overlapping helical pattern along the length of the tubule (24). That view has been recently challenged (25). Of practical importance is the need to recognize that not all stages of differentiation of germ cells may be seen in any one cross-sectional view of a seminiferous tubule. Mature spermatozoa and late spermatids may be seen in one portion of a tubule cross section, and the opposite wall may show maturation only to the early spermatid level (Figure 37.3). It has been recognized for many years that not all spermatogonia or spermatocytes progress to become spermatozoa and that apoptotic or degenerative changes in these precursor cells can be seen regularly in the seminiferous tubules (26). This normal physiologic process should not be mistaken for maturation arrest. The germ cell elements can be recognized with relative ease, and one should be able to distinguish spermatogonia, primary spermatocytes, secondary spermatocytes, and spermatids.

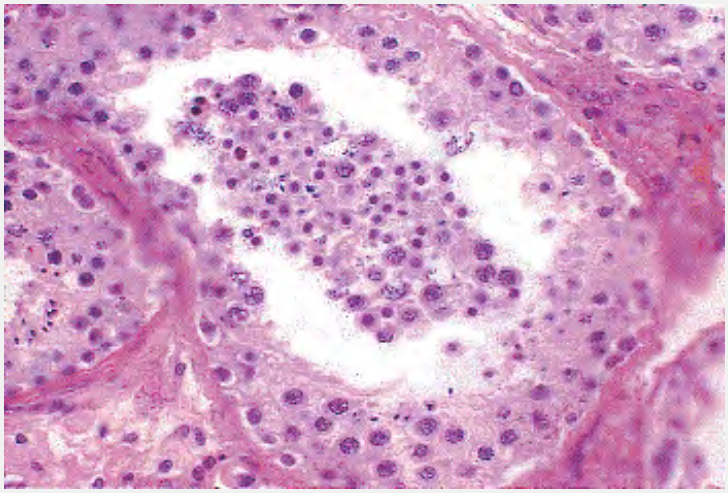

Figure 37.8 Seminiferous tubule with artifactual sloughing of germ cell elements into tubule lumen.

Spermatogonia are located in the basal compartment of the seminiferous tubule, the basal portion of most of the cells being in contact with the tubule basement membrane. They have been subdivided into three types, mainly on the basis of the nuclear chromatin pattern, as type A dark, type A light, and type B. Type A dark cells have a central nuclear cleared area, referred to as the nuclear vacuole, and contain glycogen in their cytoplasm. The type B cells tend to have a more coarsely clumped chromatin pattern than either of the type A cells. It should be pointed out that the nuclear chromatin pattern differences among these spermatogonia is usually evident only with fixatives such as Zencker-formal and that fixatives such as Bouin's produce coarse clumping in the nuclei of all of the spermatogonial subtypes, making subtyping difficult (23). The spermatogonia nuclei are oval to round and contain one or two easily identifiable nucleoli (Figure 37.9). Within the cytoplasm in a perinuclear location are the crystalloids of Lubarsch. These structures, measuring up to 3.0 Âµm in length, may be found in adults and infants as early as the fifth postnatal

week.

They are composed of a mixture of parallel arrays of fibrils 80 to 150 Ã… thick and ribosome-like granules (27).

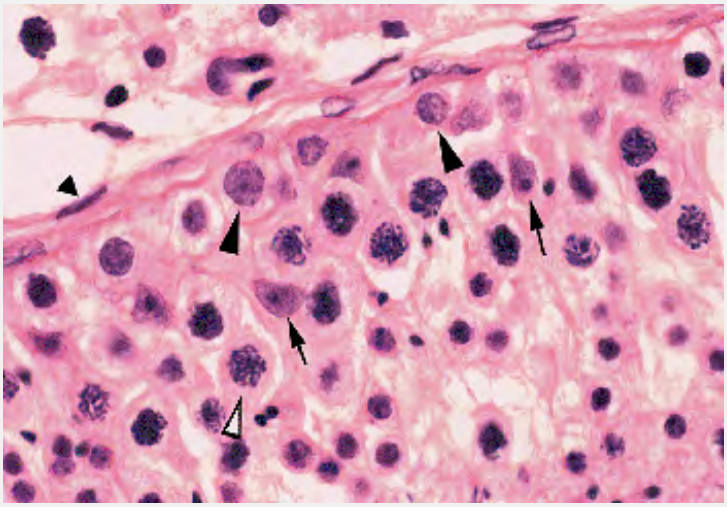

Figure 37.9 Portion of seminiferous tubule showing spermatogonia (solid arrowhead), primary spermatocytes (open arrowhead), Sertoli cells (arrow), and fibromyocyte of tunica propria (solid triangle). The smaller cells in the lower right are mainly secondary spermatocytes and early spermatids.

The classification of primary spermatocytes is based on the alteration of the nuclear chromatin pattern (23). These cells are distinctive because of the doubling of the amount of DNA in their nuclei as a result of the duplication of each chromosome into chromatid pairs in preparation for the first meiotic division. The leptotene primary spermatocytes are characterized by a change in the chromatin pattern into a filamentous structure with a fine-beaded arrangement. Zygotene spermatocytes have an even coarser granularity of the chromosome filaments, and there is a

tendency for the chromatin material to gather eccentrically within the nucleus. Pachytene and diplotene spermatocytes are the most easily recognized of the primary spermatocytes because of their large size and their prominent nucleus, containing thick, short chromatin filaments (Figure 37.9).

Secondary spermatocytes, having an extremely short half-life, make up only a small minority of the cells seen in a cross section of the tubule. Their nuclei, substantially smaller than in the primary spermatocytes, have a finely granular chromatin pattern and a haploid number of chromosomes but a diploid amount of DNA because of the presence of the chromatid pairs. These cells, located near the tubule lumen, differ only slightly in appearance from the very early spermatids with which they are closely associated. (Figures 37.4, 37.9).

The spermatids have a heavily stained granular pattern to the nucleus and, if the plane of section is appropriate, a slight depression on the surface of the cell, representing the beginning of the acrosome. The late spermatid form is characterized by a change in the nucleus, first to an oval shape with highly condensed chromatin material, then to an elongated form, and eventually assuming the configuration of the nucleus of a mature spermatozoon. One of the last steps in the maturation process is the separation of the interconnected progeny.

Elaborate methods have been developed for quantitatively assessing the germ cell elements and the relationship of spermatogenesis to seminal fluid sperm density (28,29,30,31,32). The method of Johnson (29) applies a score of 1 to 10 for each tubule cross section examined. The criteria are as follows: 10, complete spermatogenesis and perfect tubules; 9, many spermatozoa present but disorganized spermatogenesis; 8, only a few spermatozoa present; 7, no spermatozoa but many spermatids present; 6, only a few spermatids present; 5, no spermatozoa or spermatids present but many spermatocytes present; 4, only a few

spermatocytes present; 3, only spermatogonia present; 2, no germ cells present; 1, neither germ cells nor Sertoli cells present. The mean score count should be at least 8.90 with an average of 9.38, and 60% or more of the tubules should score at 10.

Two relatively simple methods are helpful to the surgical pathologist. The first method (32) involves establishing a germ cell to Sertoli cell ratio by counting at least 30 tubule cross sections. This ratio is relatively constant at approximately 13:1 in young healthy men. An average of 10 to 12 Sertoli cells per tubule cross section is considered normal, and approximately half the germ cell elements within the tubule should be in the spermatid stage. An assumption is made that the Sertoli cell population is stable throughout adult life. A reasonably good assessment of the presence or absence of hypospermatogenesis or maturation arrest can be made with this technique. A second method involves counting spermatids per tubule cross section (33). Only the mature spermatids, that is those with oval nuclei and dark, densely stained chromatin, are counted. Excellent correlations have been made with seminal fluid sperm counts. A spermatid/tubule cross section count of 45 corresponds to a seminal fluid sperm count of 85 Ã— 10^6/mL. Spermatid/tubule counts of 40, 20, and 6 to 10 correspond to sperm counts of 45, 10, and 3 Ã— 10^6/mL, respectively. A minimum of 20 tubules must be counted.

Interstitium

The interstitium of the testis accounts for 25 to 30% of the testicular mass. It can be divided loosely into intertubular and peritubular regions. Within the former are Leydig cells, blood vessels, lymphatics, nerves, macrophages, and mast cells. The macrophages are often found in close association with Leydig cells (34), where the two cells form complex cell-cell interdigitations. There is increasing evidence for an important paracrine role for

macrophages in Leydig cell function (35). Surrounding each seminiferous tubule in a sheathlike fashion is the lamina propria or tunica propria, which consists of an inner basal lamina, surrounded by a

zone of multilayered spindle-shaped cells, intermingled with collagen and elastic fibers (Figure 37.9). The outermost two layers of cells stain for vimentin and actin but not for desmin. The inner layers of three to five cells stain intensely for desmin as well as actin and vimentin, findings that are characteristic of myofibroblasts (36). These same cells also contain androgen receptors in their nuclei (11). Elastic fibers first appear at puberty in the outermost layer of the lamina propria (37). There is a striking absence of elastic fibers in the lamina propria of sclerotic tubules in patients with Klinefelter's syndrome, in contrast to their abundance in the lamina propria of patients with postpubertal tubular sclerosis of multiple other causes (38).

A common finding in patients with oligozoospermia or azoospermia due to primary testicular failure is the accumulation of eosinophilic, acellular material in the lamina propria. This material is an admixture of increased collagen fibers, elastic fibrils, and basement membraneâ€“like material (39). The peritubular tissue of patients with hypogonadotropic hypogonadism is underdeveloped, having only one or two layers of myoid cells mixed with a few collagen fibers. In contrast, there is a large accumulation of collagen in the lamina propria of some of the seminiferous tubules of adult patients with cryptorchidism.

Leydig Cells

Adult Leydig cells, the source of testicular androgens, only rarely undergo mitotic division (40). They are found singly and in clusters within the interstitium of the testis; some lie immediately adjacent to capillaries, whereas others lie close to the peritubular

myofibrocytes (Figure 37.10). They also may be seen in the tunica albuginea, epididymis, spermatic cord, and mediastinum of the testis. They are often located in intimate association with large nerve fibers, sometimes as a large cluster adjacent to the nerve (Figure 37.11) and, at other times, scattered randomly throughout the nerve fiber (41). They may be found at these sites in the fetus as well as the adult. The single nucleus of the cell is round and vesicular, with one to two eccentrically located nucleoli. Occasional binucleated cells are present. The cytoplasm is usually abundant and stains intensely with acid dyes. Lipid droplets and lipofuscin pigment are found in the cytoplasm, first appearing at the time of puberty and increasing in prominence in the aging testis. The characteristic intracytoplasmic Reinke crystalloids are present only in the postpubertal state (Figure 37.10). Their presence is highly variable in the normal testis, and they are frequently absent in Leydig cell tumors. The nature of the material is still unknown, although it is presumed to represent a protein product of the cell (42). The crystalloids stain negatively for actin, vimentin, and desmin.

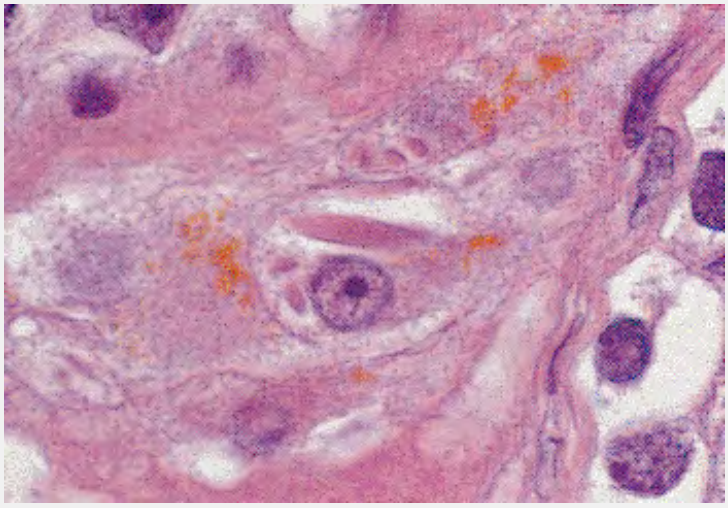

Figure 37.10 Leydig cells in interstitium of testis. An eosinophilic crystalloid of Reinke and abundant lipofuscin are

prominent features in the cytoplasm of the Leydig cell in the center of this field.

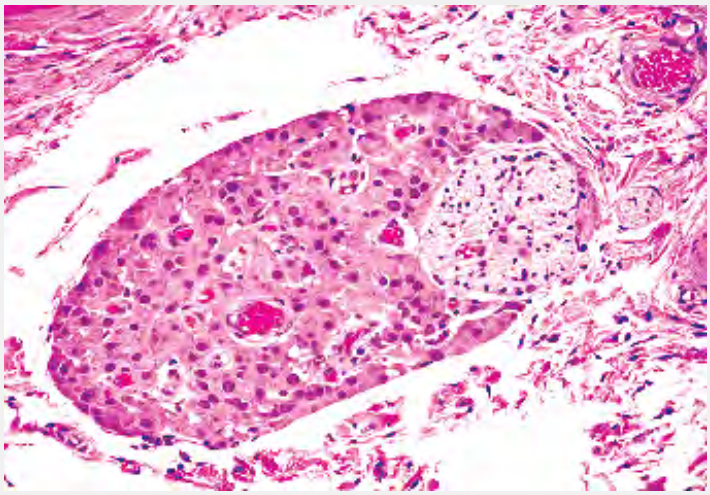

Figure 37.11 Leydig cells in intimate association with a nerve in the hilus of the testis.

Quantitation of Leydig cells has been a difficult parameter to assess. Several indices have been used: mean Leydig cell number or Leydig cell cluster number per seminiferous tubule; mean number of Leydig cells per Leydig cell cluster; Leydig cell to Sertoli cell ratio; and ratio of Leydig cell area to seminiferous tubule area (43). Heller et al. (44), using the Leydig cell to Sertoli cell ratio, found a value of 0.39 and a range of 0.19 to 0.72. In that same study, they also determined the average number of Sertoli cells per tubular cross section to be 10.03 Â± 0.6. They made an assumption that the Sertoli cell population was stable in their calculation of the Leydig cell population. As a rule, normal adults should have four to five Leydig cells for each tubular cross section.

Vimentin represents the predominant intermediate filament, but actin filaments and neurofilament triplet proteins have also been identified in both Leydig and Sertoli cells (13). Androgen receptors are found within the nuclei but at a much lower intensity than found in Sertoli cells (11).

Calretinin, a protein found primarily in the cytoplasm and to a lesser extent in the nucleus, has been shown to be a reliable marker for normal and neoplastic Leydig cells. Theca interna cells of the ovary stain equally well, but Sertoli cells, granulosa cells, and theca externa cells stain little or not at all (45). Relaxin-like factor, also known as the Leydig cell insulin-like factor, stains strongly in the cytoplasm of Leydig cells, as well as theca interna cells and hilar cells in the ovary (46,47). Leydig cells stain positively for S-100, glial fibrillary acidic protein (48), synaptophysin, chromogranin A-B, and neuron-specific enolase but not for vimentin or desmin. A subpopulation of cells will stain intensely for nestin, an intermediate filament seen mainly in nerve and muscle progenitor cells (49). The presence of these substances undoubtedly indicates an important paracrine function that Leydig cells share with Sertoli cells, peritubular cells, macrophages, and nerves.

Vascular Supply

The blood supply to the testis is derived primarily from the internal spermatic (testicular) artery with a smaller contribution from the branches of the vasal portion of the internal (superior) vesicle artery. The testicular artery, arising from the aorta immediately distal to the renal artery, is highly coiled and extremely long relative to its diameter. It has a low pulse pressure as it enters the testis (50). The artery plays an important role in thermal regulation via countercurrent heat exchange with the veins of the pampiniform plexus. The combination of this vascular heat exchange and the heat lost via the thin scrotal covering

layers serves to maintain the testicular temperature 2Â°C below body temperature. Arterial branches of the testicular artery arborize over the surface of the testis, penetrate the capsule, and pass in a centripetal fashion within the septa to the mediastinum, where they form a dense cluster. Only a few branches enter the lobules from these centripetal arteries. From the mediastinum, the small arterial segments then pass in a centrifugal fashion within the parenchyma, where they branch into arterioles and capillaries. The veins run either centrifugally or centripetally to the capsule or mediastinum, respectively, and eventually anastomose posteriorly to form the pampiniform plexus of the testicular vein. Biopsy specimens of the testis of patients with varicoceles often show a striking sclerosis of vascular walls (51). These changes appear to involve both arteries and veins. The significance of these vascular alterations with respect to seminiferous tubule function in patients with varicoceles is uncertain.

At puberty, there is extensive development of the intratesticular microvascular architecture, the most notable features being a marked coiling of the arteries and a great expansion of the peritubular capillary network. Unlike other capillaries of the systemic system, the testicular capillary walls have a prominent basement membrane and an incomplete outer layer of pericytes (52). Arteriovenous anastomoses occur in two locations: (a) beneath the tunica albuginea between branches of the centripetal artery and vein and (b) deep within the parenchyma between branches of the centrifugal artery and vein. The role of these anastomoses is unknown.

The capillary network appears to have a very structured arrangement with respect to the Leydig cells and the seminiferous tubules, ramifying around and within the Leydig cell-macrophage clusters and then penetrating the tunica propria of the seminiferous tubules. Not all areas of the tubule wall appear to be supplied with this elaborate network, and the reason for this is still unclear. The capillaries then reenter the loose interstitium as

postcapillary venules, where they receive other capillaries coming from the Leydig cell clusters (53). The intralobular veins then enter the septa, where they move either to the mediastinum or to the tunica vasculosa.

There is a remarkable species-to-species variation in the distribution of lymphatic channels in the testis (54). In humans, ill-defined lymphatic spaces are found in the interstitium adjacent to Leydig cell clusters, but a peritubular lymphatic network is lacking. The lymphatic channels drain into the septa and thence to either the capsule or the mediastinum, where they join on the posterior aspect of the testis. They then anastomose with lymphatic channels from the epididymis, enter the spermatic cord, and drain into the periaortic lymph nodes.

Fetal and Prepubertal Testis

The fetal testis becomes recognizable at seven to eight weeks of gestation, at which time primitive testicular cords become evident. By the ninth week, the primordial germ cells, having migrated from their extraembryonal origin at the base of the allantois, have found their way into the cords, and are now referred to as gonocytes. These mitotically active cells, with a round nucleus and a prominent nucleolus, are scattered throughout the tubuli but usually are found in the center, surrounded by immature Sertoli cells (Figures 37.12,37.13). During the latter half of fetal life and the first six months after birth, the gonocytes undergo a maturation process in which they enter mitotic arrest. They become larger, acquire more cytoplasm, develop a prominent nucleus with a coarse chromatin pattern, and migrate to the periphery of the tubule to reach the basal lamina. At this time, these cells are variously referred to as prespermatogonia, prospermatogonia, M (multiplying) spermatogonia, T (transitional) spermatogonia, or simply spermatogonia (Figure 37.14). At birth, the germ cells average 4 per tubule cross section, two-thirds of

equal numbers of gonocytes and spermatogonia, with an average of 4 to 5 per tubule cross section (55). By the sixth postnatal month, virtually all of the germ cells are spermatogonia. This transition from the fetal stem cell pool to the adult stem cell pool is an important first step in the germ cell maturation process and appears to be defective in patients with cryptorchidism (56). From the age of one to four years, the number of germ cells average 1 to 2 per tubule cross section, and this number should double between the ages of 5 and 8 years (55). Although for the most part kept in mitotic arrest until just prior to puberty, occasional germ cells may be found in infancy, childhood, and even in the fetus that have entered the meiotic phase to form spermatocytes or even spermatids. In early puberty, repeated waves of incomplete spermatogenesis take place, with an orderly processs of complete maturation not appearing until the end of puberty (57). Several studies have demonstrated a marked diminution in the number of germ cells in the prepubertal cryptorchid testis (Figure 37.15) and a less predictable decrease of germ cells in the truly ectopic testis (27,58).

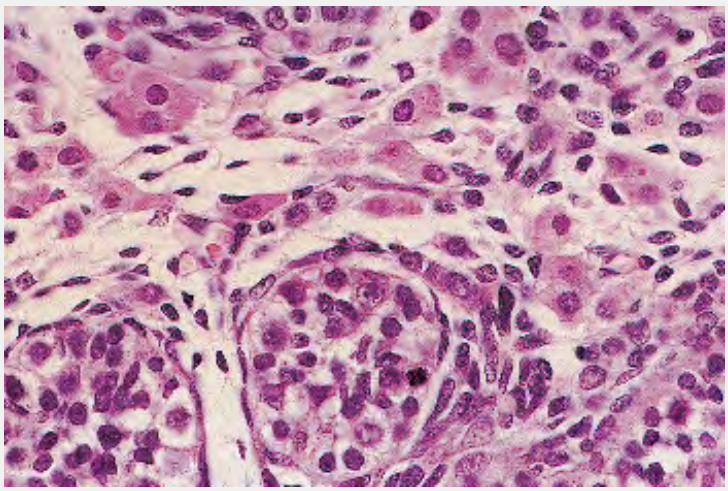

Figure 37.12 Fetal testis of 20 weeks' gestation, with numerous Leydig cells throughout the interstitium.

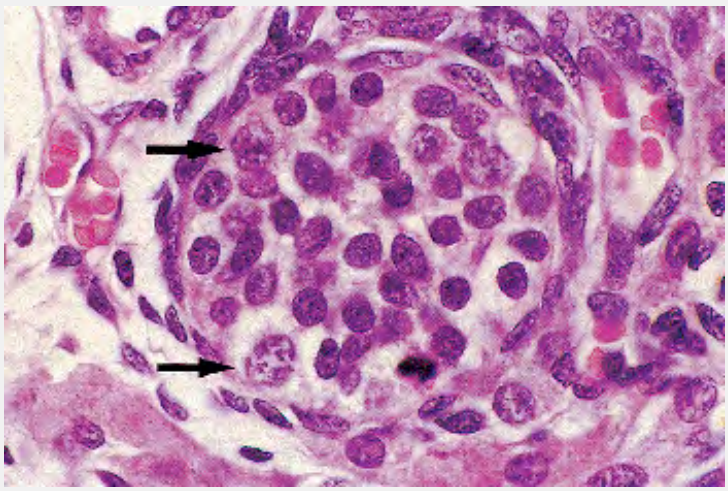

Figure 37.13 Same testis as shown in Figure 37.12. Note the mitotic figure, probably of a Sertoli cell. Larger cells (arrows) are undifferentiated germ cells. The remaining cells are immature Sertoli cells.

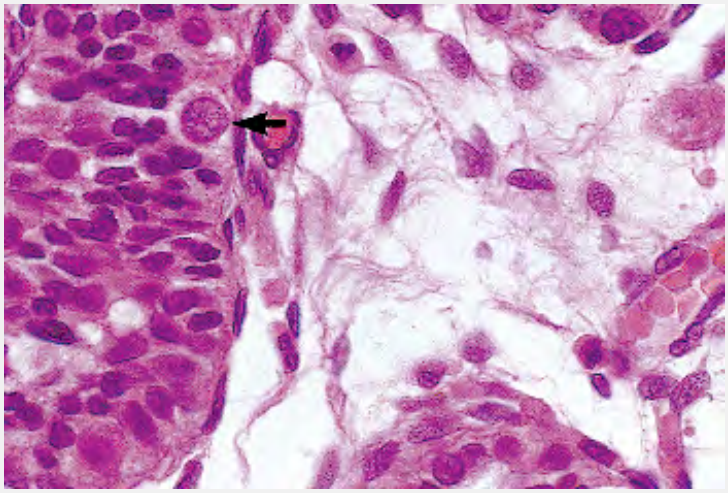

Figure 37.14 Testis of an 11-month-old child. A spermatogonium is present adjacent to the basement membrane (arrow). The interstitium contains undifferentiated spindle cells.

Gonocytes and, less commonly, spermatogonia express a number of markers that are employed in evaluating germ cell neoplasms in adults, including the cytoplasmic placenta-like alkaline phosphatase (PLAP), the cell membrane proto-oncogene receptor c-kit, and the nuclear transcriptional regulator Oct3/4 (also known as Oct3 and Pou5F1). These markers first appear early in the first few weeks of gestation and gradually disappear at birth or soon thereafter. They are not seen in Leydig, Sertoli, or interstitial cells nor are they found in normal adult germ cells. Beginning at about the twentieth week of gestation, PLAP is the first to decrease, followed by Oct3/4, and then by c-kit. These declines correspond to the maturation process of the gonocytes into spermatogonia. Since the rate of disappearance is different for these markers, it is possible to observe germ cells staining positive for all three of these markers

simultaneously, positive staining only for c-kit and Oct-4 and not PLAP, or positive staining only for c-kit. Corresponding to their mitotic activity and eventual entry into mitotic arrest, gonocytes and spermatogonia both reveal strong nuclear staining with Ki-67 throughout gestation but with only a few cells reacting after birth (59).

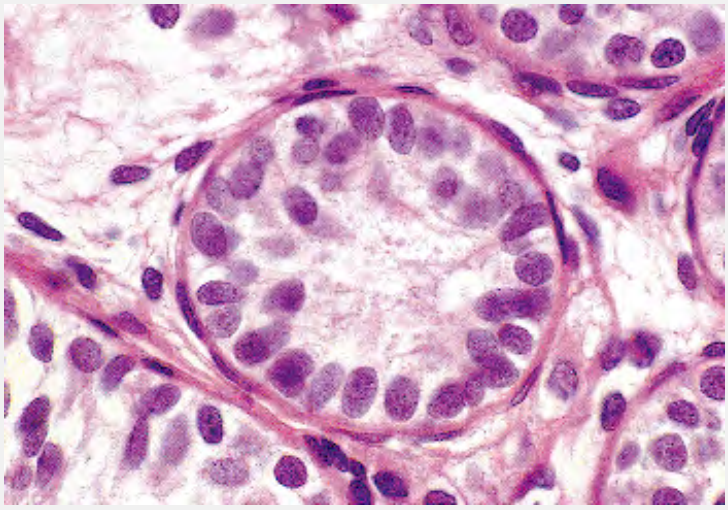

Figure 37.15 Thirteen-year-old prepubertal boy with bilateral cryptorchidism. Mature Leydig cells are absent in the interstitium. The tubules lack a lumen. The Sertoli cells are immature, and germ cells are absent.

At 20 weeks of fetal life, the testis is characterized by abundant, well-developed Leydig cells filling the interstitium (Figure 37.12). The seminiferous tubules are solidly filled with Sertoli cells and germ cells, measure 45 to 50 Âµm in diameter, and lack a well-defined lumen (60). The postnatal tubules slowly increase in size to reach a prepubertal diameter of 64 Âµm (range: 43â€“70Âµm), at which time lumens begin to appear (61).

Fetal Sertoli cells outnumber germ cells in a ratio of 7:1 (61) and

undergo active mitotic division during this period. Unlike its adult counterpart, the immature Sertoli cell has an oval to round nucleus and an inconspicuous nucleolus (Figure 37.13). Vimentin and cytokeratins 8 and 18 are expressed in the cytoplasm, as noted above. Nuclear androgen receptors are not identified.

Early studies had suggested that the Sertoli cell is mitotically inactive after birth, but stereologic studies indicate their number increases from 260 million late in fetal life, to 1,500 million between 3 months and 10 years, and to 3,700 million in the adult testis (62). They account for 95% of the tubule mass, with the germ cells comprising the other 5%. The testis shows a sixfold increase in size in the first year after birth, primarily as a result of Sertoli cell proliferation and the marked lengthening of the seminiferous tubules rather than a significant increase in tubule diameter (57). To a lesser degree, Sertoli cells continue to proliferate until puberty. Sertoli cells per cross section average 30 in the fetal testis after 20 weeks, increase to 42 at the fourth postnatal month, decrease to 26 at age 13 years, and to 12 to 15 in the adult testis (27,60). At puberty there is a fivefold increase in Sertoli cell volume, at which time Charcot-BÃ¶ttcher crystalloids first appear. The cryptorchid testis commonly contains microscopic collections, or â€œcongeries,â€• of very immature Sertoli cells, having either a round or fusiform-shaped nucleus and an inconspicuous nucleolus (Figure 37.16) (63).

The early prepubertal lamina propria is relatively undeveloped and is separated from the tubules by a thin basement membrane that lacks the knoblike thickening and splitting of the adult testis. The collagen fiber layer is relatively thin, and only one or two spindle-shaped cells are seen in the outer portion of the lamina propria.

Leydig cells are first recognizable by the eighth week of fetal life and become prominent in the fetal testis at 14 to 18 weeks of gestation (Figure 37.12), after which there is a progressive decline in number, with few mature-appearing Leydig cells being evident

at birth. A second wave of Leydig cells appears at two to three months of neonatal life, corresponding to the activation of the hypothalamus/pituitary/gonad axis (64). This population is a mix of cells, some with the characteristics of mature Leydig cells, smaller cells with a round nucleus and fairly prominent nuleolus but without the prominent eosinophilic cytoplasm of typical adult Leydig cells, and spindle cells. After this second phase of Leydig cell activity ends at about the fourth neonatal month, only spindle cells (Figure 37.14) are recognized until just before puberty, when the precursor Leydig cells progressively differentiate and eventually take on the appearance of adult Leydig cells. Still unclear is whether adult Leydig cells are derived from dedifferentiated fetal Leydig cells or from the primitive fibroblast cell population (64,65).

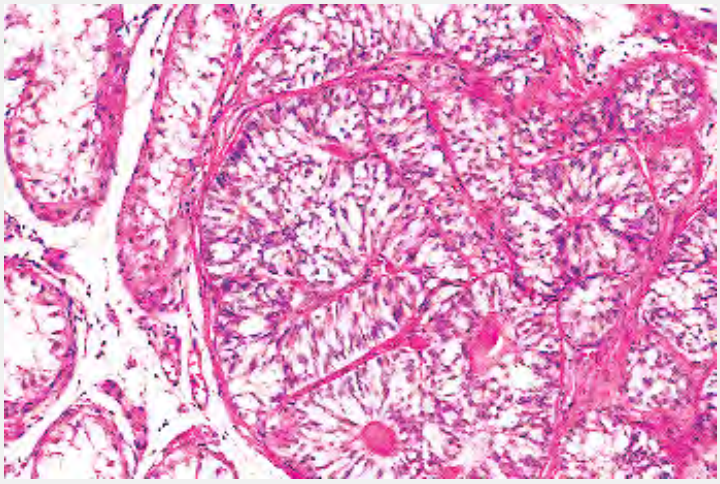

Figure 37.16 Sertoli cell collections, or congeries. The tubules are composed of immature Sertoli cells and lack both germ cells and lumens.

Aging Testis

There is a general consensus that a decline in testicular function occurs with advancing age. These physiologic changes are matched by involutional changes in the testicular parenchyma, including hypospermatogenesis, peritubular fibrosis, and hyalinization of the seminiferous tubules. A few sclerotic tubules are found occasionally in the normal adult testis (66), but larger, focal, or diffuse areas of sclerosis are distinctly pathologic. Although the total number of peritubular cells is maintained in elderly men, there is a sharp decline in the proportion of cells that stain positively for desmin and actin (36).

Thickening of the testicular arterial walls with hyalinization, sometimes seen in otherwise normal testes, is found in over 90% of testes in which there are large zones of tubular fibrosis. The capillary bed in the aged testis becomes sparse and poorly organized (67). These vascular changes probably play a causal role in the peritubular sclerosis and tubular hyalinization.

Substantial controversy exists regarding the Leydig cell population in the aging testis (68,69,70,71). According to

Neaves et al. (72), Leydig cell numbers and size both progressively decline with advancing age, the total Leydig cell population decreasing by 50% during the first 30 years of adult life. The production of testosterone by Leydig cells is relatively maintained despite a loss of total Leydig cell mass, probably because of the large reserve of these cells in the adult testis. When the Leydig cell mass decreases to a certain threshold point, daily sperm production is depressed. The aged Leydig cell contains large amounts of lipofuscin pigment and numerous vacuoles within the cytoplasm.

Abnormal sperm maturation, sloughing of germ cells into the tubule lumen, degeneration of germ cell elements, and Sertoli cell lipid accumulation and cytoplasmic vacuolization are frequent findings in the aged testis. Earlier studies indicated that the

Sertoli cell population is stable throughout the postpubertal years (73,74). However, Johnson et al. (75) found that men 20 to 48 years of age had significantly more Sertoli cells per tubule cross section than did men 50 to 85 years of age, and there was a relatively constant relationship between Sertoli cells and germ cells in both age groups. Furthermore, these investigators suggested that the decline in spermatozoa production in the elderly may be due to a decrease in Sertoli cell function and mass. Sertoli cells of those tubules demonstrating hypospermatogenesis have increased amounts of vimentin microfilaments and the reappearance of cytokeratins 8 and 18, suggesting that the reversion to the intermediate filament pattern of the fetal/prepubertal testis is related to the alteration of the normal spermatogenic process (6).

Rete Testes

The rete testis, a network of channels at the hilus of the testis, receives the luminal contents of the seminiferous tubules (Figure 37.1). It is divided into three components: the septal portion containing the tubuli rete, the mediastinal rete, and the extratesticular portion also known as the bullae retis (76,77). The tubuli rete are short tubules, 0.5 to 1.0 mm in length, that connect the two ends of the seminiferous tubule loop to the mediastinum testis. The terminal end of the seminiferous tubule usually consist only of Sertoli cells, forming an epithelial pluglike structure as it protrudes into the rete lumen (Figure 37.17). There are approximately 1,500 entrances of seminiferous tubules into the rete. A few tubules may enter the mediastinal rete directly without intervening tubuli rete. The mediastinal rete is a cavernous network of interconnecting channels that exits from the testis to form several dilated, vesicular channels or antechamber-like structures called the bullae retis. These structures, measuring up to 3.0 mm in width, anastomose together to form the ductuli efferentia.

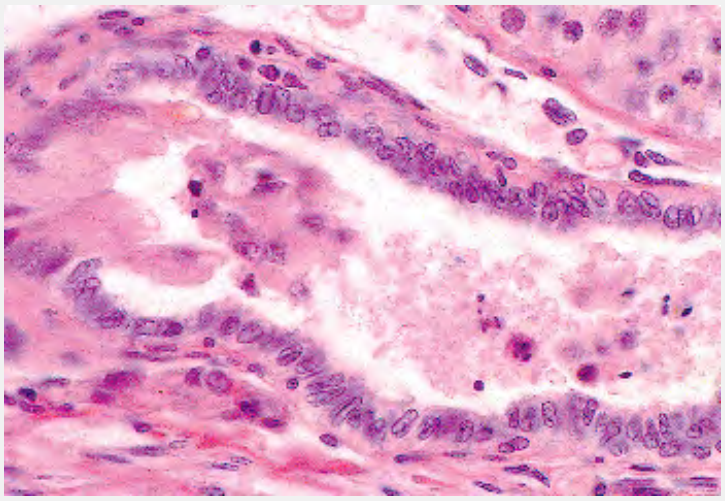

Figure 37.17 Junction of septal rete testis and terminal end of seminiferous tubule. Note the Sertoli cells â€œpoutingâ€• into the lumen of the rete. Rete epithelium is a low columnar type.

The rete epithelium is a simple squamous or low columnar type (Figure 37.17), the luminal surface of which is studded with microvilli. Each cell contains a single, central flagellum that is inconspicuous on light microscopic examination. The epithelium sits on a relatively thick basal lamina, beneath which are a few fibroblasts and myoid cells intermixed with collagen and elastic fibers. Traversing the mediastinum and the extratesticular rete are epithelium-covered columns or strands called chordae retis. These columns, often appearing as islands on a cross section of the rete testis (Figure 37.18), vary greatly in length (15â€“100 Âµm) and thickness (5â€“40 Âµm) and serve to connect opposing walls of the chambers. The cytoplasm of the rete epithelium contains keratin and vimentin intermediate filaments, the former being located primarily in the apical portion of the cell and the latter being found in the basal region. The keratins, primarily of low-

molecular weight types, can be first identified at the tenth week of fetal life and precede

the appearance of vimentin by two to three weeks (78). One would expect coexpression of these two intermediate filaments in the rare carcinoma of the rete or in hyperplasia of the rete. However, a report of nine cases of hyperplasia of the rete testis showed strong cytokeratin and epithelial membrane antigen staining but a negative reaction for vimentin (79). Sometimes found with hyperplastic or otherwise normal rete are hyalin refractile, eosinophilic globules, which are periodic acid-Schiff (PAS) positive, sometimes Î±1-antitrypsin positive, but Î±-fetoprotein negative (80). These should not be confused with the globules produced by yolk sac tumors of the testis. The rete epithelium, as well that of efferent ductules and the caput (head) of the epididymis, also contains receptors for estrogen, progesterone, and androgen (81), the presence of estrogen receptors perhaps accounting for the hyperplasia of the rete and efferent ductules seen in patients undergoing sex-reversal procedures (82).

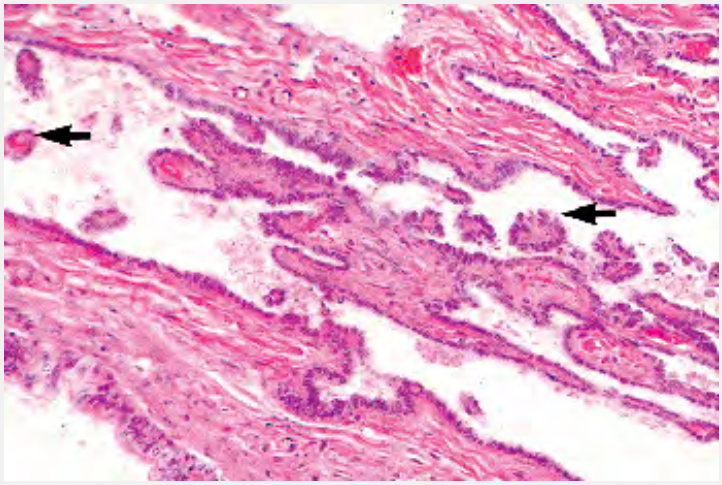

Figure 37.18 Rete testis, mediastinal portion, with irregular cavernous channels and cross sections of intratubular chordae

(arrows).

The rete serves multiple functions: (a) as a mixing chamber for the contents of the seminiferous tubules, (b) as a pressure gradient between the seminiferous tubules and the epididymis, (c) as a possible source of as yet unknown components of the seminal fluid, and (d) as a reabsorptive site of proteins from the luminal contents (83).

Ductuli Efferentia

The ductuli efferentia consist of five to six tubules that arise from the extratesticular rete testis (Figure 37.1) (84). They are involved primarily in resorption of fluid and do not appear to store spermatozoa for any length of time. These tubules aggregate to form a significant portion of the caput of the epididymis proper (Figure 37.19). Unlike the body of the epididymis, the lumens have an undulating border. The cells of the efferent ductules are composed of ciliated and nonciliated columnar cells, basal cells, and scattered intraepithelial lymphocytes, giving the epithelium a pseudostratified appearance (Figure 37.20). Occasional cells with a Paneth cellâ€“like appearance are seen (Figure 37.21). These numerous and brightly eosinophilic globules are PAS positive and diastase resistant and chromogranin A negative; they most likely represent prominent lysosomes. They are less frequently seen in the rest of the epididymis and are most often encountered in patients with epididymal obstruction (85). Coexpression of low-molecular weight cytokeratins and vimentin, as well as epithelial membrane antigen, is evident within the epithelial cytoplasm (78).

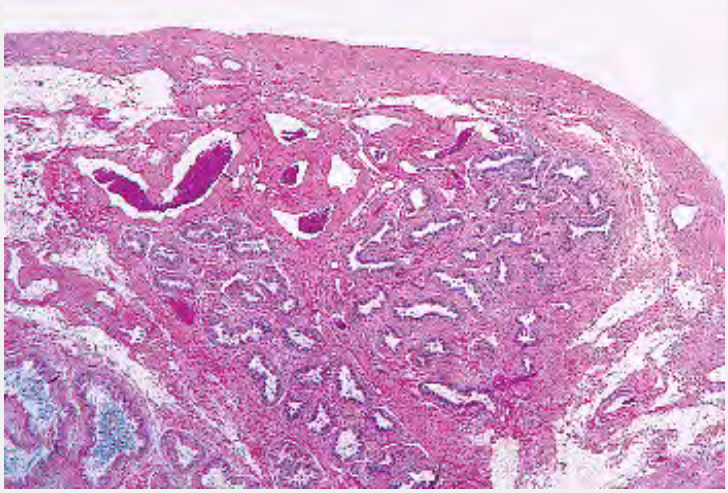

Figure 37.19 Caput (head) of epididymis, showing cross sections of distal portions of ductuli efferentia (upper right) and epididymis (lower left).

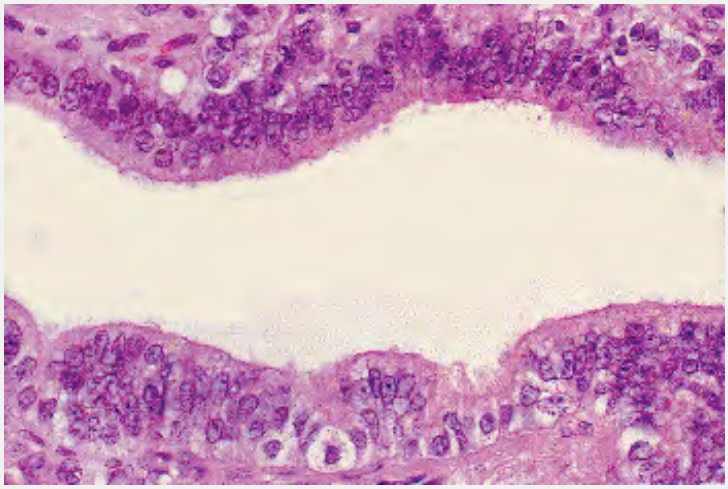

Figure 37.20 Epithelium of efferent ductulus. The columnar epithelial cells are mixed with basal cells and occasional intraepithelial lymphocytes, giving the epithelium a pseudostratified appearance.

The epithelium sits on a thick basement membrane, surrounding which is a coat of smooth muscle cells and fibroblasts, as well as a few scattered macrophages. Intraluminal macrophages, actively phagocytizing spermatozoa, are occasionally present, particularly when duct obstruction exists.

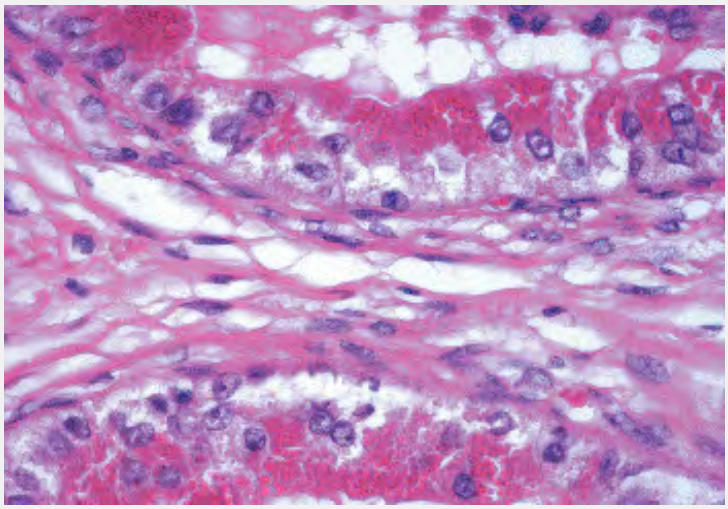

Figure 37.21 Epithelium of ductulus with prominent Paneth cellâ€“like intracytoplasmic vacuoles.

Epididymis

The epididymis, a highly coiled, tubular structure, can be divided anatomically into caput, corpus, and cauda portions (Figure 37.1). The epididymis plays an important role in (a) sperm transport, (b) sperm maturation, including the acquisition of motility, (c) sperm concentration, and (d) sperm storage. The average sperm transit time through the epididymis in humans is 12 days (86). The transport mechanism is by way of muscle contractions of the thick,

muscular coat that surrounds the epididymal tubules. There is extensive reabsorption of intraluminal fluid, particularly in the caput portion of the epididymis. Most of the sperm are stored in the caudal segment until ejaculation occurs, and it is in this location in humans that sperm maturation takes place (87). Many spermatozoa apparently undergo senescence and degeneration in the cauda via an unknown mechanism.

The epithelium of the epididymis consists of tall columnar or principal cells, basal cells, clear cells, tall slender or apical cells rich in mitochondria (apical mitochondria-rich cells), and scattered intraepithelial lymphocytes and macrophages (88). The principal cells, comprising over 95% of the columnar cells, have straight stereocilia (Figure 37.22), which are tall and nearly obliterate the lumen in the caput but become progressively shorter as the cauda is reached. The principal cells stain strongly for vimentin, epithelial membrane antigen (EMA), and acid phosphatase. Both basal and principal cells stain positively for low-molecular weight cytokeratins, with more intense staining in the corpus and cauda sections than the caput region (89). In cryptorchid testes the intensity of staining of low-molecular weight keratins, particularly cytokeratin 18, is markedly diminished (90). Intense CD10 paraluminal staining of the columnar cells is evident both in the epididymis and vas deferens, a finding that has been utilized to ascertain the possible origin of glandular structures found adjacent to the epididymis or vas deferens (91). The intensity of the vimentin staining progressively declines in the cauda section (89). The mitochondria-rich apical cells, located primarily in the caput, show intense staining for cytokeratins and acid phosphatase and less intense reactivity for EMA and vimentin. Their configuration varies from slender cells extending from the basement membrane to the lumen to those that appear to be located only in the apex of the duct (Figure 37.23). Small foci of epithelium may rarely have the appearance of prostatic epithelium, including positive immunostaining for prostate-specific antigen. Whether this process

represents metaplasia or ectopia is unclear (92). Epididymal cells may contain lipofuscin pigment, which tends to be more prominent in the caput segment and is particularly evident when there is obstruction of the epididymis (93). The lumens are generally round and regular. In up to 50% of individuals, a cribriform pattern is seen, which may represent either a normal variation or a hyperplastic process (85,94). Importantly, this changes should not be mistaken for intraepididymal spread from a testicular germ cell tumor or a primary epididymal carcinoma. The absence of either prominent nucleoli or mitoses should be helpful features supporting a benign process.

Figure 37.22 Epithelium of epididymis. Compare the tall columnar cells of the epididymis with the pseudostratified cells of the efferent ductulus. A few intraepithelial lymphocytes are present. The stereocilia are somewhat short, indicating the caudal segment. A layer of muscle cells forms the wall.

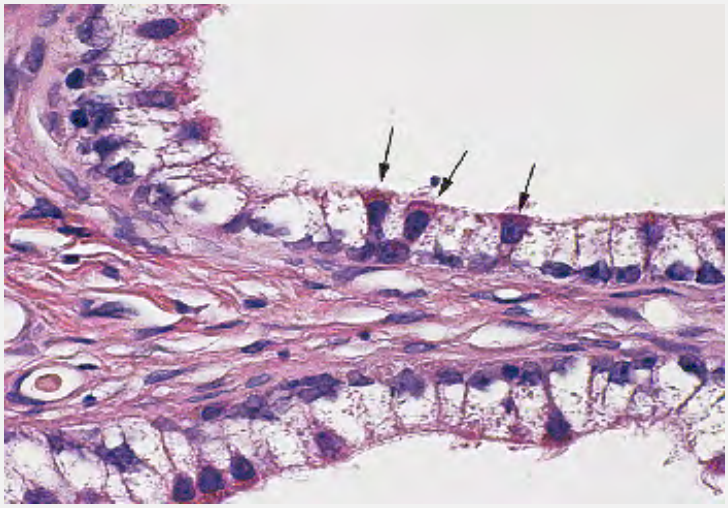

Figure 37.23 Epithelium of caput epididymis, demonstrating clear cells and apical mitochondrial-rich cells (arrows).

Intranuclear, eosinophilic, PASâ€“positive, and diastase-resistant inclusions (Figure 37.24), measuring 1 to 14 Âµm, are found in the columnar cells of the adult epididymis as well as throughout the vas and seminal vesicles. Electron microscopic examination shows the electron-dense globules to be enclosed by a single membrane and to lack any features suggesting viral structures (95). They are most common in the distal epididymis and adjacent vas and least common in the ampulla of the vas and seminal vesicles.

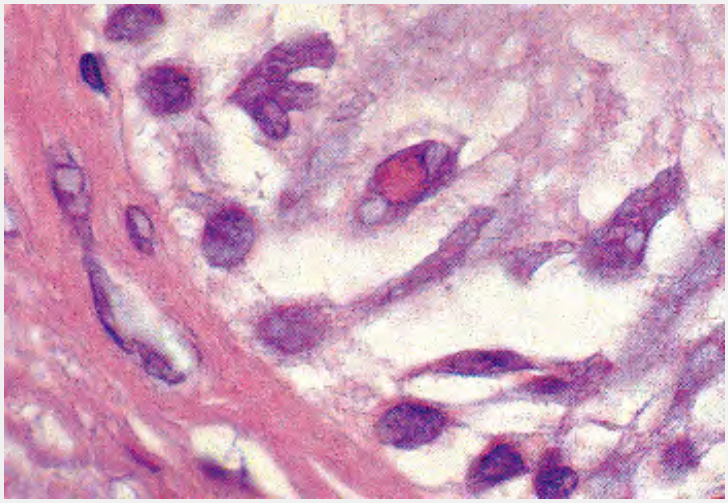

Figure 37.24 Intranuclear inclusions present in the epithelium of the epididymis. Similar inclusions are found in the epithelium of the ductus (vas) deferens.

The epididymis is supported by a thick basement membrane, surrounding which is a well-defined muscular coat. The latter plays an important role in sperm movement through the epididymis. Mast cells are found throughout the connective tissue of the epididymis in a pattern similar to that seen in the tunica and interstitium of the testis (96), being numerous in infancy, decreasing in childhood, and then increasing at the time of puberty. A progressive decline in numbers occurs in adulthood.

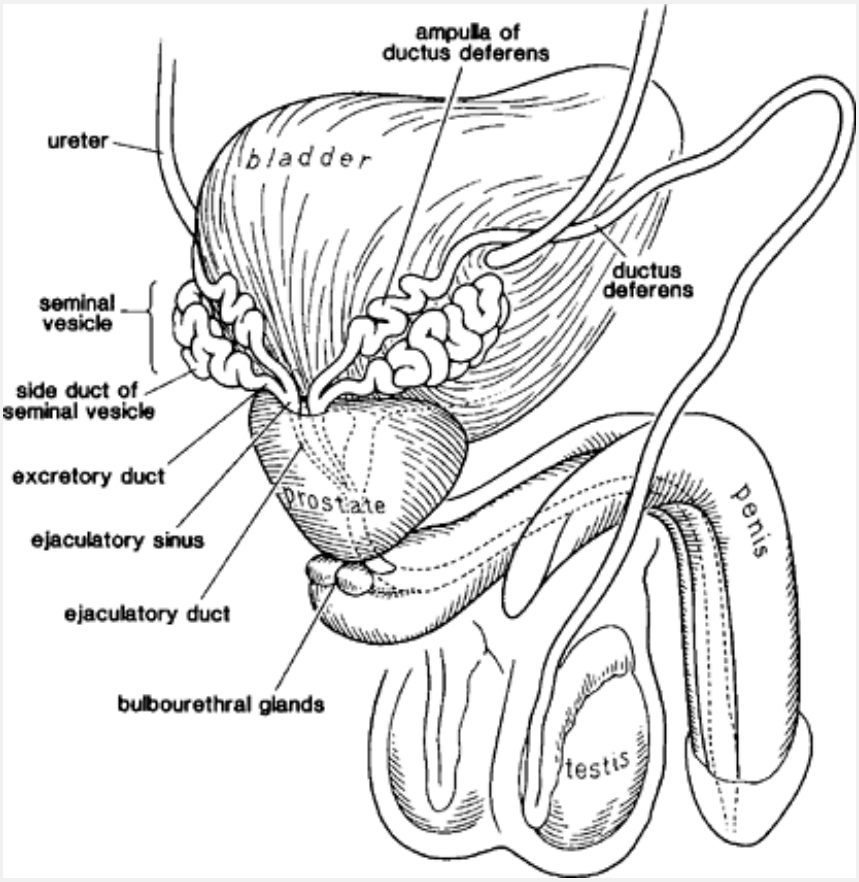

Figure 37.25 Diagram of excretory duct system from the vas to the ejaculatory ducts.

Ductus (VAS) Deferens

The ductus (vas) deferens, a tubular structure arising from the caudal portion of the epididymis, measures 30 to 40 cm in length. The distal 4 to 7 cm portion is enlarged to form the ampulla. The latter joins the excretory duct of the seminal vesicle to form the ejaculatory duct (Figure 37.25). The adult vas is lined by a pseudostratified, columnar epithelium, composed of columnar cells and basal cells by light microscopic examination. Ultrastructural studies show four different cell types: principal cells, pencil or peg

cells, mitochondria-enriched cells, and basal cells. The luminal surface of the columnar cell is lined by tall stereocilia throughout most of the vas (97). These stereocilia are substantially shorter and sparser in the ampullary region. Prominent intranuclear inclusions, as described above in the epididymis, may be seen (95). In addition, occasional lipid-positive vacuoles are present within the cytoplasm. The epithelium of the vas is thrown into folds, which are relatively simple in the proximal vas (Figure 37.26) but become much more complicated in the ampullary segment (Figure 37.27). The ampulla has highly complex infoldings and many outpocketings or diverticula that reach into the muscle coat. Beneath the epithelium of the vas is a loose, connective tissue stroma that, after puberty, contains a well-defined, circumferentially oriented layer of elastic fibers (98). These fibers, lacking in infants and children, become frayed and fragmented in the aged vas. The muscle coat is an extraordinary thick structure with inner and outer longitudinal

coats and a middle oblique or circular zone. The entire muscle mass progressively decreases as one approaches the ampulla, although the inner longitudinal layer becomes somewhat thicker as one progresses distally (97). The epithelium in the ampulla contains significant amounts of lipofuscin pigment and rather closely resembles the epithelium seen in the seminal vesicles. Active phagocytosis of degenerated spermatozoa has been demonstrated in the ampullary region of a number of mammalian species (99).

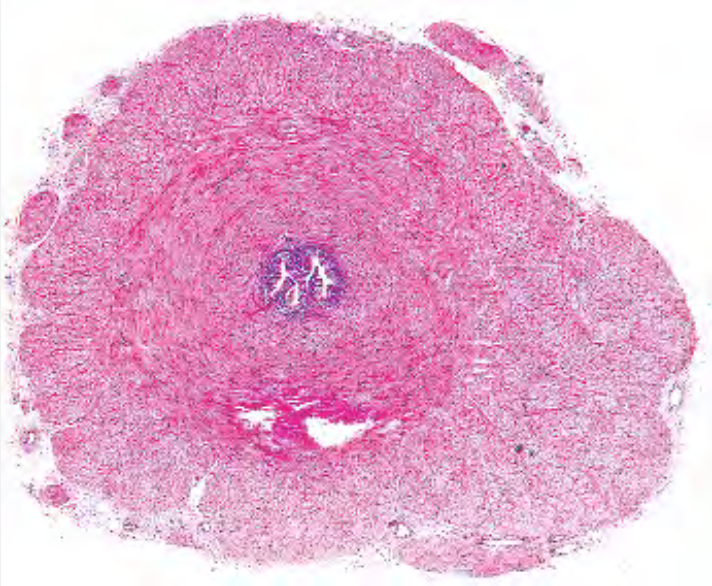

Figure 37.26 Proximal ductus (vas) deferens. This cross section shows a thick muscle coat, tiny lumen, and slightly folded mucosa.

Seminal Vesicles

The seminal vesicles are paired, highly coiled, tubular structures, lying posterolateral to the base of the bladder and in a parallel path with the ampulla of the vas deferens (Figure 37.25). Each vesicle measures 3.5 to 7.5 cm in length and 1.2 to 2.4 cm in thickness in the adult. The main duct, which is duplicated in approximately 10% of individuals, measures 10 to 15 cm in length when unraveled. Six to eight first-order side ducts extend off the main duct, and several secondary side ducts are derived from these. The upper part of the main duct is bent backward in a hooklike fashion. A short excretory duct combines with the ampulla of the vas to form the ejaculatory duct (Figure 37.25). The wall of the seminal vesicle has a thin external longitudinal and a thicker internal circular muscle layer. The mucosal folds, relatively simple

and shallow in infancy and childhood, become highly complex and alveolus-like in the reproductive years (Figure 37.28) and are blunted in the aged vesicle. The lumen may contain a few sloughed epithelial cells and debris. Commonly seen within the lumens are eosinophilic secretions, often with crystalloid structures. The latter usually have a platelike arrangement but sometimes appear as smaller crystalloids similar to those seen in the lumens of well-differentiated prostate carcinomas. Their significance is unknown, but one should be aware of their presence in biopsies where the seminal vesicle is inadvertantly sampled (100). Spermatozoa, refluxed from the ejaculatory duct, occasionally may be present, although they are not normally stored within the seminal vesicles.

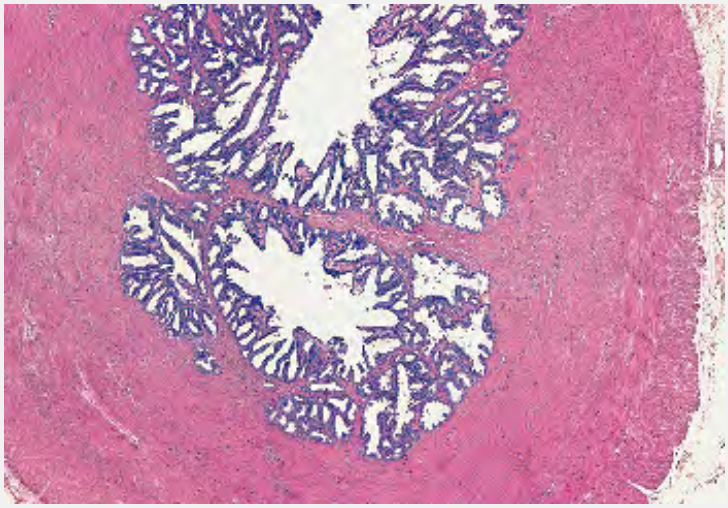

Figure 37.27 Ampullary region of ductus (vas) deferens. Note the complex folding and outpouching of the mucosa into the muscular coat.

The vesicle epithelium is composed of columnar and basal cells. The former have short microvilli projecting from the surface. The cytoplasm characteristically contains a large amount of lipofuscin pigment, a feature important in recognizing these cells obtained by

needle biopsy or aspiration cytology studies of the prostate. Similar lipofuscin pigment is found in the ampulla of the ductus deferens and in the epithelium of the ejaculatory ducts. The pigment has been divided into two different types, based on its appearance. Type 1 consists of coarse, highly refractile, golden brown granules of uniform diameter (1â€“2 Âµg). Type 2 granules are much more variable in size (0.25â€“4 Âµg), faintly or nonrefractile and yellow-brown, grey-brown, blue, or pink.

Both types 1 and 2 granules are found in the seminal vesicle, vas, and ejaculatory ducts, whereas only the type 2 granules are found in prostatic epithelium (101).

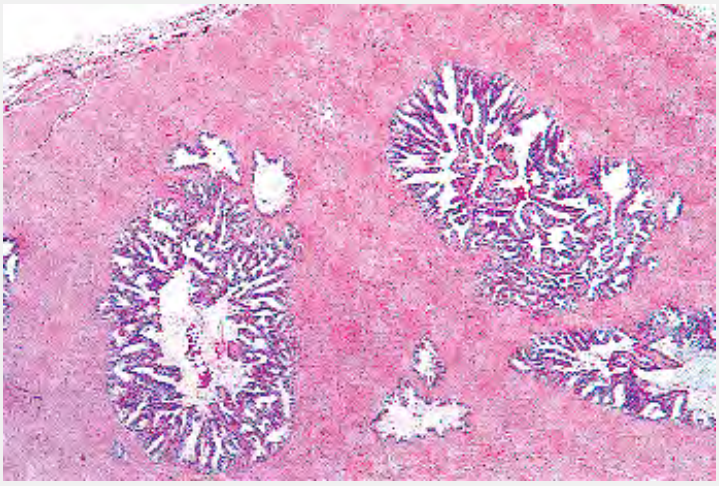

Figure 37.28 Seminal vesicle: alveolus-like arrangement of mucosal folds and cross sections of side ducts.

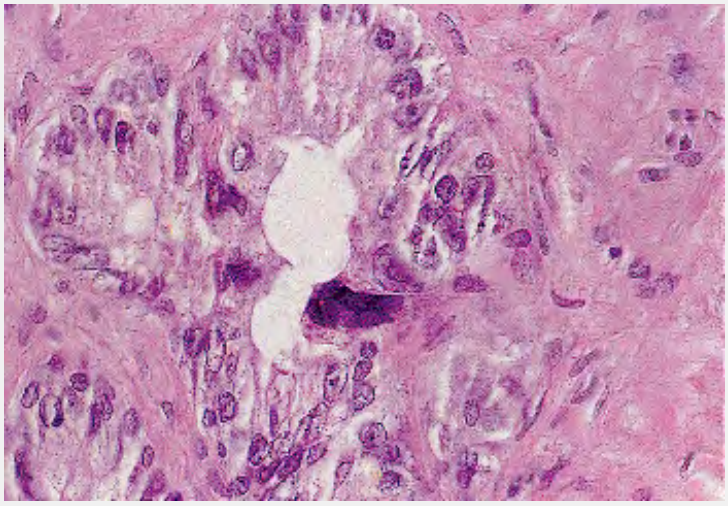

Figure 37.29 Seminal vesicle epithelium. Tall columnar cells line the lumen. A single hyperchromatic â€œmonsterâ€• cell is present. These cells should not be mistaken for malignant cells.

An unusual feature of the seminal vesicular epithelium is the presence of peculiar, monstrous epithelial cells (Figure 37.29). Similar cells may be seen in the ampulla of the vas and, less commonly, more proximally in the vas or epididymis. These cells have enlarged, hyperchromatic, and often irregularly shaped nuclei and are found in approximately three-quarters of adult seminal vesicles. They are not seen in infants or children. Their genesis is unknown but may be related to endocrine influences, similar to the Arias-Stella cells seen in gestational endometrium. Because these cells may be encountered in both needle biopsy and aspiration biopsy specimens, the surgical pathologist must be alert to avoid identifying them as malignant cells (102).

Also encountered in the muscle portion of the seminal vesicle are hyalin, pink globules (Figure 37.30), thought to represent degenerating smooth muscle cells. They also may be seen

occasionally in the muscular coat of the vas and within the prostatic parenchyma (103).

Ejaculatory Ducts

The ejaculatory ducts are short (1.5 cm) paired ducts, arising from the confluence of the excretory duct of the seminal vesicle and the ampulla of the vas, that quickly converge and enter the prostate (Figure 37.31). They run through the central zone of the prostatic parenchyma and enter the posterior aspect of the distal prostatic urethra at the verumontanum (104). The outer portions of the ejaculatory ducts have a thin muscle coat that progressively becomes more attenuated as the ducts pass through the prostate. The epithelium of the ejaculatory ducts resembles that of the seminal vesicle and ampulla of the vas (Figure 37.32). On occasion, a needle biopsy of the prostate will sample a portion of one of these ducts, making it imperative that the surgical pathologist be aware of the characteristics of these cells. The presence and character of the lipofuscin pigment in the cytoplasm should give a clue to the cell origin. Immunoperoxidase stains for prostate-specific antigen demonstrate a sharp contrast between the positively stained prostatic parenchyma and the negatively stained cells of the intraprostatic ejaculatory ducts (Figure 37.33).

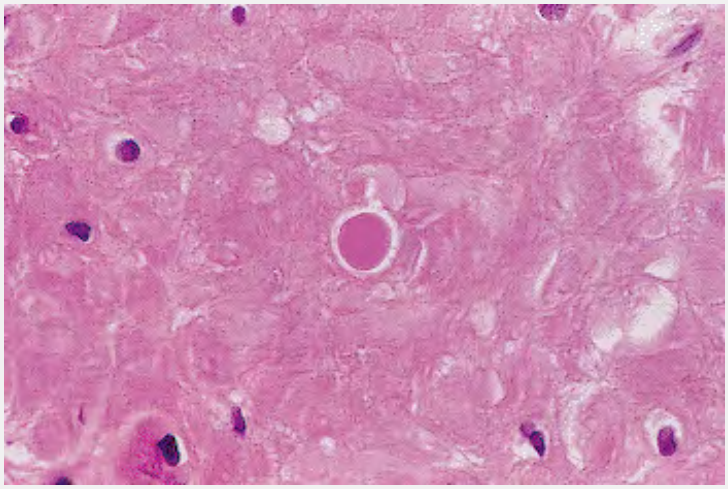

Figure 37.30 Muscle coat of seminal vesicle showing a hyalin globule, which probably represents a degenerated smooth muscle cell.

Testicular Appendages

The testicular and paratesticular appendages are remnants of either the mesonephric duct or the paramesonephric (mÃ¼llerian) duct (77). The four testicular appendages are

the appendix testis (hydatid of Morgagni), appendix epididymis, vas aberrans (organ of Haller), and paradidymis (organ of Giraldes) (Figure 37.1).

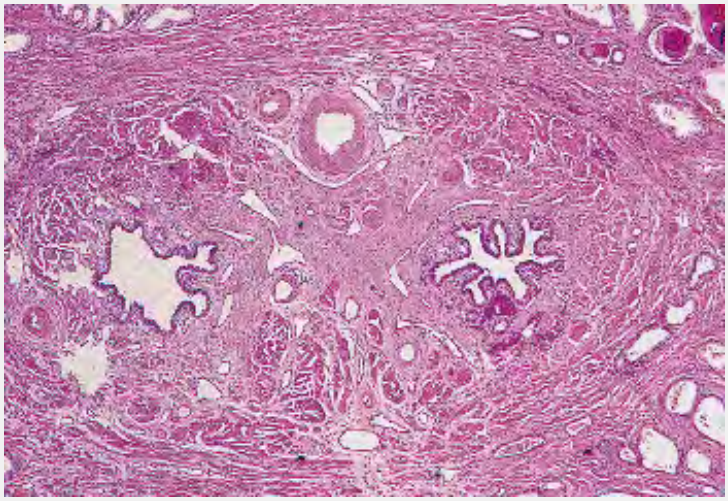

Figure 37.31 Paired ejaculatory ducts within the prostatic parenchyma. This section is adjacent to the verumontanum of the prostatic urethra.

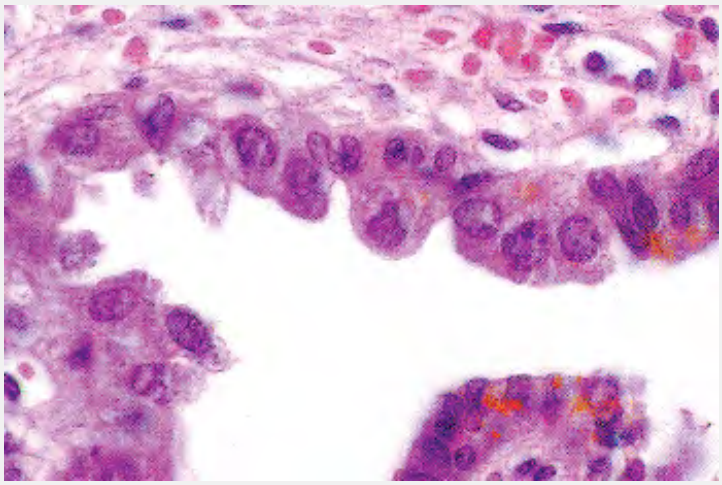

Figure 37.32 Epithelium of prostatic portion of ejaculatory duct. This epithelium may be encountered in a needle biopsy or aspiration biopsy of the prostate and should not be misinterpreted as malignant.

The appendix testis, a remnant of the cranial portion of the mÃ¼llerian duct, is attached to the tunica vaginalis on the anterosuperior aspect of the testis just below the caput of the epididymis. Occasionally, it is attached to both the testis and the epididymis. It is most often sessile and either oval or fan-shaped (approximately 90%) and, less commonly, pedunculated (approximately 10%) and measures 0.5 to 2.5 cm in greatest dimension (Figure 37.34) (105,106). It is occasionally represented by only a slight roughening or a calcified thickening of the tunica vaginalis. Approximately 80% of individuals have an appendix testis, with bilaterality in one-third of them. The appendix is covered by a cuboidal or columnar epithelium, which may be ciliated (Figure 37.35). The structure has a highly vascular fibrous core, containing variable numbers of smooth muscle cells. Tubular invaginations and small glandlike structures may also be found in the stroma. Rarely, a macroscopic cyst may be present. Because of its pedunculated structure, the appendix testis can become twisted, causing hemorrhagic infarction and producing severe testicular pain (107). This event occurs most often in prepubertal or pubertal boys and may be related to the presence of androgen and estrogen receptors known to be present in the appendix epithelium (and the appendix epididymis) and the possible growth of the appendix as a result of stimulation by androgens and estrogens at this period of time (108).

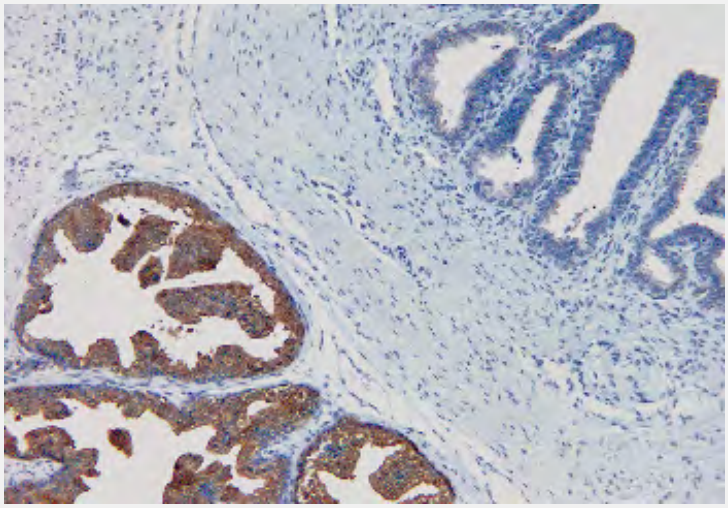

Figure 37.33 Intraprostatic ejaculatory duct (right) and adjacent prostatic tissue (left). Prostate-specific antigen immunoperoxidase from the central zone of the prostate is used to demonstrate strongly positive cytoplasmic staining of the prostatic secretory cells and negative staining of ejaculatory duct epithelium.

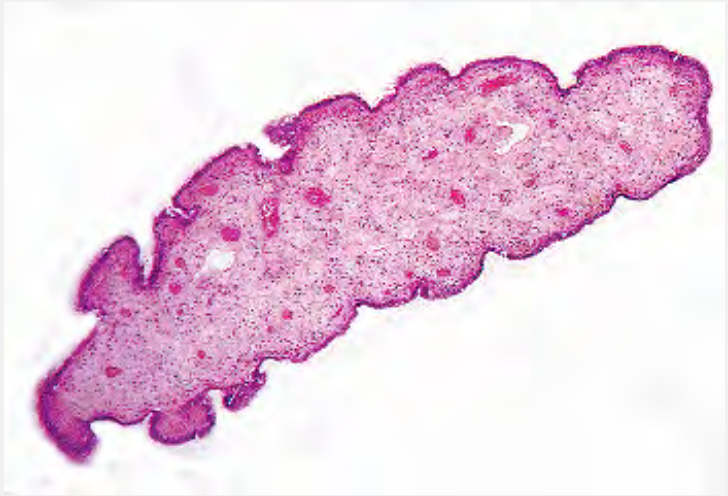

Figure 37.34 Appendix testis. This specimen was an

incidental finding in a surgically removed testis. It was pedunculated and measures 0.9 cm in greatest length.

The appendix epididymis (Figure 37.36), a remnant of the most cranial portion of the mesonephric duct, is present in approximately 25% of testes (106). It is almost invariably cystic, the vesicle lumen being filled with amorphous protein secretions. The epithelium lining the cyst is

columnar and often ciliated (Figure 37.37). The external surface is covered by a flattened layer of serosal cells. Because it may be pedunculated, it is also subject to torsion and infarction.

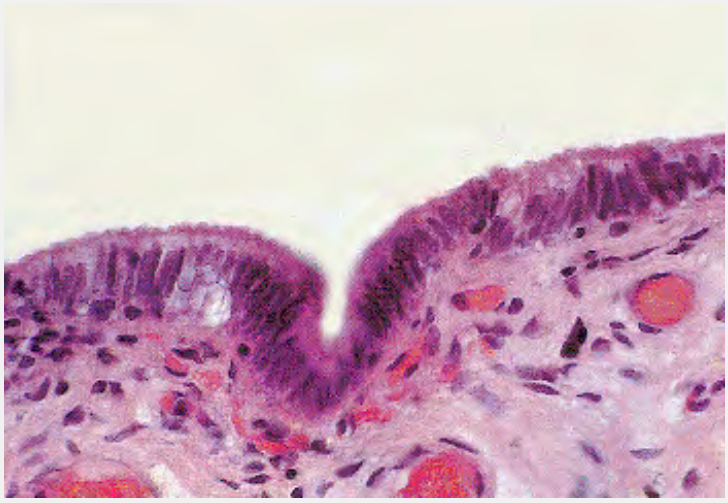

Figure 37.35 Appendix testis with covering of low columnar, nonciliated epithelium.

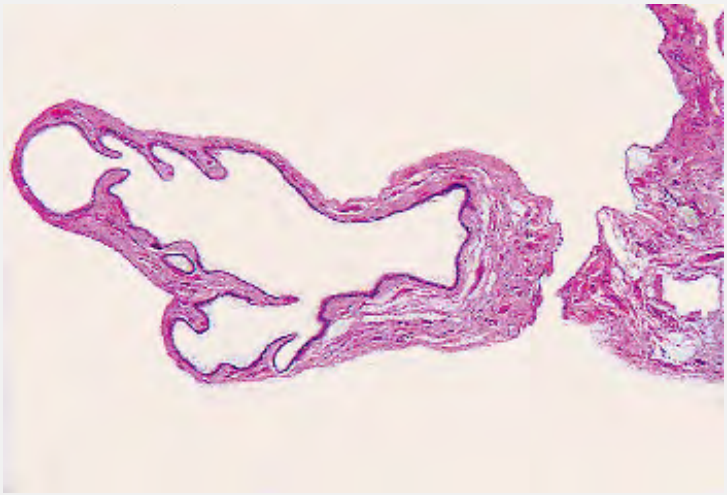

Figure 37.36 Appendix epididymis. A pedunculated cystic structure is attached to the caput of the epididymis.

The other appendicular structures are derived from remnants of either the mesonephric tubules or the paramesonephric ducts and are variably encountered in the fat, usually as microscopic incidental findings. These are the vas aberrans inferior, the vas aberrans superior, and the paradidymis. They all have somewhat similar histologic features, with a low columnar epithelium lining a small cystic space and a thin muscular coat. Some investigators collectively refer to these structures as the paradidymis (109). The vas aberrans inferior is a tubular structure (Figure 37.38) located near the junction of the vas and the caudal portion of the epididymis and which may or may not communicate with either structure.

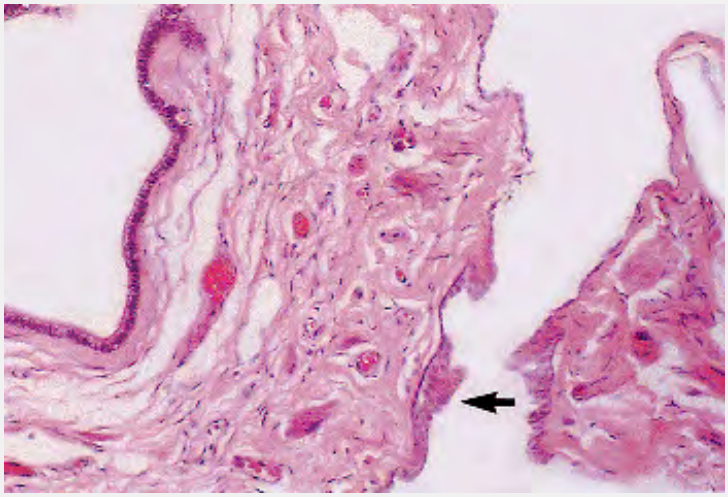

Figure 37.37 Appendix epididymis. Low columnar epithelium lines the cystic space. The outer covering of simple squamous epithelium has become stratified at the point of attachment to the caput of the epididymis (arrow).

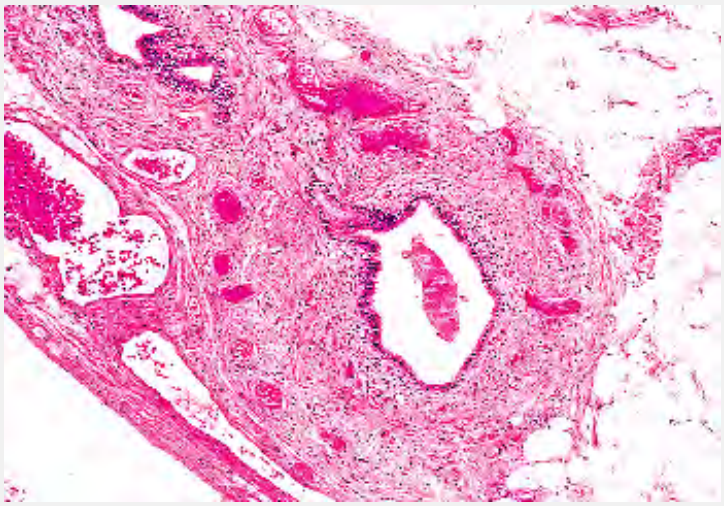

Figure 37.38 Vas aberrans inferior. A tubular structure is found near the caudal portion of the epididymis.

The vas aberrans superior is a small collection of tubules located near the caput or body of the epididymis. It may communicate with the epididymis or the rete testis. Remnants of the vas aberrans may be the origin of cord cysts, seen sporadically in isolated individuals, in patients whose mothers had been treated with diethylstilbestrol (110), or in patients with von Hippel-Lindau syndrome (111).

The paradidymis is represented by one or more tubules embedded in the spermatic cord, adjacent to the ductus (vas) deferens, and near the caput of the epididymis. These tubules may be encountered in a section of the wall of an inguinal hernia sac and should not be mistaken for a portion of the ductus deferens (112). The relatively thick muscle coat of the true vas should allow for the correct interpetation. Rarely, macroscopic cysts may form in the spermatic cord (113).

Although not part of the paradidymis, infrequently one may find adrenal cortical rests in the fat of the spermatic

cord, adjacent to the vas, the epididymis or the rete testis (Figure 37.39). Very rarely, adrenal medullary tissue may also be present. Even less commonly seen is splenogonadal fusion, in which the splenic and gonadal anlages fuse in early embryonal life. This process is almost always on the left side and most commonly is found as an incidental finding in a cryptorchid testis (Figure 37.40). Occasionally it presents as a mass in the scrotum or inguinal canal.

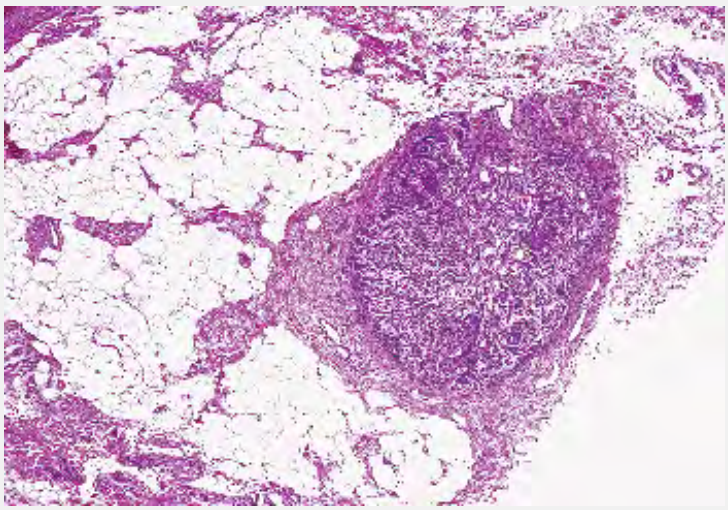

Figure 37.39 Adrenal cortical rest in fat adjacent to the epididymis.

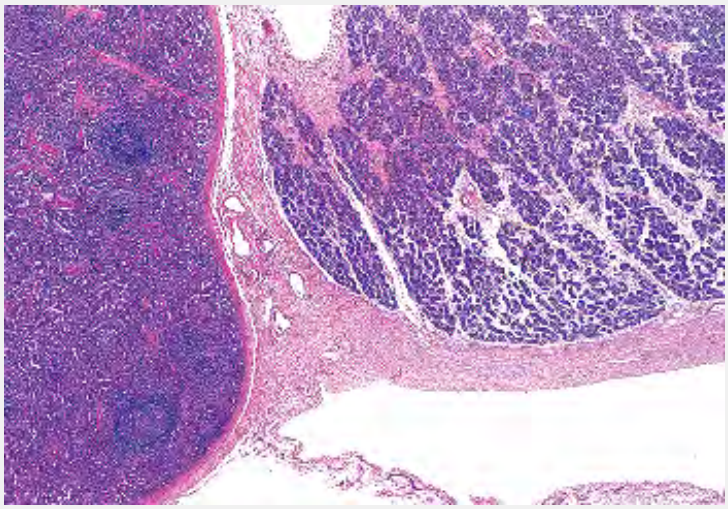

Figure 37.40 Splenogonadal fusion of a cryptorchid testis in a 3-year-old child. Spleen is on the left and gonad on the right.

Gubernaculum

The gubernaculum has been the center of attention with respect to the descent of the testis since it was first described by John Hunter in 1762, and its specific role is still being debated. In the fetus, this cylindrical, gelatinous structure is attached cranially to the testis and epididymis (Figure 37.41) and caudally to the anterior abdominal wall at the site of the inguinal canal. Just before the descent of the testis through the inguinal canal, the gubernaculum increases in net weight disproportionately to the testis, supporting the theory that this structure plays a crucial role in this phase of the passage of the testis into the scrotum.

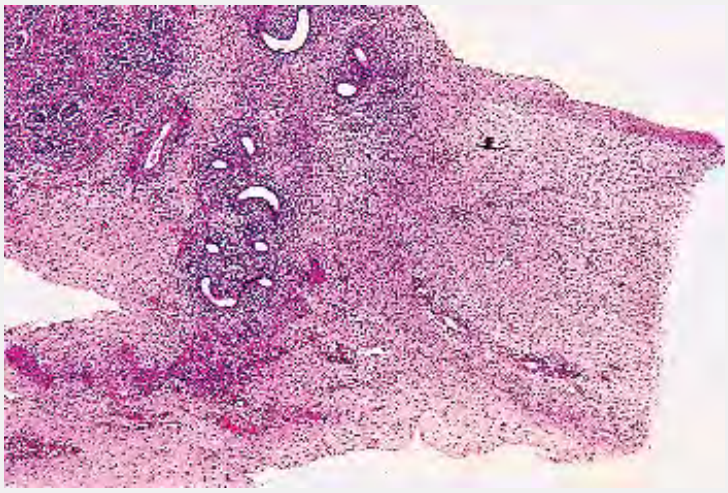

Figure 37.41 Gubernaculum and cranial attachment to epididymis and testis in a 26-week-old fetus.

Histologically, the fetal gubernaculum is composed of a loose undifferentiated mesenchymal tissue similar to Wharton's jelly. Large amounts of glycosaminoglycans fill the extracellular space and separate the individual spindle cells. At the periphery of the gubernaculum, where it attaches to the inguinal wall, a few striated muscle cells can be identified. These fibers are derived

from the developing cremaster muscle. The cranial portion of the early fetal gubernaculum is completely devoid of striated muscle. After the testis descends into the scrotum, the gubernaculum undergoes degenerative changes, loses much of the intercellular matrix, and becomes infiltrated by blood vessels, collagen fibers, and striated muscle.

Penis and Distal Urethra

Elsa F. Velazquez
Christopher J. Cold
JosÃ© E. Barreto
Antonio L. Cubilla

Introduction

Three cylindrical, firmly adherent, tubular erectile tissues (the corpora cavernosa and the corpus spongiosum) and the pendulous urethra are the basic constituents of the penis that can be subdivided into a distal portion that includes glans, coronal sulcus, and foreskin and a proximal portion, the corpus or shaft (1) (Figure 38.1). The vast majority of penile carcinomas arise from the distal portion of the organ (Figure 38.2).

Distal Penis

Glans

Anatomic Levels of the Glans (Figure 38.2)

- Epithelium
- Lamina Propria
- Corpus Spongiosum
- Tunica Albuginea*
- Corpus Cavernosum*

Footnote

* The distal portions of the corpora cavernosa encased by the tunica albuginea are part of the glans in 77% of the cases.

Anatomic Features

The conically shaped glans, covered by a pink smooth mucous membrane, is the most distal portion of the organ and shows in its central and ventral region, the meatus urethralis. The expanded anterior end of the corpus spongiosum, which has the shape of an obtuse cone similar to the cap of a mushroom, is the central and main tissue of the glans. It is molded over and attached to the blunt extremity of the corpora cavernosa and extends farther over their dorsal than their ventral surfaces (1). The base of this conus is an elevated rim or border, the corona, occupying 80% of the circumferential head of the glans; it is interrupted in the ventral portion of the glans by the mucosal fold of the

frenulum (Figure 38.1). The diameter of the corona is wider than the shaft and the remainder of the glans.Within the corpus spongiosum, there is the distal portion of the urethra that opens at the summit of the glans as a vertical, slitlike external orifice termed the urethral meatus (Figures 38.1,38.2). Normal anatomical structures frequently found in sexually active males and commonly located in the proximal

glans are called pearly penile papules, hirsutoid papillomas, or papillomatosis corona penis or glandis (2,3,4,5). Grossly, they appear as 1- to 3-mm skin-colored, domed papules evenly distributed circumferentially around the corona and extending proximally on each side of the frenulum. They may be mistaken for warts and be the source of much anxiety for worried adolescents (2).

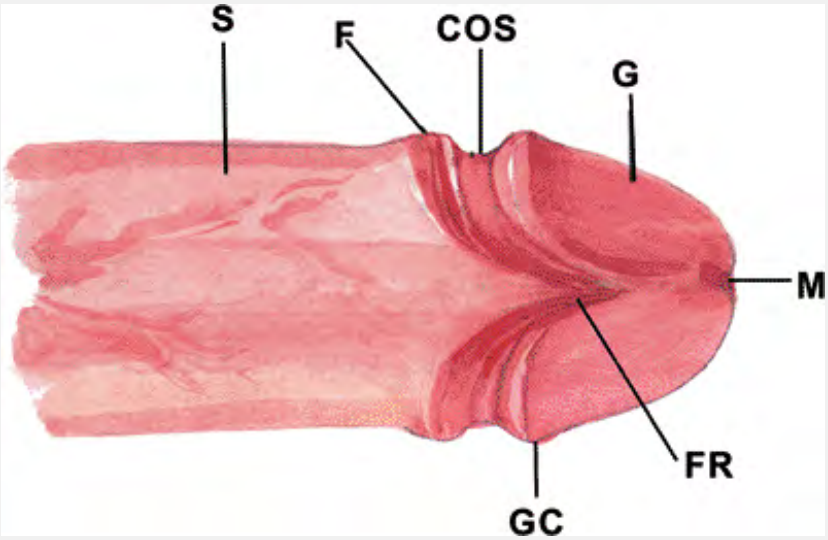

Figure 38.1 The penis can be subdivided in a distal portion that includes glans (*G*), coronal sulcus (*COS*), and foreskin (*F*) and a proximal portion, the corpus or shaft (*S*). (*M* urethral meatus; *GC*, glans corona; *FR*, frenulum)

Considering the glans as the distal tissues to a line passing through the coronal sulcus, the distal portions of the corpora cavernosa encased by the tunica albuginea extend out into the glans in approximately 77% of the cases (Figure 38.3) (6). However, since they are the main constituents of the shaft, they are discussed in detail in that section.

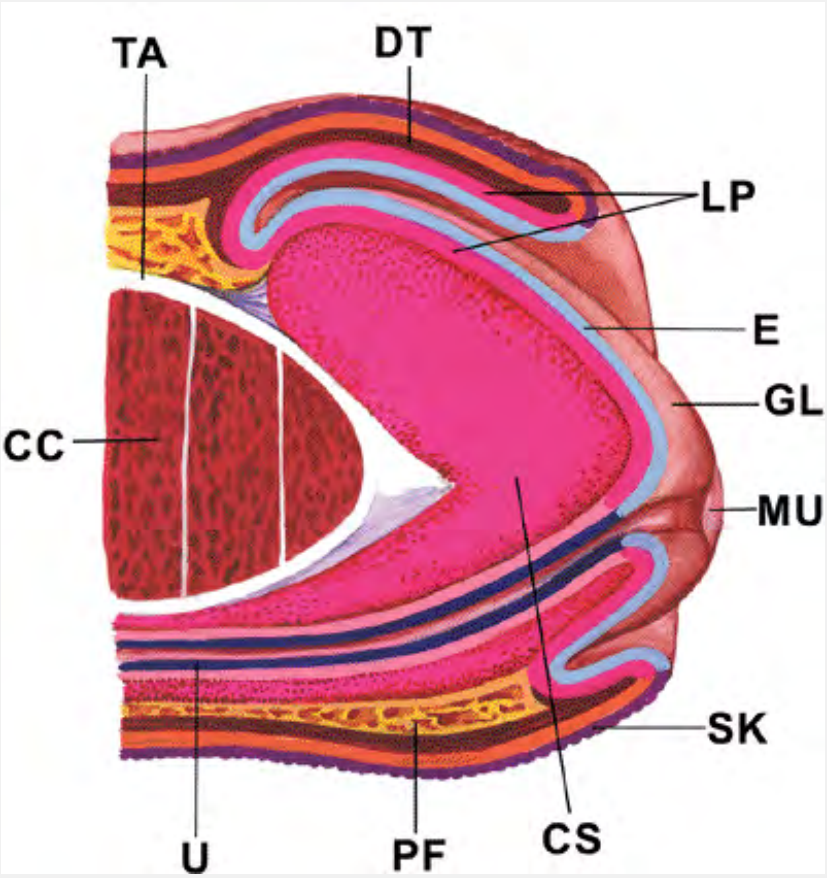

Figure 38.2 Diagram illustrating the distal portion of the penis, which includes glans (*GL*), coronal sulcus, and foreskin. (*E*, epithelium; *LP*, lamina propria; *CS,* corpus spongiosum; *TA,* tunica albuginea; *CC,* corpus cavernosum; *DT,* dartos; *SK,* skin; *U,* urethra; *MU,* meatus urethralis; *PF,* penile, or Buck's, fascia.

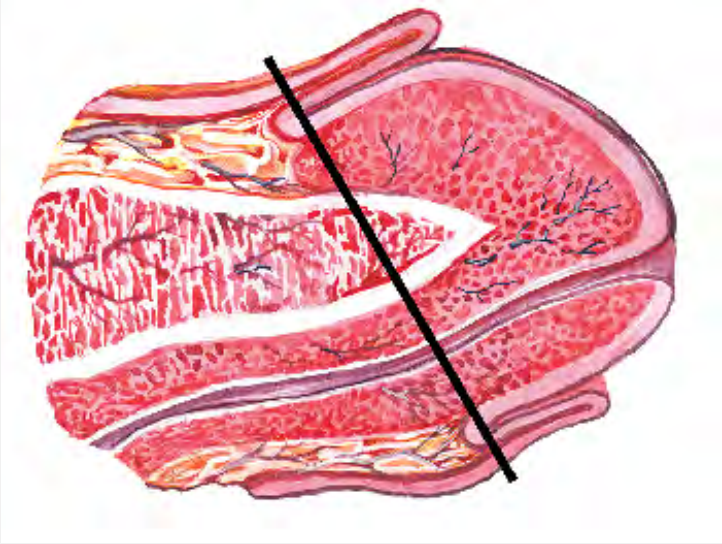

Figure 38.3 The distal portion of corpora cavernosa encased by the tunica albuginea is part of the glans in the majority of cases. The diagonal line passing through the coronal sulcus divides glans from shaft.

Microscopic and Immunohistochemical Features

Epithelium

Both circumcised and intact (uncircumcised) men have partially keratinized stratified squamous epithelium five to six layers thick (Figure 38.4). Some textbooks state that the circumcised glans is much thicker and more keratinized than in an intact man, but no well-controlled studies support this belief. The superficial cells usually contain no glycogen. The normal squamous epithelium is usually positive for the cytokeratins AE1/AE3, 34Be12 and CK7, and the epithelial membrane antigen (EMA). It is negative for the cytokeratins CAM 5.2 and CK20. Langerhans

cells are found scattered among keratinocytes, and they are increased in number in different inflammatory conditions. Langerhans cells express S-100 protein and CD1a (Figure 38.5). Very rare Merkel cells are also present, and they are very difficult to demonstrate by routine or immunohistochemical techniques. They are usually negative for chromogranin and positive for CK20 (7). The glans epithelium and the mucosal epithelium of the foreskin appear to not contain melanocytes (8,9). Rarely, mucus-producing cells can be noted in the perimeatal region of the glans epithelium (10). They may be the source of the adenosquamous carcinoma of the glans penis. Intraepithelial free nerves ending close to the surface of the epithelium are noted (11). No adnexal or glandular structures are present in the glans. Histologically, the pearly penile papules appear like fibrovascular papillary projections lined by squamous epithelium (Figure 38.6) (2). No koilocytosis is seen in these structures.

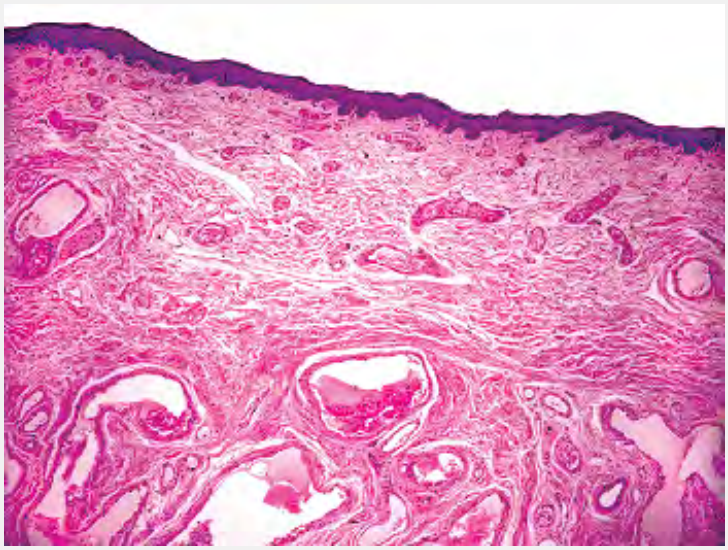

Figure 38.4 The three layers of the glans are noted: partially keratinized stratified squamous epithelium, lamina propria, and corpus spongiosum.

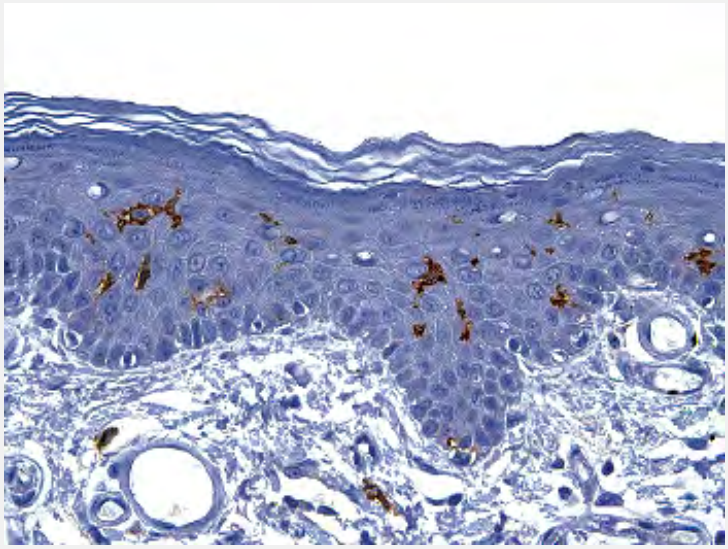

Figure 38.5 CD1a immunostain highlights the presence of scattered Langerhans cells in the glans epithelium.

Figure 38.6 Pearly penile papule appears histologically as a papillary structure with a fibrovascular core lined by squamous epithelium with no evidence of koilocytosis.

Lamina Propria

The lamina propia is the prolongation of the foreskin lamina propria and separates the corpus spongiosum from the glans epithelium. In the glans, the loose connective tissue of the penile fascia and the fibrous tunica albuginea are lacking so that the lamina propria adheres firmly to the underlying corpus spongiosum (Figure 38.4) (12). The connective tissue of the lamina propria is somewhat similar to that of the corpus spongiosum, although it is more compact and contains fewer peripheral nerve bundles and elastic fibers than the erectile structure. The transition between lamina propria and corpus spongiosum is sometimes difficult to determine at medium or high magnifications. However, at low power or even after a careful gross inspection or with a magnifying lens, this delimitation is evident and follows a line corresponding to the geographic limit of the extension of venous sinuses of the corpus spongiosum. The thickness of the lamina propria varies from 1 mm at the glans corona to 2.5 mm near the meatus. Scattered specialized genital corpuscles are identifed in the lamina propria underneath the squamous epithelium. These genital corpuscles are found mainly in the glans corona and frenulum and may be less numerous in the glans when compared to the foreskin. Additional quantitative studies are needed to confirm or deny this belief. A predominance of free nerve endings over the genital corpuscles has been described in the glans (8,13). A few dermal Merkel cells have been identified at the end of the free nerves.

Corpus Spongiosum

The corpus spongiosum is the principal tissue component of the glans penis and is composed of specialized venous sinuses (Figure 38.7). In the glans, the erectile tissue has the character of a dense, venous plexus (12). As compared to the corpora cavernosa, the interstitial

fibrous connective tissue of the corpus spongiosum is more abundant and

contains more elastic fibers and less smooth muscle bundles (14,15) (Figures 38.8,38.9). The stroma between the vascular spaces is a loose fibrous tissue containing some nerve endings and lymphatic vessels. In this erectile tissue, we also find nutritional veins and arteries (Figure 38.8).

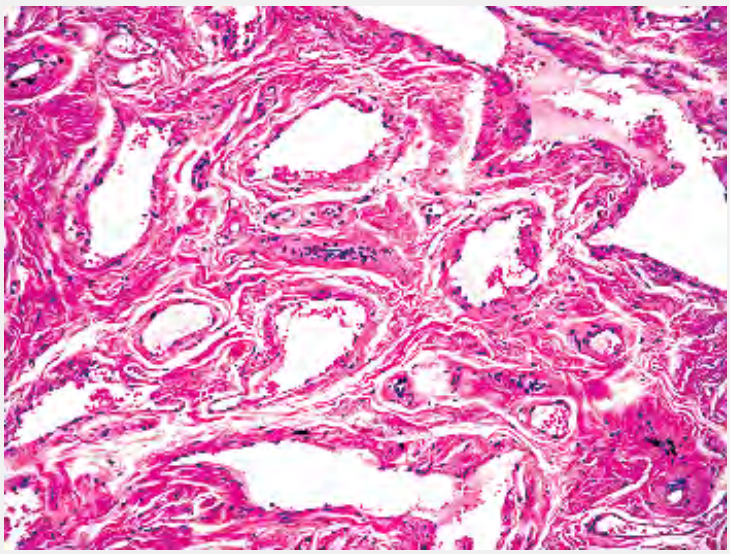

Figure 38.7 Glans. Higher power view of the corpus spongiosum showing specialized venous sinuses.

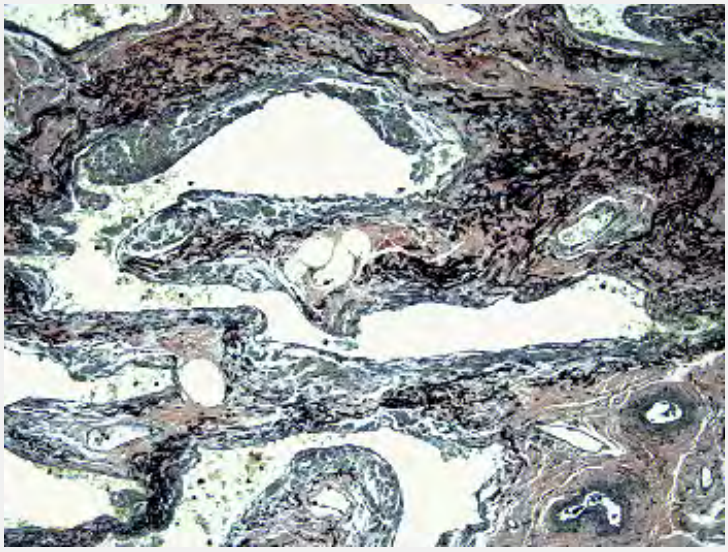

Figure 38.8 Corpus spongiosum. The interstitial fibrous connective tissue is more abundant and contains more elastic fibers than in the corpus cavernosum. Note the presence of nutritional veins and arteries in the interstitium of this erectile tissue. (Van Giesson's elastic stain.)

Coronal Sulcus

Anatomic Levels of the Coronal Sulcus

- Epithelium
- Lamina Propria
- Buck's Fascia

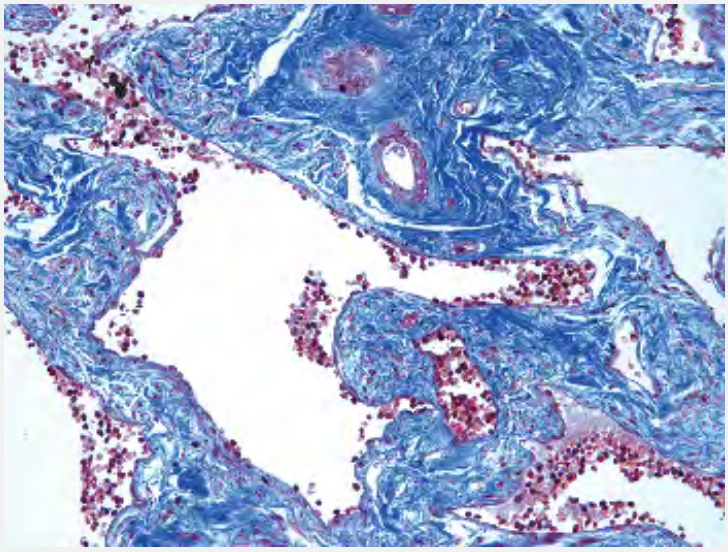

Figure 38.9 Corpus spongiosum. The interstitial fibrous connective tissue contains fewer smooth muscle fibers than does the corpus cavernosum (Masson's trichrome).

Anatomic Features

The coronal sulcus is a narrow and circumferential cul-de-sac located proximal to the glans corona (Figure 38.1,38.2). It is found in both lateral and dorsal aspects of the penis but not in the ventral region, which is occupied by the frenulum, a mucosal fold that fixes the foreskin to the inferior portion of the glans, just below the urethral meatus. The mucous membrane of the glans continues to cover this region as well as the inner surface of the foreskin.

Microscopic and Immunohistochemical Features

Three histologic layers are seen in the coronal sulcus: (a) the squamous epithelium, identical to the glans epithelium; (b) a thin lamina propria, or chorion, which is a prolongation of the foreskin

and glans lamina propria; and (c) Buck's fascia and the point of insertion of some of smooth muscle fibers coming from the penile body dartos (Figure 38.10).

The coronal sulcus has been reported as the most frequent site of so-called Tyson's glands (1,14,16,17,18,19,20), described as modified sebaceous glands and reported as responsible for smegma production. Smegma represents epithelial debris and secretions collected in this space (21). There has been some question about the existence of the Tyson's glands (8,21,22). Several studies with numerous tissue sections failed to demonstrate these glands (21,23). We could not find Tyson's glands in a pathologic study of 67 totally sectioned penises removed for carcinoma of the penis. Apparently the original descriptions by Tyson (24) were based on primate studies that could not be confirmed in humans. After circumcision, occasionally some sebaceous glands can be found in the mucosa adjacent to the skin. They are probably skin sebaceous glands misplaced after surgery. Sebaceous glands associated with or without

hair follicles are found in the penile shaft and cutaneous aspect of the foreskin. We have observed the presence of sebaceous glands that are nonrelated to hair follicles at the mucocutaneous junction of the foreskin and adjacent mucosa but not in the coronal sulcus. The presence of sebaceous gland hyperplasia or ectopic sebaceous glands (Fordyce's condition) is more frequent on the penile shaft and foreskin but may also occur in the glans (2).

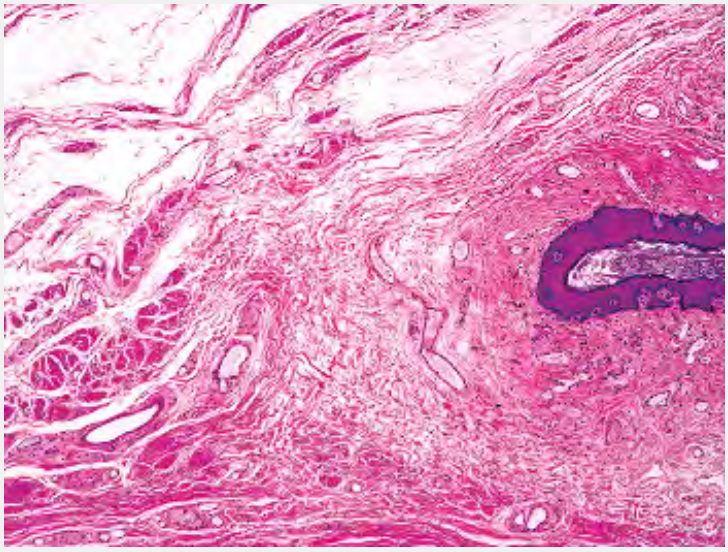

Figure 38.10 A section of the coronal sulcus. Histologic components of both glans and penile body are present. This specimen from an uncircumcised person (a portion of the foreskin is seen on top) shows the squamous epithelium (*right*), lamina propria below, then Buck's fascia and dartos smooth muscle bundles (*left*).

Foreskin

Anatomic Levels of the Foreskin

- Epidermis
- Dermis
- Dartos
- Lamina propria
- Epithelium

Anatomic Features and Circumcision

The foreskin, or prepuce, is a unique genital structure of primates that has been present for over 65 million years, and it is present in all living primates and most mammals. The foreskin is the prolongation of the shaft's skin and normally covers most of the glans, reflecting beyond itself and transforming into a mucosal inner surface. This mucous membrane covers the coronal sulcus as well as the surface of the glans (Figures 38.1,38.2). Grossly, the adult foreskin shows a cutaneous surface that is dark and wrinkled and a mucosal surface that is pink to tan (Figure 38.11).

From very early years to the present, there have been discussions and controversies regarding the role of the foreskin and the importance of circumcision (25,26,27,28), a type of surgery known to mankind as early as 12,000 BCE and practiced for religious or tribal rites by, among others, Egyptians, Jews, Muslims, and Aztecs (29,30). Although circumcision has been practiced for thousands of years, circumcision of infants has only been practiced for approximately 4000 years, as described in Genesis 17. Circumcision on the eighth day represents a mark of the covenant between God and the Jewish people. Genesis 17 marks a significant change in the circumcision ritual since before this time circumcision was always performed on young boys and adolescents. Preputial functions are related to protection of the glans from external irritation or contamination, and it has been shown that the foreskin is normal erogenous tissue (8,31,32).

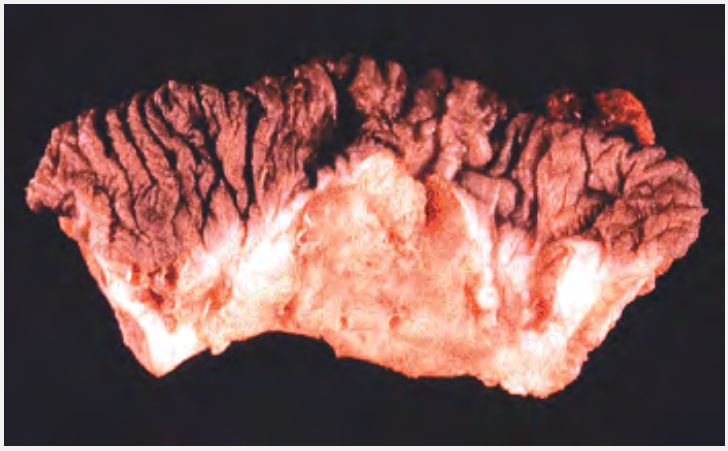

Figure 38.11 Gross appearance of an adult foreskin (prepuce). The cutaneous surface (*top*) is darker and more wrinkled. The mucosa (*bottom*) is pale beige and slightly irregular. A squamous cell carcinoma is present in the mucosal surface, the most common location of preputial carcinomas.

In addition, it has been demonstrated that the squamous mucosa of the glans, coronal sulcus, and foreskin are fused during the embryologic development of the penis (Figure 38.12), and they can be considered as one tissue compartment. The fused mucosa of the glans and inner lining of the foreskin separate gradually over the years (8). Most newborn males show an unretracted foreskin at the time of delivery (33). When boys reach the age of 5 to 6 years, the foreskin can be completely retracted in most cases beyond the level of the glans corona, but in some cases this can be done only at puberty. According to these observations, a tight preputial orifice due to an immature preputial plate does not represent an adhesion but a normal stage of penile development. Therefore, neonatal circumcision before the foreskin has naturally separated involves tearing the common prepuce/glans mucosa apart, with the possible complications of excoriation and injury to the glans and ablation of the frenular artery and meatal stenosis (8).

On the other hand, different studies have been published suggesting that circumcision may reduce the risk of penile carcinoma, urinary tract infection, common sexually transmitted diseases, and human immunodeficiency virus

infection (25,34,35). It has also been proposed that the mucosal inner surface of the foreskin from newborns shows a propensity to be colonized by fimbriated bacteria, with the subsequent occurrence of serious urinary tract infection (36). A recent study suggested that male circumcision is beneficial because it is associated with a reduced risk of penile HPV (human papillomavirus) infection and, in the case of men with a history of multiple sexual partners, a reduced risk of cervical cancer in their current female partner (37). However, it appears clear that the risk of sexually transmitted disease, including HPV infection, correlates with sexual behavior, and behavioral factors appear to be a far more important risk factor than circumcision status.

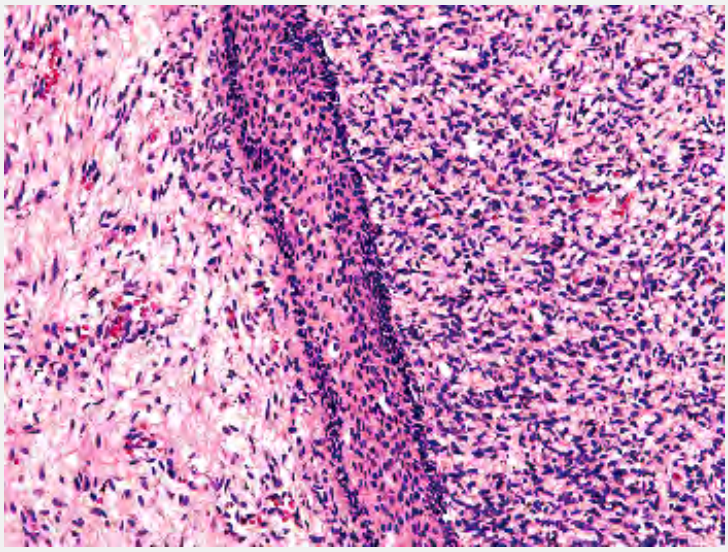

Figure 38.12 Fused squamous mucosa of the glans, coronal sulcus, and foreskin during the embryologic development of the penis. Note the common immature epithelial plate (*center*).The

dense stromal cells of the glans will form the corpus spongiosum (*right*). The lamina propria of the glans is not yet formed. The foreskin is on the left.

Review of existing literature supports that most children who are uncircumcised do well from a medical standpoint and, thus, the question of whether U.S. health care practitioners are subjecting neonates to an unnecessary surgical procedure remains (35). The clearest medical benefit of circumcision is the relative reduction in the risk for a urinary tract infection, especially in early infancy. Although this risk is real, the absolute numbers are small (risk ranges from 1 in 100 to 1 in 1000). Most of the other medical benefits of circumcision probably can be realized without circumcision as long as access to clean water and proper penile hygiene are achieved (35). Moreover, proper hygiene and access to clean water has been shown to reduce the rate of development of squamous cell carcinoma of the penis in the uncircumcised population (38), and the American Academy of Pediatrics stated that the benefits of male circumcision are not significant enough to merit its routine use. (35).

In adult populations, the variable length of the foreskin has motivated some studies, especially those related to the relation of length and amount of smegma in the balanopreputial sulcus (25,30,39). Phimosis is found in 4% of boys 6 to 17 years of age, but with a diminishing incidence in later years (from 8% in the 6- to 7-year-old group to 1% in the 16- to 17-year-old group) (39). In nonphimotic boys, where the preputial space can be inspected, smegma is present in 5% of the cases. Production of smegma appears to increase in quantity in the 16- to 17-year-old group (39). In a recent prospective study in a high-risk population, we found that long phimotic foreskins were significantly more frequent in patients with penile carcinoma as compared with the general population (25). Coexistence of a long foreskin and phimosis may explain the high incidence of penile cancer in some geographic regions, and

circumcision in patients with long and phimotic foreskins living in high-risk areas may be indicated (25). However, additional studies are necessary to confirm whether the length of the foreskin is a significant risk factor, when all other known risk factors (multiple sex partners, foreskin tears, lack of indoor plumbing, tobacco use, etc.) are controlled. Also, studies in nonmestizo populations, in particular European countries that have low circumcision and low cancer rates, would be interesting.

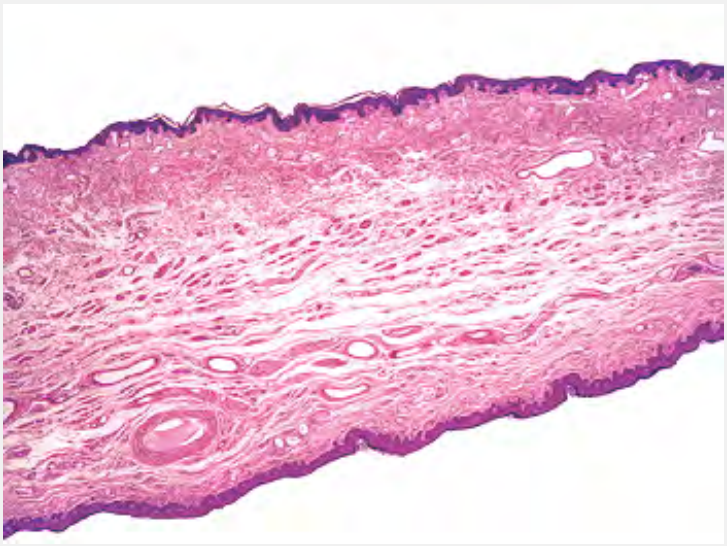

Figure 38.13 Full-thickness of the foreskin showing all five layers: keratinized stratified squamous epithelium (*top*), dermis, dartos, submucosa, and squamous epithelium of the mucosal portion (*bottom*).

Microscopic and Immunohistochemical Features

The male foreskin is formed by a midline collision of ectoderm, neuroectoderm, and mesenchyme, resulting in a pentalaminar

structure (8). There are five layers in the histologic evaluation of the foreskin (Figure 38.13):

- The epidermis consists of a keratinized stratified squamous cell epithelium that is similar to the epidermis seen in the cutaneous tegument. Melanocytes, Langerhans cells, and Merkel cells are also present. Compared to the mucosal epithelium, the epidermis is thinner with better developed rete ridges and usually a pigmented basal layer (Figure 38.14). Vellous hairs, sebaceous, and sweat glands may be seen connected to the epidermis.

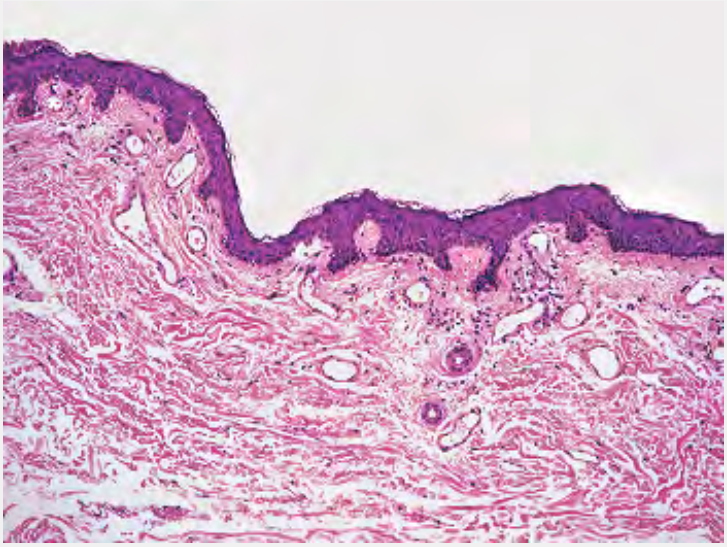

Figure 38.14 Compared to the mucosal epithelium, the epidermis is thinner with better developed rete ridges and usually a pigmented basal layer. The ductal portion of sweat glands connected to the epidermis can be appreciated in this photomicrograph.

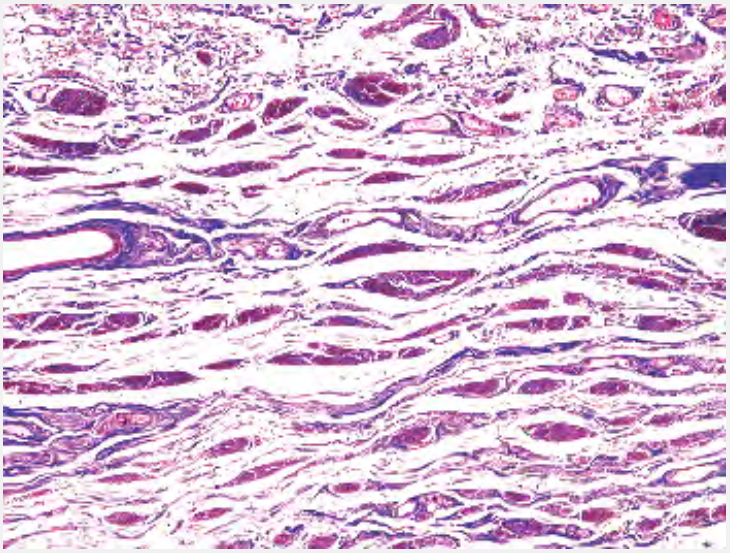

Figure 38.15 Smooth muscle bundles, the main component of the preputial dartos, are shown in red (Masson's trichrome).

- The dermis of the foreskin consists of connective tissue with blood vessels and nerve bundles. Meissner corpuscles are present in the dermal papillae and a few Vater-Pacini corpuscles in deeper areas. Few vellous hair structures and sebaceous and sweat glands are noted, and they are not present beyond the dartos. The dermis appears to have more elastic fibers than does the lamina propria.
- The dartos consists of smooth muscle fibers invested with elastic fibers, and it is the central axis of the foreskin (Figure 38.15). From the foreskin, the delicate penile dartos muscle surrounds the penile shaft and is continuous with the scrotal dartos muscle. Similar to the penile body dartos, the smooth muscle fibers vary in their disposition. At the level of the edge of the foreskin, the fibers are transversely arranged to form a sphincter to close this

edge over the anterior end of the glans. There are numerous nerve endings in close association with the smooth muscle fibers (Figure 38.16). Nerve bundle density in the foreskin was noted to be highest in the ventral preputial tissue (mean: 17.9 bundles/nm) as opposed to lateral (8.6/nm) or dorsal (6.2/nm) tissues (40). A few Vater-Pacini corpuscles may be found scattered between these nerve bundles (Figure 38.17).

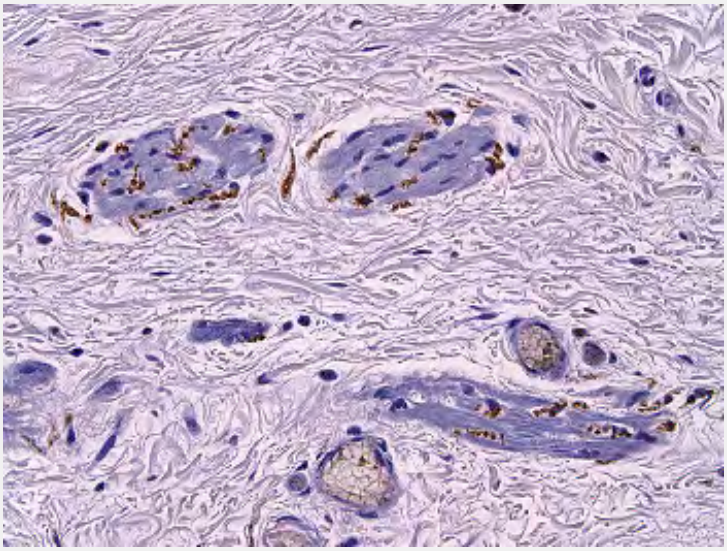

Figure 38.16 Neurofilament immunostain highlights numerous free nerve endings associated with smooth muscle bundles in the foreskin dartos.

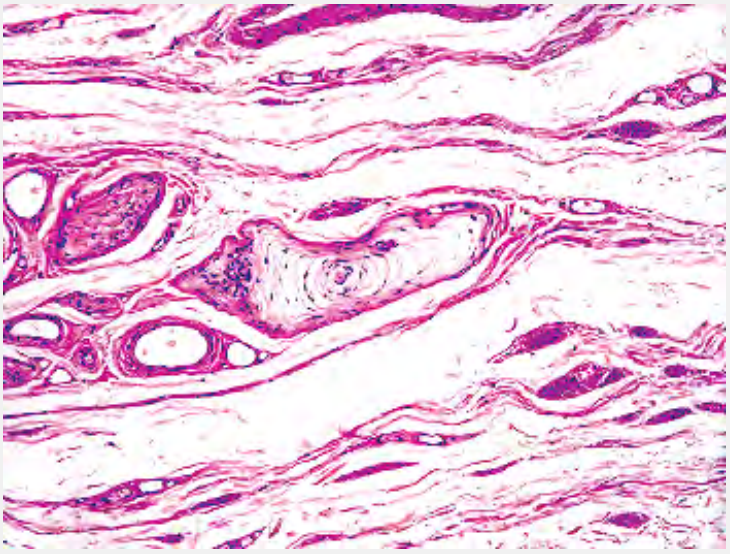

Figure 38.17 A Vater-Pacini corpuscle is present deep in the dartos layer of the foreskin.

- The lamina propria, or chorion, is composed of a vascular connective tissue looser than the glans lamina propria. Scattered genital corpuscles and free nerve endings are seen in the lamina propria immediately underneath the epithelium. The genital corpuscles are usually found in clusters of three to five (Figure 38.18). Some authors believe that the corpuscular receptors are more numerous at the mucocutaneous junction of the foreskin; this assertion needs further study (8,31). The mucosal lamina propria is devoid of lanugo hair follicles and sweat and sebaceous glands. We have observed

a few specimens with rare sebaceous glands unrelated to hair structures at the mucocutaneous junction and immediately adjacent foreskin mucosa, but it is not clear if these represent ectopic glands or variation of normal anatomy.

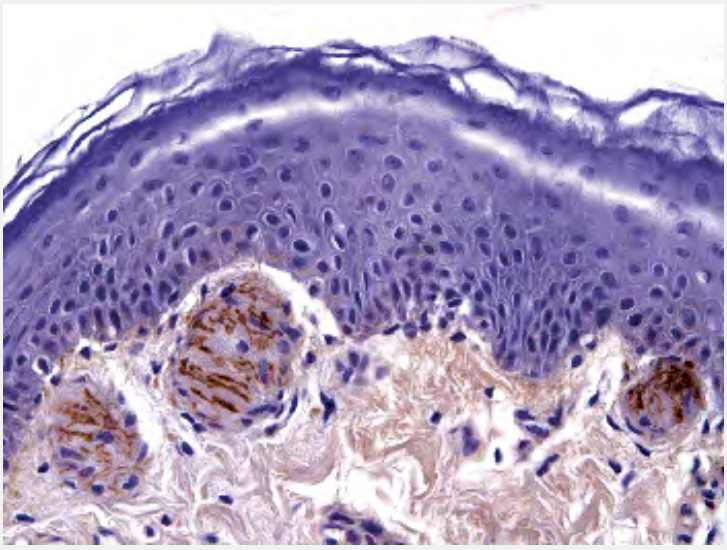

Figure 38.18 The genital corpuscles are usually found in clusters of three to five underneath the mucosal epithelium, in the lamina propria of the foreskin (neurofilament immunostain).

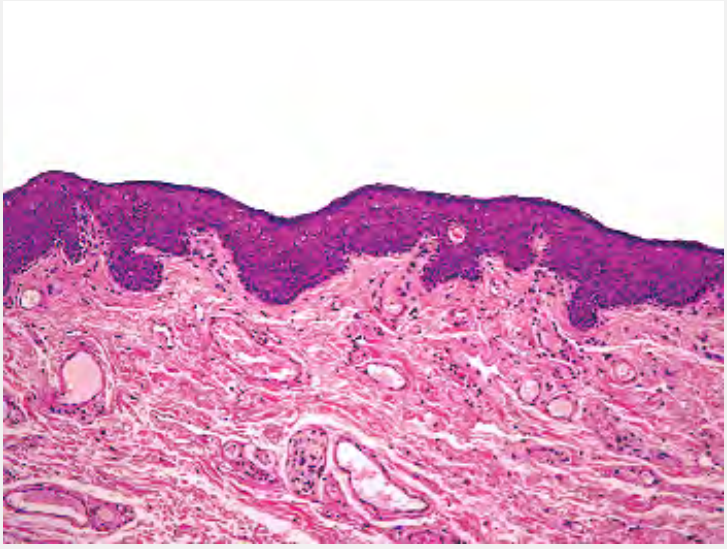

Figure 38.19 The squamous epithelium of the mucosal

portion of the foreskin is usually thicker with more irregular and broad rete ridges than in the cutaneous portion. Adnexal structures are absent.

- The squamous epithelium (Figure 38.19), which is identical to and a prolongation of the glans and coronal sulcus' epithelia except that the basal layer shows a progressive pigmentation toward the free edge of the foreskin where it reaches the skin epidermis. The immunohistochemical features of this epithelium are identical to the glans squamous epithelium. Langerhans and Merkel cells are present but not melanocytes. Intraepithelial nerves have been described (8,11).

Proximal Penis (Or Shaft)

Anatomical Levels of the Penile Shaft

- Epidermis
- Dermis
- Dartos
- Buck's fascia
- Tunica Albuginea
- Corpora cavernosa
- Corpus spongiosum

Anatomic Features

The penile shaft, body, or corpus, of the penis is mainly composed of three cylindrical masses of erectile tissue, the two corpora cavernosa

and a corpus spongiosum with central urethra (Figure 38.20Aâ€“B). The posterior portion of the corpora cavernosa are two divergent and gradually tapering structures, called the crura, that insert in the ischiopubic bone from where they converge to fuse at the level of the inferior portion of the pubic symphysis. The distal three-fourths of the two corpora cavernosa are intimately bound together and make up the greater part of the shaft of the penis. They retain a uniform diameter in the shaft and terminate anteriorly in a bluntly rounded extremity, being embedded in a cap formed by the corpus spongiosum of the glans (1). The erectile tissue of the corpora cavernosa is a vast, spongelike system of irregular vascular spaces fed by the afferent arteries and drained by the efferent veins. In the flaccid condition of the organ, the cavernous spaces contain little blood and appear as collapsed irregular clefts. In erection they become large cavities engorged with blood under pressure (14).

The corpora cavernosa are surrounded by a firm, thick, fibrous envelope, the tunica albuginea. In the flaccid state the tunica albuginea measures 2 to 3 mm in thickness and becomes thinner (about 0.5 mm) during erection. On longitudinal sections of the organ, the albuginea covering the corpora cavernosa terminates in a â€œ>â€•-shaped pattern variably ending beyond or at the level of coronal sulcus or, less frequently, behind it (Figure 38.20Aâ€“B) (6). The tunica albuginea enveloping the corpora cavernosa is thicker and less elastic than that surrounding the corpus spongiosum (14,15). The superficial longitudinal fibers of the tunica albuginea form a single tube that encloses both corpora cavernosa while the deep fibers are arranged circularly around each corpus, forming the septum of the penis by their junction in the median plane (Figure 38.21) (1). The septum is thick and complete in the proximal shaft and discontinous distally. A shallow groove that marks their junction on the upper surfaces lodges the deep dorsal vein of the penis.

The corpus spongiosum and central urethra are located in the concave space on the undersurface of both corpora cavernosa (Figure 38.21). The middle portion of the corpus spongiosum located in the

penile shaft is a uniform cylinder somewhat smaller than the corpus cavernosum. At its ends, it expands, the distal extremity forming the glans and the proximal forming the bulb. The urethra enters the corpus spongiosum 1 to 2 cm from the posterior extremity of the bulb by piercing the dorsal surface. The bulb is just superficial to the urogenital diaphragm, and its posterior portion projects backward towards the anus beyond the entrance of the urethra.

The three cylindrical structures forming the penile shaft are covered by a thin, delicate, and elastic skin. Beneath the dermis, there is a discontinuous smooth muscle layer called the dartos (Figure 38.21) embedded in a thin layer of connective tissue corresponding to the superficial fascia of the classical descriptions. Between the dartos and the albuginea, there is a highly elastic yellowish tubelike sheath encasing all three corpora cavernosa and spongiosum; this is designated as Buck's fascia (deep penile fascia of the classical descriptions) (Figures 38.20Aâ€“B, 38.21). A septum of fascia extends inward between the corpora cavernosa and the corpus spongiosum, providing separate tubular investments for these columns of erectile tissue and dividing the penis into its dorsal (corpora cavernosa) and ventral (corpus spongiosum)

portions as can be also seen via CT (computed tomography) or MRI (magnetic resonance imaging) (41). When using the terms *fascia* or *penile fascia* in this chapter, we are referring to the Buck's fascia since the superficial fascia is just part of the connective tissue surrounding the dartos.

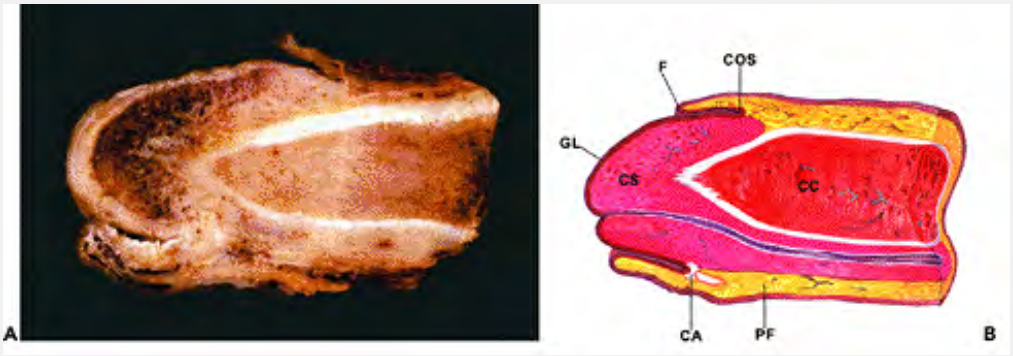

Figure 38.20 Gross picture (A) and diagram (B) of two longitudinal sections of a partial penectomy specimen with a small squamous cell carcinoma (CA) located in the coronal sulcus (COS). The albuginea (in white) surrounds the corpus cavernosum. The diagram from a parallel but more central section of the same specimen, illustrates the urethra running within the corpus spongiosum. (F, foreskin; GL, glans; PF, Buck's fascia; CS, corpus spongiosum; CC, corpus cavernosum).

Microscopic Features

Skin

The skin covering the penile shaft is rugged and elastic. It shows a thin epidermis composed of a few cell layers and minimal keratinization. The epidermal papillae are thin and deep. The basal layer is hyperpigmented. Hair follicles are present in the dermis of the penile body and are more numerous in the proximal body. Hair follicles and other adnexa can extend out to the cutaneous foreskin in some individuals. They are scanty and contain no piloerector muscle. There are a few sebaceous glands not related to hair follicles. Occasionally there are also poorly developed sweat glands.

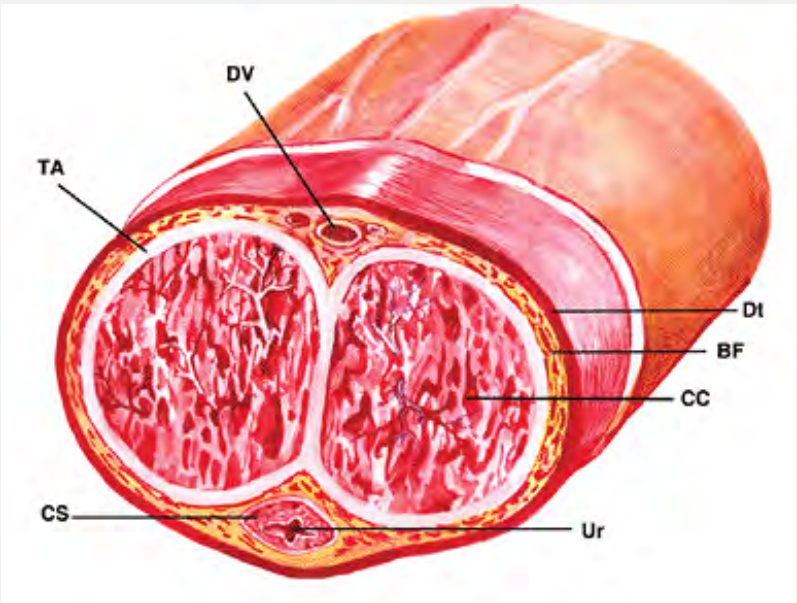

Figure 38.21 Cross section of the penis illustrating both corpora cavernosa (*CC*), each surrounded by the tunica albuginea (*TA*); they form the septum of the penis by their junction in the median plane. A shallow groove that marks their junction on the upper surfaces lodges the deep dorsal vein of the penis (*DV*). The dorsal arteries are located on both sides of the vein. Note the corpus spongiosum (*CS*) and central urethra (*Ur*) located in the concave space on the undersurface of both corpora cavernosa. (*BF*, Buck's fascia; *Dt*, dartos)

Dartos

The penile dartos is composed of a discontinuous layer of smooth muscle fibers, variably arranged in transverse and longitudinal branches. Some bundles end at the balanopreputial sulcus while others run farther to become the preputial dartos. The dartos is embedded in a loose fibrovascular connective tissue with numerous nerve bundles that correspond to the superficial penile fascia of the

classical anatomic description, and it is the skin equivalent of the penile hypodermis but without adipose tissue (1). The penile dartos, similar to scrotal smooth muscle fibers, produces a retraction of genital structures when the exterior temperature falls.

Buck's Fascia

The Buck's fascia is a fibroelastic continuous membrane that encases the corpora cavernosa and the corpus spongiosum. It is composed of loose connective tissue with numerous blood vessels and peripheral nerve bundles running within and beneath it. Vater-Pacini corpuscles are often seen in the penile fascia. The yellow color is related to the numerous elastic fibers and adipose tissue present in the fascia (Figure 38.22). The skin and dartos slide over this fascia. The Buck's fascia is a well-developed sheath of close up fibrovascular tissue that is very important from the

surgical pathology point of view since it is a frequent pathway of tumor invasion in penile cancer progression (42). This is most likely due to the loose quality of this tissue and the presence of numerous lymphovascular and neural structures. Some investigators point to Buck's fascia as the site of origin of Peyronie's disease (43).

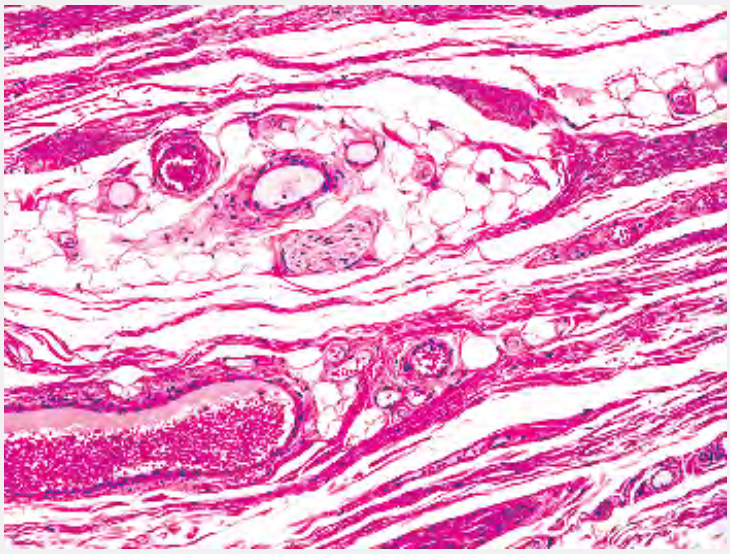

Figure 38.22 The Buck's fascia is composed of loose connective tissue with adipose cells and numerous blood vessels and peripheral nerve bundles.

Tunica Albuginea

The tunica albuginea is a thick sheath of partially hyalinized collagen fibers covering both the corpora cavernosa and corpus spongiosum. It is a poorly vascular structure, with only a few branches of circumflex vessels traversing through it, as demonstrated by factor VIII and CD31 immunostains. It is mainly composed of collagen fibers arranged in an outer longitudinal and an inner circular layer (14,15). The outer layer, which appears to determine the variation in the thickness and strength of the tunica, is absent in the ventral portion of the corpus spongiosum, transforming this portion of tunica into a vulnerable area to perforation. This anatomic aspect probably explains why most prostheses tend to extrude in this area (44). The tunica albuginea forms an incomplete fibrous septum separating both corpora cavernosa. The collagen fibers are wavy in the flaccid state and become straight during erection. The fibers are arranged in such a way so as to permit some elasticity necessary for erection. Elastic fibers are rare in the tunica albuginea of the corpora cavernosa. The tunica albuginea surrounding the corpus spongiosum is thinner and contains more elastic fibers than the one around the corpora cavernosa. In some unusual cases of Fournier's gangrene (45), an infection of the lower urinary tract can spread to the corpus spongiosum. Eventually the tunica albuginea may be penetrated; and, with involvement of Buck's fascia, the infection can rapidly spread to the dartos and directly extend to Colles' scrotal fascia and Scarpa's fascia of the anterior abdominal wall. The infection can spread to the buttocks, thigh, and ischiorectal space (46). The tunica albuginea is probably the real barrier to infiltration of squamous cell

carcinoma, contrary to the old concept that the Buck's fascia was the barrier to the spread of the cancer (47).

Corpora Cavernosa

The corpora cavernosa are the main anatomic structures used during erection. The substance of the corpora cavernosa consists of a three-dimensional network of trabeculae. These are composed of connective tissue and smooth muscle and are covered by endothelium, creating a network of interanastomosing vascular spaces between them. These spaces tend to be larger in the more central parts of each corpus cavernosum and smaller at their periphery (14,15). It seems that the smooth muscle bundles are the main component of the trabeculae in the corpora cavernosa (Figure 38.23). There is a highly structured criss-crossing of interconnected fibers and spaces that are tensed as the cylinder expands during erection (48,49). This creates an internal strength and rigidity that is far greater than that possible in a hollow tube filled to equivalent pressure. This specialized network appears to be necessary for erection (49). In the flaccid state, the vascular spaces are 1-mm slits that increase several times in diameter with erection. The interconnection between the venous sinuses is so wide that if a contrast is injected at one point, both corpora cavernosa can be immediately and completely visualized. The precise nature of vascular connections between the corpora cavernosa and corpus spongiosum remains controversial. Cavernospongious arterial anastomoses were described by different authors; however, their physiological role in erection remains unknown (50). These arterial anastomoses could explain

how drugs penetrate into the corpora cavernosa via the corpus spongiosum after transurethral diffusion (50,51). No arteriovenous shunts or venous connections were found between the corpora cavernosa and the corpus spongiosum (51).

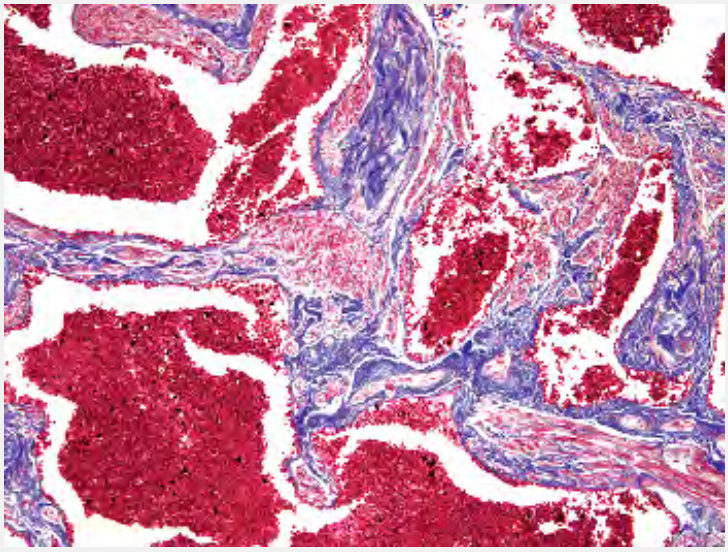

Figure 38.23 Corpus cavernosum. The interstitial fibrous connective tissue contains more smooth muscle fibers than in the corpus spongiosum (Masson's trichrome).

A progressive increase of collagen fibers and decrease of smooth muscle and elastic fiber may be seen in the cavernous trabeculae over the course of time (52).

Corpus Spongiosum

In the corpus spongiosum of the shaft, there are widely interconnected, branching vascular spaces separated by trabeculae. These vascular spaces of variable caliber are lined by endothelial cells and are surrounded by a thin layer of smooth muscle fibers. These fibers coalesce in various extraluminal parts of the vessels to form the subendothelial cushions or polsters. Toward the urethra, the lacunae become continuous with a mucosal plexus of veins; at the periphery, they communicate with the venous network of the albuginea (12). Compared to the corpus spongiosum of the shaft, the substance of the glans corpus spongiosum is made up of convolutions

of large veins rather than spaces separated by trabeculae (15).

The main differences between corpus spongiosum and corpora cavernosa from the penile shaft are that the blood spaces in the corpus spongiosum, unlike those of the corpora cavernosa, are the same size in peripheral and central areas and the trabeculae between them contain more elastic fibers, whereas smooth muscle bundles are relatively scarce when compared to the trabeculae of the corpora cavernosa (Figure 38.24) (14,15). However, there is variability and sometimes it can be difficult to distinguish corpus cavernosum from spongiosum by histology alone.

Distal Urethra

Anatomic Levels of the Urethra and Periurethral Tissues

- Urethral Epithelium
- Lamina Propria
- Corpus Spongiosum
- Tunica Albuginea
- Buck's Fascia

Anatomic Features

The distal (anterior) urethra consists of the bulbous and penile (pendulous) segments. The 3- to 4-cm bulbous urethra is located between the inferior margin of the urogenital diaphragm and the penoscrotal junction and courses in the root of the penis within the bulb of the corpus spongiosum. The penile urethra measures approximately 15 cm in length and extends from the penoscrotal junction to the external meatus; it is closely associated to the corpus

spongiosum that forms a protective cylindrical sheath around it (1,10,20). The distal 4 to 6 mm of the penile urethra corresponds to the fossa navicularis, a distal saccular expansion that is contiguous to the urethral meatus. The penile urethra has a more central position within the corpus spongiosum, in contrast to the more dorsally positioned bulbous urethra. The mucosa of the distal urethra has numerous recesses, called Morgagni's lacunae, which extend deeply into the mucin-secreting LittrÃ©'s glands that are present in the lateral walls of the bulbous and penile urethra. A stellate-shaped lumen can be noted in cross section of the penile urethra owing to these folds of epithelium and lamina propria (Figures 38.25Aâ€“B). From the surgical pathology point of view the urethra with surrounding periurethral tissues is an important margin to be carefully evaluated in partial penectomy specimens with penile carcinoma since is the most frequent positive resection margin, as was shown in a recent review of penectomies with carcinoma (42). The anatomical levels at the urethral margin of resection are: epithelium, lamina propria, periurethral corpus spongiosum, tunica albuginea, and Buck's fascia (Figure 38.25B).

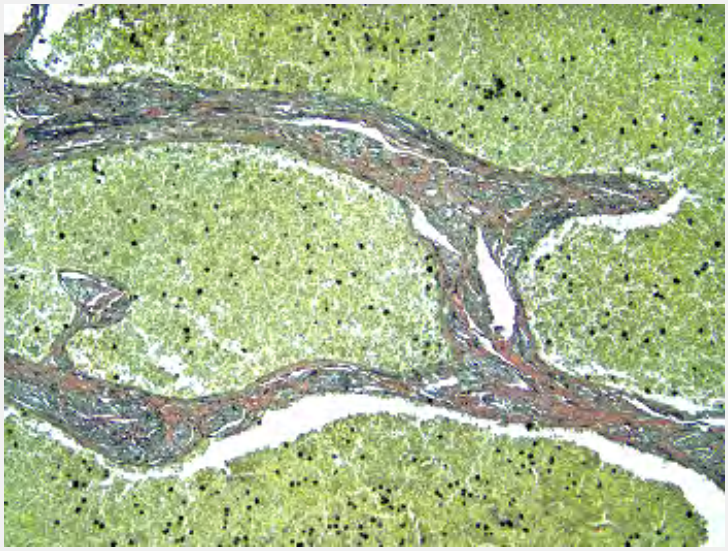

Figure 38.24 Corpus cavernosum. The interstitial fibrous

connective tissue contains fewer elastic fibers than does the corpus spongiosum (van Giesson elastic stain).

Microscopic and Immunohistochemical Features

Urethral Epithelium

There are two conflicting embryological explanations of the differentiation of the distal urethra: the ectodermal ingrowth theory (the distal urethra originates in the ectoderm, penetrating from glans to urethra) and the endodermal differentiation theory (distal urethra is formed by differentiation of endodermal tissues from urethra to

glans) (53,54). Independently of the embryogenesis, there are histological differences between the epithelium of the anterior urethra and the classical transitional urothelium of the posterior urethra and the urinary tract. The fossa navicularis is lined by nonkeratinizing squamous epithelium, and it is similar and continuous to the epithelium covering the glans penis. In the pendulous and bulbous urethra, the surface cell layer is columnar without the â€œumbrellaâ€• cells noted in bladder urothelium and prostatic urethra. In addition to the columnar cells, the epithelium of the anterior urethra is composed of 4 to 15 stratified layers of uniform small cells, usually categorized as stratified or pseudostratified columnar epithelium (Figure 38.26). The distinctive epithelium appears to be related to the squamous rather than to the transitional urothelium. This would explain the high frequency of squamous metaplasias, as well as the predominance of carcinomas of squamous type in the anterior urethra compared with a much higher frequency of transitional cell carcinomas in the prostatic urethra. The tumors in the membranous portion of the posterior urethra are more similar to

those of the bulbous urethra. Adenocarcinomas preferentially arise in the bulbomembranous urethra; however, squamous cell carcinomas are significantly more frequent than adenocarcinomas in these portions (10). The frequent finding of intraepithelial precancerous lesions in the penile urethras of patients with penile squamous cell carcinoma is noteworthy because it indicates that the urethra participates either as a mechanical pathway of penile cancer progression in a continuous manner or as an independent site of primary tumor growth in discontinuous lesions (54).

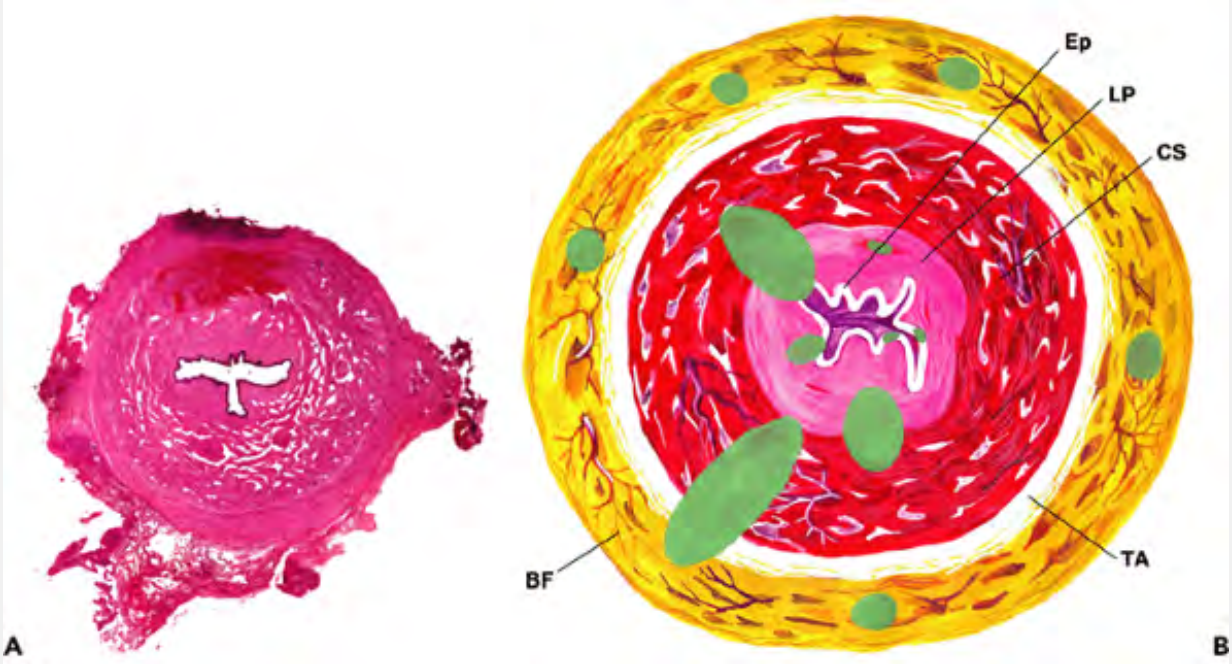

Figure 38.25 A. Cross section of the penile urethra and periurethral tissues. Note the stellate-shaped lumen at the center. B. Diagrammatic cross section of penile urethra and periurethral tissues. The anatomical levels at the urethral margin of resection are epithelium (*Ep*), lamina propria (*LP*), periurethral corpus spongiosum (*CS*), tunica albuginea (*TA*) and Buck's fascia (*BF*).

Immunohistochemical studies show that the penile urethral epithelium expresses CK7, 34Be12, and p63 but is negative for CK20. The CK7 immunostain is positive in the upper layers of the epithelium, including the columnar cells (Figure 38.27), in contrast to the expression of p63 and 34Be12 that is mostly seen in basal and parabasal cells but not in the superficial layer of columnar cells (Figures 38.28,38.29). Occasional chromogranin-positive cells may be found close to the basal membrane by immunohistochemical stains.

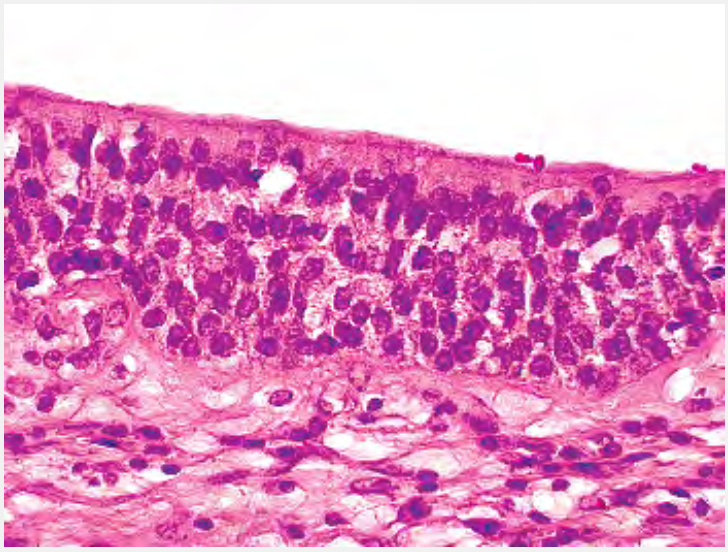

Figure 38.26 The epithelium of the anterior urethra is composed of columnar cells overlying 4 to 15 stratified layers of uniform small cells, usually categorized as stratified or pseudostratified columnar epithelium.

Figure 38.27 The expression of CK7 is seen in the upper layers of the urethral epithelium, including the columnar cells.

Urethral and Periurethral Glands

There are two different types of glands in the anterior urethra: the intra- or juxtaepithelial glands, with a dense eosinophilic cytoplasm and rounded basal nuclei, and the classical mucinous LittrÃ©'s glands, with clear mucinous cytoplasm and basally compressed nuclei resembling pyloric glands of the gastrointestinal tract (Figure 38.30). There are histologic transitions from the intra- or juxtaepithelial glands with dense eosinophilic cytoplasm to more mucinous cells.

The recesses of the urethra (Morgagni's lacunae) are lined by paraurethral mucinous LittrÃ©'s glands. LittrÃ©'s glands are tubuloacinous mucous structures located along the full length of the corpus spongiosum, in close relation with erectile tissue (Figure 38.31). LittrÃ©'s glands end in the urethra at the level of the intraepithelial lacunae. Some cysts have been described as

originating in the parameatal LittrÃ©'s glands (55). Inflammation of LittrÃ©'s glands can clinically simulate a tumor (56). Cohen et al. recognized the normal presence of prostatic epithelial cells in periurethral glands along the penile urethra. These â€œminor prostatic glandsâ€• may be entirely composed of prostatic cells or, more commonly, mixed prostatic and mucinous epithelium (57) (Figure 38.32). The same authors suggested that these glands may be partially responsible for the minimal but persistently elevated levels of serum PSA (prostate-specific antigen) in some cases of successful radical prostactectomy (57).

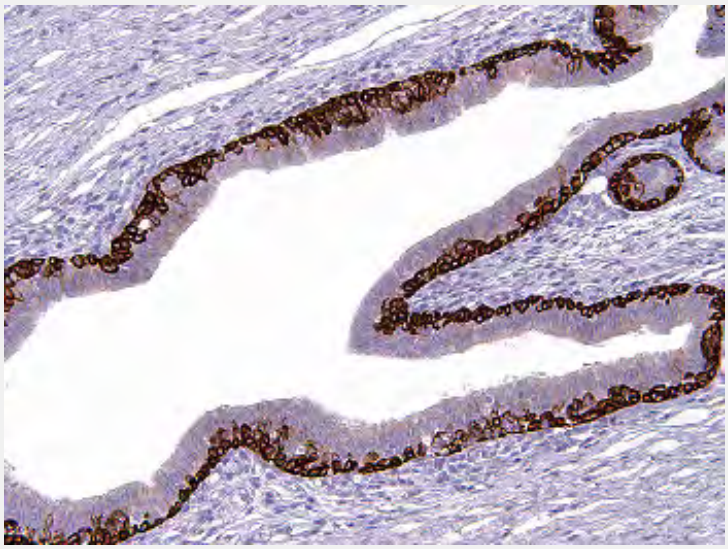

Figure 38.28 Urethral epithelium. Basal and parabasal cells express 34Be12. The superficial layers are negative.

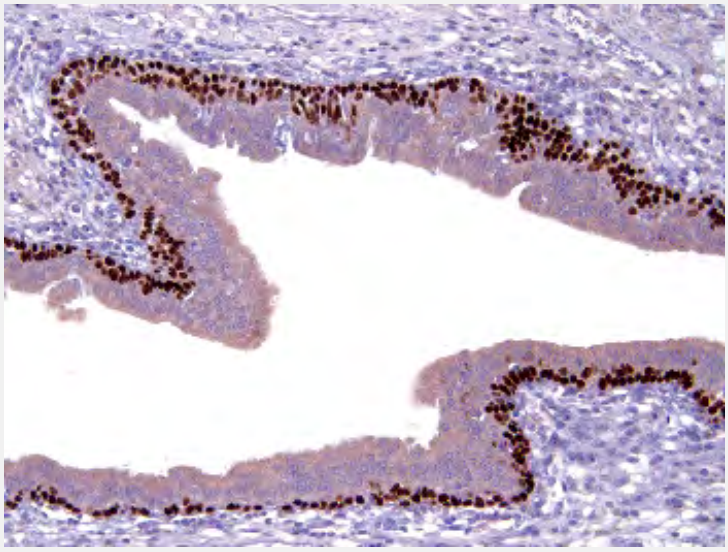

Figure 38.29 Urethral epithelium. In contrast to the superficial layers, basal and parabasal cells show p63 nuclear expression.

The bulbourethral or Cowper's, glands are two small structures deeply located at the level of the membranous (or bulbous) urethra where they terminate in two small ducts (58). They are mucous-acinous structures (Figure 38.33). The clear cells of these glands can be confused with prostatic carcinoma in a core needle biopsy specimen.

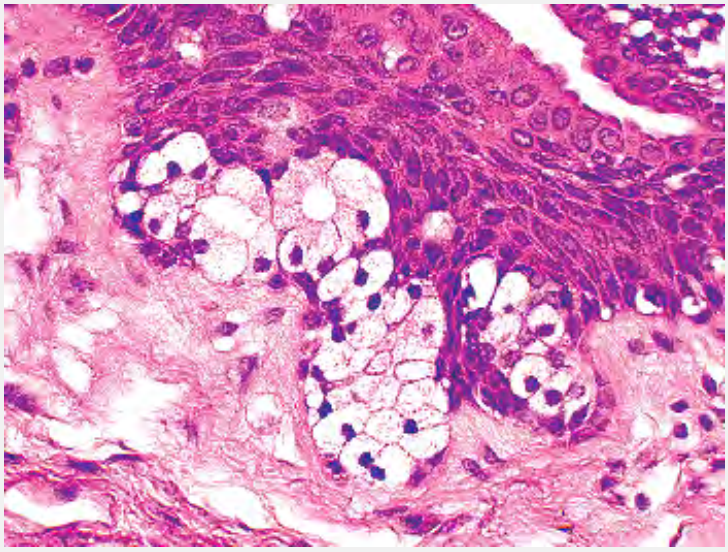

Figure 38.30 Penile urethra. A section illustrating intraepithelial mucinous glandular structures.

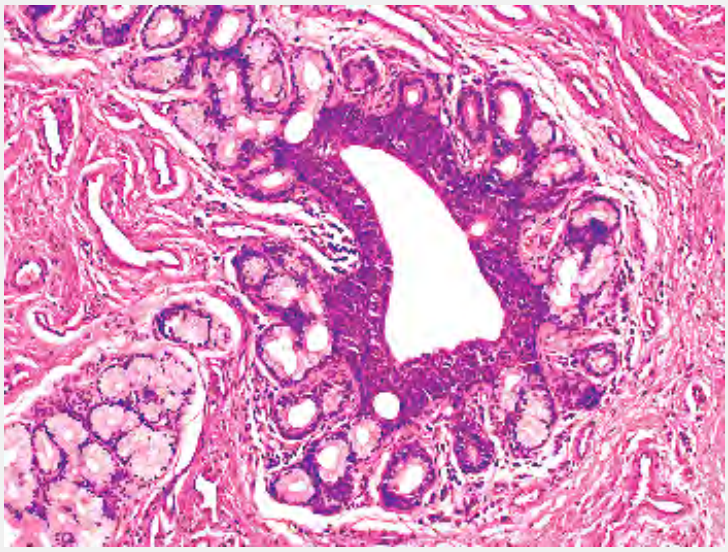

Figure 38.31 Penile urethra. Photomicrograph illustrating a cluster of tubular and acinar LittrÃ©'s mucous glands.

Lamina Propria

The urethral lamina propria is a thin layer of loose fibrous and elastic tissue. Genital corpuscles are identified in the lamina propria of the most distal portion of the urethra, which is lined by squamous epithelium; however, they are not seen in other portions of the penile urethra. We have seen cases of lichen sclerosus affecting the glans and extending into the lamina propria of the anterior urethra (54).

The corpus spongiosum, tunica albuginea, and Buck's fascia were discussed in a previous section.

Arteries

The arteries of the penis are branches of the internal pudenda, which is a branch of the iliac. There are two systems: the dorsal and the cavernous arteries. The dorsal arteries are located from the base of the penis near and on both sides of the dorsal profunda vein within Buck's fascia and in the superior groove formed by the corpora cavernosa (Figure 38.21). Small-caliber branches, or circumflex arteries, irrigate the corpora cavernosa and the periurethral corpus spongiosum. They also perforate the albuginea to reach the corpora. The terminal branches irrigate the glans, and collateral branches provide the skin nutrients. Cavernous arteries penetrate the corpora cavernosa at the site where the corpora join, and they run longitudinally near the central septum, which divides the corpora. From the cavernous arteries originate the vasa vasorum, small arteries that irrigate the erectile tissues. The helicine branches also

originate from the cavernous arteries, and they are responsible for filling the vascular spaces during the process of erection; their name derives from the fact that they are coiled and twisted along the trabeculae when the penis is flaccid (59,60). These arteries have thick muscular walls; and, in addition, many possess inner thickenings of longitudinal muscle fibers that bulge into their lumina. Many of the terminal branches of the helicine arteries open directly into the spaces of the erectile tissue.

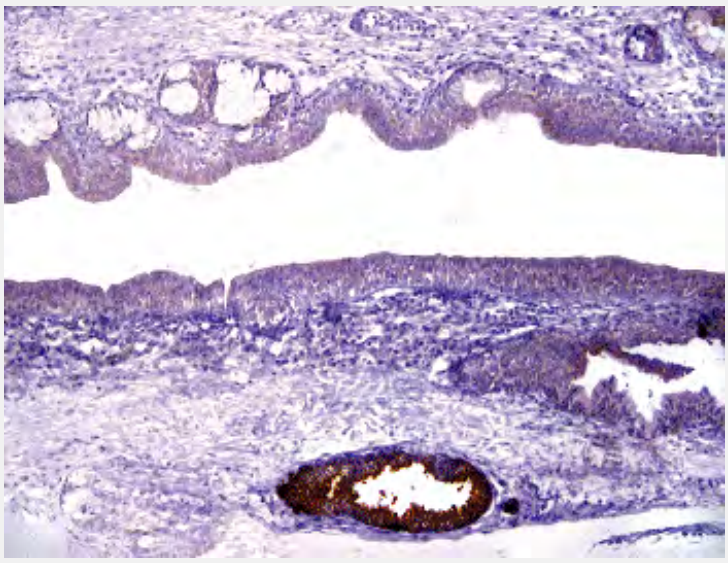

Figure 38.32 Some periurethral glands are positive with PSA (prostate-specific antigen) immunostain.

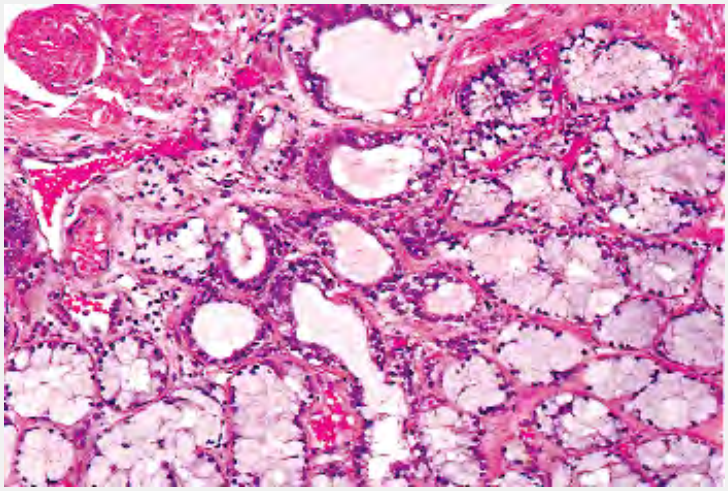

Figure 38.33 Bulbourethral (Cowper's) gland. Specimen was taken from autopsy and shows acinous-mucous structures, which are located deeply in the membranous urethra. (Courtesy Dr. Victor Reuter, Memorial Sloan-Kettering Cancer Center.)

Veins

The superficial veins are irregularly distributed and easily noted under the skin. They end in the superficial dorsal vein; this vascular structure runs straight from the foreskin to the base of the penis. It drains the foreskin venous blood and the skin and is located in the space between the dermis and Buck's fascia. The deeper venous system, for which the axis is the deep dorsal vein, runs along the superficial dorsal vein but in a plane separated by the Buck's fascia (Figure 38.21). The circumflex veins originate in the periurethral

corpus spongiosum and terminate in the deep dorsal vein system. Similarly, there are veins originating in the corpora cavernosa that, after forming a small plexus at the base of the penis, terminate in the internal pudendal vein. The cavernous venous system, unlike the venous drainage from the glans penis, delays venous drainage and in

doing so assists in maintaining erections (61).

Penile erection is a vascular phenomenon that results from trabecular smooth muscle relaxation, arterial dilation, and venous restriction. In further support of the concept of restriction of outflow is the observation that the walls of the circumflex veins are unusually muscular. In addition, these veins exhibit unique specializations of their lumina caller *polsters.* These are local accumulations of fibroblasts and smooth muscle cells beneath the endothelium that form conspicuous longitudinal thickenings or ridges that can be followed throughout hundreds of serial sections. These are believed to have a role in constricting the lumen and retarding venous outflow during erection (14). There are, however, controversies regarding the real presence and significance of the polsters in the penile veins and arteries, and some authors have proposed that they represent degenerative changes (62).

The deep dorsal vein of the penis has a connection with the vertebral veins, hence it is possible for metastases to make their way to the vertebrae or even to the skull and brain without going through the heart and lungs. Pyogenic organisms may be transported by the same route (1).

Lymphatics

The lymphatics of the foreskin spring from a network that covers its internal and external surfaces; they arise from the lateral aspect and converge dorsally with the skin of the shaft lymphatics to form 4 to 10 vessels that run toward the pubis, where they diverge to drain into the right and left superficial inguinal lymph nodes. The lymphatics draining the glands form a rich network that, beginning in the lamina propia, course toward the frenulum, where they coalesce with two or three trunks from the distal urethra to form several collecting trunks following the coronal sulcus. A collar of lymphatics entirely surrounds the corona, forming two or three trunks that run along the dorsal surface of the penis deep to the fascia and

accompanied by the deep dorsal vein. At the presymphyseal region they form a rich anastomosing plexus draining into superficial and deep inguinal lymph nodes (63). The male urethra has a dense plexus in the muscosa. The lymphatic capillaries are especially abundant around the fossa navicularis (1). The lymphatics of the urethra, corpus spongiosum, and corpora cavernosa run toward the ventral surface of the body of the penis, reaching the raphe and the dorsum, where they run with the dorsal vein and end in the superficial and deep inguinal lymph nodes.

Nerves

The nerves originate in the sacral and lumbar plexuses. Peripheral nerves run along the arteries. Dorsal nerves are located external to the arteries, giving circumflex branches to the corpora cavernosa (64,65). The terminal branches end in the glans and foreskin. The dorsal nerve of the penis, the principal somatosensory nerve innervating the penis, consists of two populations of axons, one to innervate the penile shaft and urethra and the other to innervate the glans. Urethral innervation by the dorsal nerve of the penis supports the view that urethral afferent impulses are a component of reflex ejaculatory activity. The pattern of glanular innervation by the dorsal nerve of the penis identifies the glans as a sensory end organ for sexual reflexes. The undulating character of the dorsal nerve of the penis is a mechanism by which the nerve can accommodate to significant changes in penile length with erection (64). The dorsal nerve of the penis supplies the glans in most men, but branches of the perineal nerve can supply the ventral penis, frenulum, and periurethral area in some men.

Vulva

Edward J. Wilkinson

Nancy S. Hardt

Clinical Perspective

Vulvar symptoms are a common cause of clinical visits to gynecologists and family practitioners. Complaints may include pruritus, burning, external dyspareunia, and a visible or palpable mass (1,2). The majority of sexually transmitted infections, as well as many granulomatous and dermatological diseases, may involve the vulva (2,3,4). Graft-versus-host disease (5) and contact dermatitis (6,7) may create symptoms requiring evaluation of the vulva and vagina. The vulva (pudendum femininum) is also a crucial area for detailed examination in cases of reported rape, sexual abuse, or female circumcision (8). Ambiguous genitalia and genital anomalies challenge the clinician and demand critical examination of the patient and the external genitalia. Clitoral enlargement in the newborn resulting from adrenal genital syndrome, maternal exposure to exogenous androgens, maldevelopment of the clitoris, benign tumors, and other conditions, such as the Lawrence-Seip syndrome (3,9,10), may result in ambiguous-appearing external genitalia. Clitoromegaly may occur in adulthood due to malignancy or endocrinopathy (11).

Surgical approaches to vulvar diseases are evolving as a result of

better understanding of vulvar anatomy and sexual function. Clitoral specimens are submitted less frequently in cases of infant genital ambiguity now that follow-up studies have indicated that permanent loss of function and sensation may result (12,13,14,15,16). In radical surgery for carcinoma of the vulva, the clitoris may be surgically spared if clinical examination does not indicate tumor involvement of that structure (17). The techniques for sentinel node evaluation used in other cancers are now applied to carcinomas of the vulva, permitting removal of less normal tissue from lymph node drainage fields (18,19,20).

Cytologic evaluation of the vulva may complement biopsy in special cases such as extramammary Paget's disease (21) and distinguishing disorders that may clinically resemble Paget's disease (22).

Special Techniques in Clinical Evaluation

Direct examination of the vulva requires adequate illumination and is enhanced by the use of a ring light or magnifying glass (23). The use of higher magnification, using a colposcope, enhances the identification of small condyloma acuminatum, vestibular papillae, vulvar intraepithelial neoplasia and superficial lacerations, microulcerations, and contusions after sexual assault (24). In cases in which

condyloma acuminatum or vulvar intraepithelial neoplasia is suspected, the use of 3% acetic acid (white vinegar) is of value. Gauze sponges soaked in acetic acid are applied for approximately five minutes, followed by prompt examination. The principle of this technique is that abnormal epithelium, especially condyloma acuminatum and vulvar intraepithelial neoplasia, becomes white immediately after exposure to acetic acid. This is related to poorly understood differences between normal epithelium and human papillomavirusâ€“associated lesions. The color change to white after application of the dilute acetic acid is referred to as aceto-whitening,

and the epithelium so changed is referred to as aceto-white epithelium. This procedure has gained wide acceptance in the evaluation of the cervical transformation zone during colposcopic examination to enhance identification of cervical intraepithelial neoplasia and carcinoma. However, its use on the vulva has two serious limitations. First, when ulcers or fissures are present on the vulva, the application of 3% acetic acid may be associated with pain and thus is unacceptable to the patient. Second, the vulvar vestibular epithelium is normally somewhat aceto-white. The inexperienced clinician may misinterpret this aceto-whitening as abnormal or as condyloma acuminatum. A biopsy is then performed of the vestibular epithelium and submitted as condyloma acuminatum. The vestibular epithelium in women of reproductive age is normally glycogenated (see section on Vulvar Vestibule) and can be misinterpreted by the unwary pathologist as koilocytosis suggestive of condyloma acuminatum, resulting in both improper diagnosis and improper therapy for the patient. Inflammation within the vestibule may be associated with epithelial spongiosis, which also may be confused with koilocytosis.

The use of 1% toluidine blue O also has been used to assist in the recognition of areas requiring biopsy when invasive carcinoma is suspected (23). A solution of 1% toluidine blue O is applied to the areas in question, which then are rinsed with 1% acetic acid. Areas with ulceration, parakeratosis, and carcinomas without a keratinized surface retain the blue stain. In principle, toluidine blue O is a DNA stain, and as such it is retained where cell nuclei are present (3,23). This test has limited usefulness in that false-positive staining patterns occur, usually due to benign superficial ulceration or fissures. The test may be falsely negative when the carcinoma or intraepithelial neoplasm has a keratinized surface. For these reasons, the test is no longer commonly used.

In addition to direct visualization techniques, imaging studies are increasingly applied in the vulvar assessment of female sexual response and have increased our understanding of the three-

dimensional anatomy of that region. These include duplex Doppler ultrasound (25) and magnetic resonance imaging (26,27,28)

From the pathologist's perspective, the majority of vulvar specimens that are examined are either diagnostic biopsies, excisional biopsies, or partial superficial or deep, or total superficial or deep vulvectomy specimens submitted as treatment for vulvar intraepithelial neoplasia, Paget's disease, carcinoma, melanoma, and other diseases (3). An understanding of the normal histology of the vulva enhances interpretive skills and assists in arriving at an appropriate diagnosis.

Anatomy

The female external genitalia can be defined as that portion of the female anatomy external to the hymen, extending anteriorly to include the mons pubis, posteriorly to the anus, and laterally to the inguinalâ€“gluteal folds. Included are the mons pubis, clitoris, labia minora, labia majora, vulvar vestibule and vestibulovaginal bulbs, urethral meatus, hymen, Bartholin's and Skene's glands and ducts, and vaginal introitus (Figure 39.1). The anterior investment of the clitoris includes the prepuce, which represents the anterior fusion of the labia minora and overlays the clitoris anteriorly, and the frenulum, which passes posteriorly and ends in its attachment to the flattened posterior aspect of the clitoris. Posteriorly, the labia minora end in the fourchette, or frenulum of the labia. The labia majora lie lateral to the intralabial sulcus and medial to the inguinal-gluteal fold. Anteriorly, the hair-bearing lateral aspects of the labia majora blend with the mons pubis, and posteriorly, the labia majora end in the perineal body. The hair follicles of the labia majora are absent in its medial portion; however, the sebaceous gland elements are retained medial and posterior to the labia minora at the junction with the vulvar vestibule at Hart's line (29,30) (Figure 39.2).

These sebaceous gland elements open directly to the epithelial surface in this portion of the vulva and can be observed as small,

slightly pale to yellow elevations of the epithelium, known as Fordyce's spots.

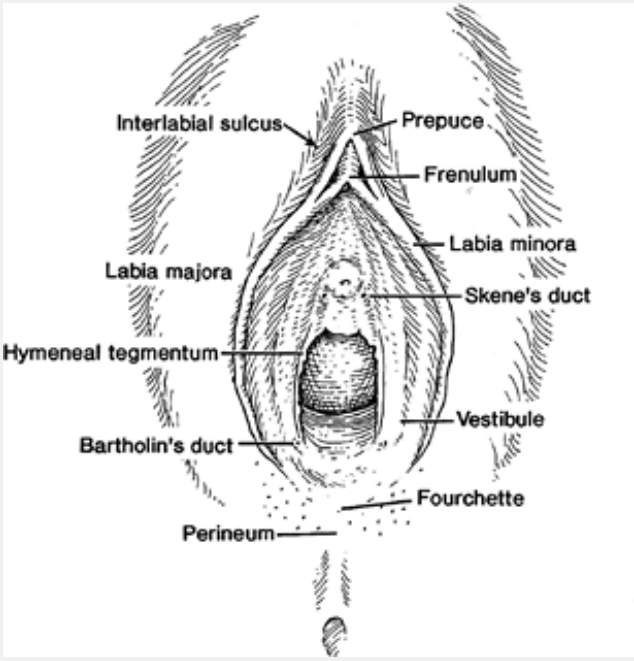

Figure 39.1 Topography of the vulva.

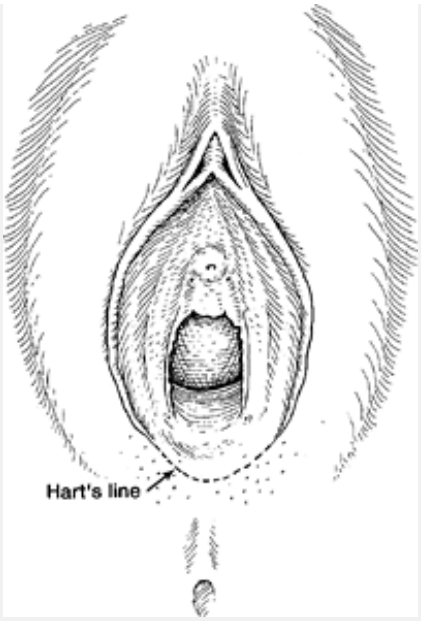

Figure 39.2 The vulvar vestibule and the position of Hart's line. Hart's line can be found on the medial aspect of the labia majora, extending in a curvilinear manner from the most inferior posterior portion of the labia minora to the vaginal fourchette.

Normal vulvar epithelium varies in thickness from 0.27 Â± 0.14 mm. When involved by vulvar intraepithelial neoplasia, the thickness of the epithelium with vulvar intraepithelial neoplasia (VIN) is reported from 0.52 Â± 0.23 mm (31). The vulvar epithelium, especially that of the lateral labia minora, labia majora, and perineal body, contains melanocytes that are distributed among the basal cells of the epithelium in a ratio from 1:5 to 1:10 basal keratinocytes (32). Increased pigmentation of these areas during pregnancy relate to increased melanin production secondary to the effects of gestational hormones.

Langerhans cells are relatively abundant in the vulvar epithelium, where they are more prevalent than within the vagina or cervix. They are present predominantly in the suprabasal layers of vulvar epithelium, with a median number of 18.7 per 100 basal squamous

cells (33). They are present in keratinized and nonkeratinized epithelium, as well as within skin appendages. These dendritic cells are bone marrowâ€“derived and can express HLA-DR antigens and Fc and C3 receptors and are capable of activating T lymphocytes as an afferent component of the immune response of the vulvar epithelium (34). Langerhans cells are also thought to be associated with control of keratinocyte maturation (35). The topical T-lymphocyte inhibitor, pimecrolimus, has recently been used to effectively treat vulvar lichen sclerosus in a 10-year-old girl. Lichen sclerosus is a dermatosis that is considered to be T-lymphocyte mediated (36).

Merkel cells are neuroendocrine cells that are present in vulvar epithelium, as well as most other skin sites. These cells are involved in paracrine regulation of skin function (37). Merkel cell tumors of the vulva have been reported (38).

Lymphocytes are also commonly found in the dermis and submucosal areas of the vulva in small numbers and are located primarily in a perivascular area within the superficial tissues. Intraepithelial lymphocytes are infrequently seen in normal vulvar epithelium (33).

Vulvar Vestibule

The vulvar vestibule is defined as that portion of the vulva that extends from the exterior surface of the hymen to the frenulum of the clitoris anteriorly, the fourchette posteriorly, anterolaterally to the labia minora, and posterolaterally to Hart's line, on the medial aspects of the labia majora (Figures 39.1,39.2). The vestibular fossa (fossa navicularis) is that posterior portion of the vestibule, from the hymen to the fourchette, that is somewhat concave as compared with the remainder of the vestibule. Unlike the remainder of the vulvar epithelium, which is of ectodermal origin, the epithelium of the vulvar vestibule is of endodermal origin. One exception is the portion of the vulvar vestibular epithelium anterior to the urethra, which some think is of ectodermal origin (39). The vulvar vestibule is predominantly nonkeratinized stratified squamous epithelium, which

peripherally blends with the thinly keratinized squamous epithelium of the labia minora, the medial labia majora at Hart's line, the prepuce, and the fourchette. Although the vestibular epithelium has an embryonic origin similar to that of the distal urethra of the male, the epithelium is not of a typical transitional type with associated surface umbrella cells. Rather, it is a stratified squamous epithelium that is rich in glycogen in women of reproductive age, similar to the mucosa of the vagina and ectocervix (Figure 39.3).

Both the vaginal opening and the urethral orifice are within the vestibule. Also within the vulvar vestibule are gland openings from both the major and minor vestibular glands, as well as the paired opening of the periurethral Skene's ducts. Skene's ducts are the homologues of the male prostate gland. The major vestibular gland, or Bartholin's gland (glandula vestibularis major), is of ectodermal origin and consists of bilateral tubuloalveolar glands located beneath the hymen, labia minora, and labia majora in the posteriolateral area of the vulva. Bartholin's gland corresponds to the male bulbourethral glands, or Cowper's glands. The epithelial cells of Bartholin's gland acini consist of mucus-secreting columnar cells (40,41) (Figure 39.4). The secretion of these acini empty into Bartholin's duct, which measures approximately 2.5 cm in length and enters the vestibule immediately exterior (distal) and adjacent to the hymen in a posterolateral location. Bartholin's duct is lined by transitional epithelium

that is adjacent to columnar epithelium as it arises from the gland (Figure 39.5) to adjoin the nonkeratinized stratified squamous epithelium of the vulvar vestibule in the distal end of the duct (41) (Figure 39.6). Within the Bartholin duct epithelium, argentaffin cells also can be identified, predominantly concentrated within the transitional ductal epithelial cell area and absent in the secretory gland area (42). Cysts that arise in the area of Bartholin's gland are primarily a result of dilation of Bartholin's duct (3,43).

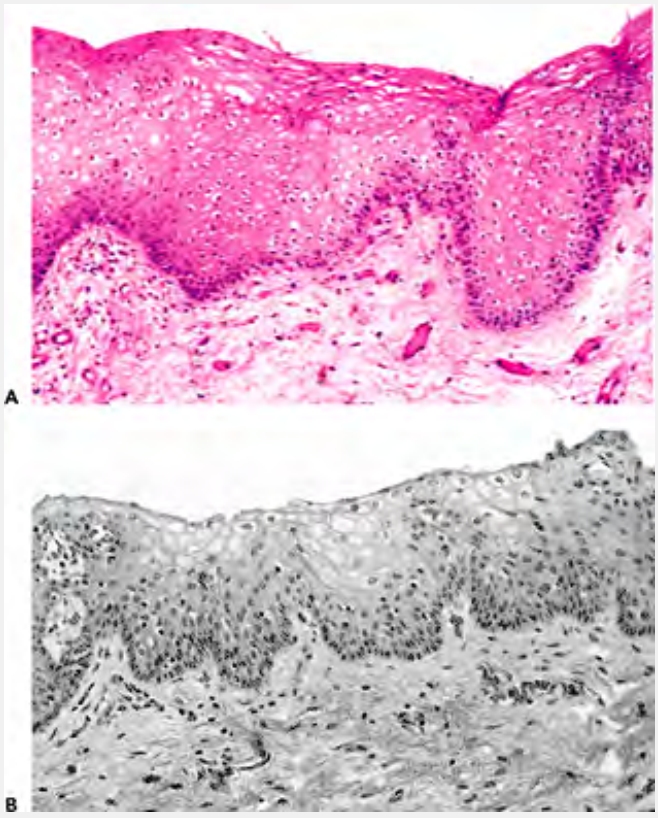

Figure 39.3 A. Vulvar vestibule with adjacent prominent vascular submucosa. Superficial thin-walled vessels are prominent and are found within the delicate fibrous stroma. A few lymphocytes are seen scattered in the superficial submucosa. B. Epithelium of the vulvar vestibule of a 27-year-old woman. Note that the epithelium is stratified squamous and that the superficial cells have cytoplasmic clearing, reflecting the glycogen-rich epithelium.

Figure 39.4 Bartholin's gland acini are lined with a columnar epithelium. The adjacent branching Bartholin's duct is present adjacent to the gland.

The periurethral, or Skene's, glands also enter the vulvar vestibule as paired gland openings found immediately adjacent to and posterolateral to the urethra. These glands, with their adjacent ducts, are generally not more than 1.5 cm in length. These periurethral glands are analogous to the male prostate gland and are lined with a pseudostratified mucus-secreting columnar epithelium. The ducts of Skene's glands are lined with transitional-type epithelium that joins with the stratified squamous epithelium of the vestibule at the gland orifices. A cyst of Skene's duct may result from obstruction of the duct.

The minor vestibular glands (glandulae vestibulares minores) consist of simple tubular glands that enter directly to

the mucosal surface of the vestibule (Figure 39.7). They are analogous to the glands of LittrÃ© of the male urethra (39). Minor vestibular glands are small and shallow, with a maximum depth of 2.27 mm (44). These glands are lined with a mucus-secreting

columnar epithelium that merges with the stratified squamous epithelium of the vestibule (44,45,46) identified minor vestibular glands within the vestibule in 47% of women studied in an autopsy-related series. We found minor vestibular glands in vulvar vestibulectomy specimens for vestibulitis in 66% of our cases (44). In the women with identifiable minor vestibular glands, Robboy et al. identified minor vestibular glands within the vestibule in 42% of women studied in an autopsy-related series (46). When present, the number ranged from 1 to over 100, with the majority having 2 to 10 identifiable minor vestibular glands. Although these glands were found to be distributed throughout the vestibule, they were found in greater numbers in the posterior vestibule,

just anterior to the fourchette. Minor vestibular glands have been described as having ducts composed of transitional epithelium; however, this epithelium is essentially the same epithelium and borders that of the adjacent vulvar vestibule, which is stratified squamous epithelium without surface umbrella cells. Minor vestibular glands may undergo squamous metaplasia, similar to that seen within the endocervix, where the mucus-secreting epithelial cells lining the glandular epithelium are replaced by stratified squamous epithelium (Figure 39.8). This metaplastic epithelium may completely replace the glandular epithelium, resulting in the formation of a vestibular cleft (44) (Figure 39.9). Obstruction of a minor vestibular gland associated with this metaplastic process may result in accumulation of mucous secretion within the simple tubular gland, leading to the formation of a vulvar mucous cyst (44,45,46). Vestibular adenomas have been described arising from these minor vestibular glands (47,48). Severe external dyspareunia, including vulvodynia, may be associated with inflammation of the vulvar vestibule, a poorly understood condition referred to as vulvar vestibulitis (1,44,49).

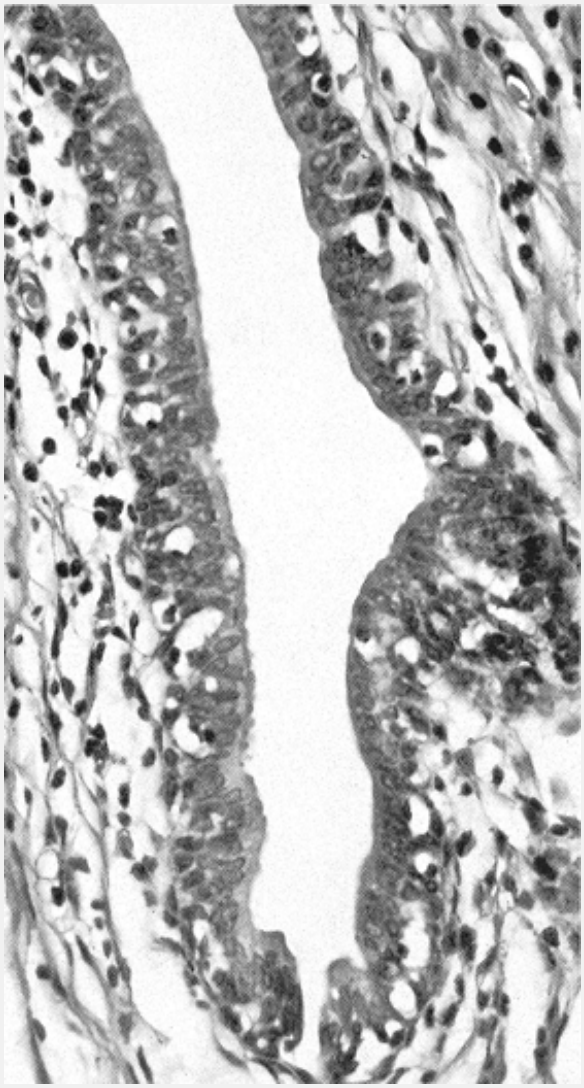

Figure 39.5 Bartholin's duct near the gland. Bartholin's duct has a transitional-like epithelial lining, with columnar cells near the surface, similar to the columnar cells lining the gland acini.

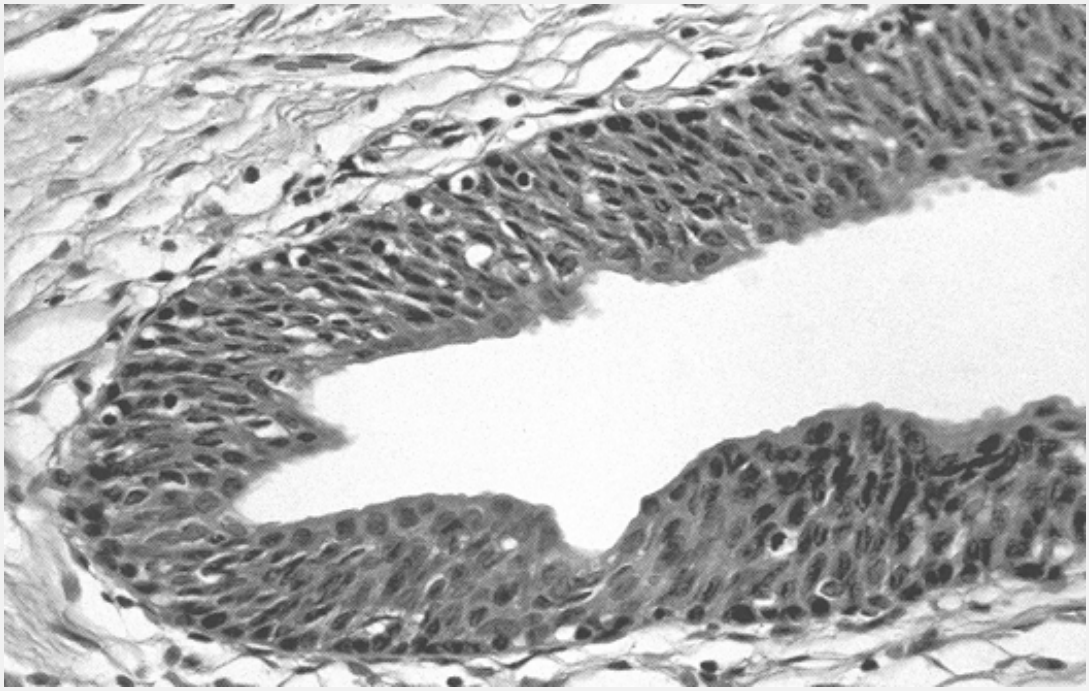

Figure 39.6 Bartholin's duct near its exit to the vulvar vestibule. At this location the duct is lined by stratified squamous epithelium, without surface columnar cells.

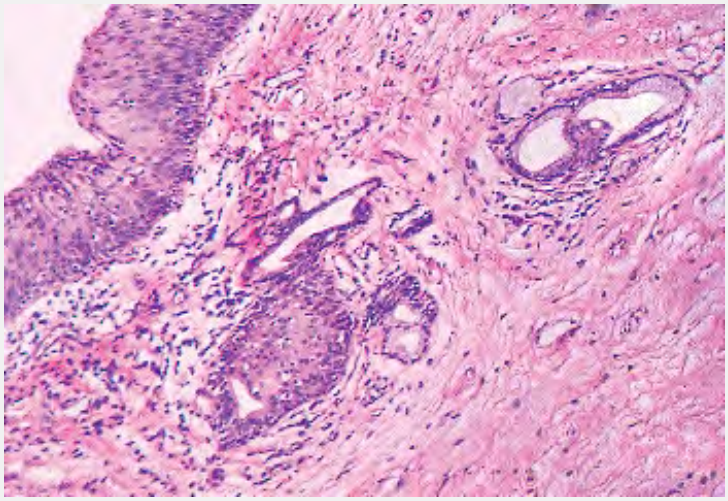

Figure 39.7 Minor vestibular glands of the vulvar vestibule. The vulvar vestibular glands are simple glands with a mucus-secreting columnar epithelial lining. Near their exit at the vestibular surface the glands have a stratified squamous epithelium. Vascular vestibular stroma surrounds the superficial gland elements.

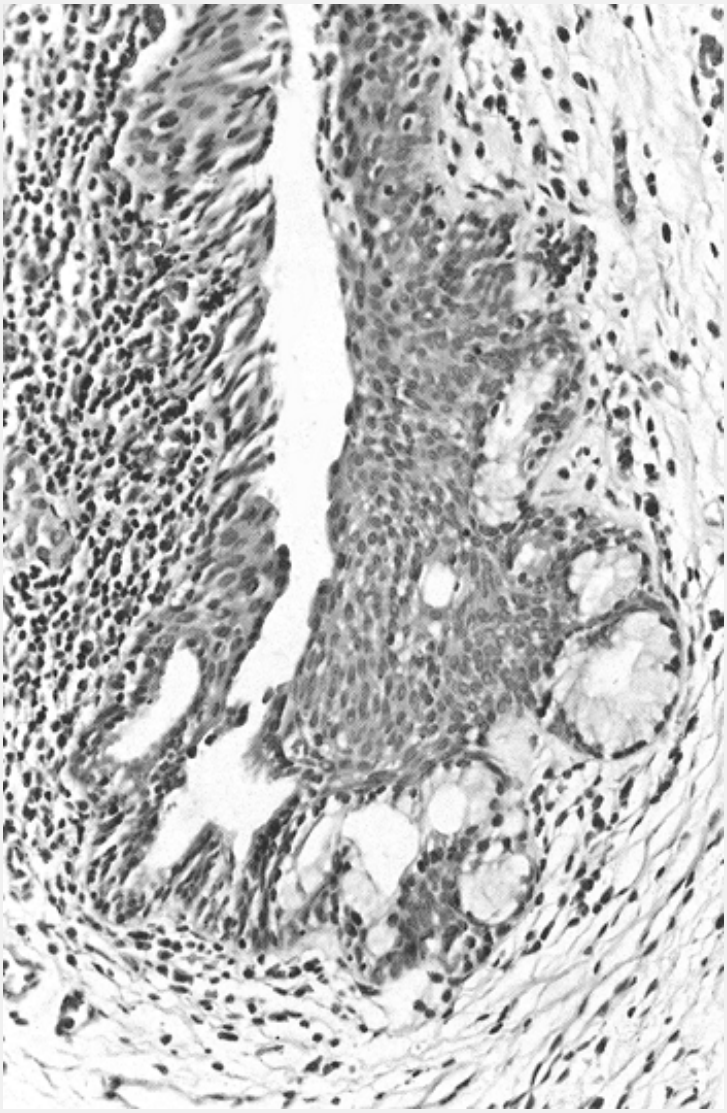

Figure 39.8 Vestibular gland with squamous metaplasia near the

vestibular surface. Moderate chronic inflammation, consisting predominantly of lymphocytes, is seen adjacent to the gland and is consistent with vulvar vestibulitis.

Urethral Orifice (Meatus Urinarius)

The urethra has a transitional epithelial lining that merges with the stratified squamous epithelium at the urethral orifice. The periurethral glands of Huffman enter into the urethra throughout most of its length (50). Obstruction or inflammation of these periurethral glands may result in a urethral diverticulum or periurethral abscess. Partial prolapse of the urethra results in a polypoid mass, often referred to as a urethral caruncle. The mucosa may become ulcerated, and the underlying stroma may become inflamed with vascular dilation and engorgement; however, it otherwise retains the normal histology of the urethra.

Hymen

The hymen marks the distalmost extent of the vagina and the most proximal boundary of the vulvar vestibule. The hymen may be imperforate, round, annular, septate, cribriform, or porous (2). On the vaginal surface, the hymen has a nonkeratinized stratified squamous epithelium, which is glycogenated upon estrogen exposure, as seen in women of reproductive age, newborn female infants, and postmenopausal women receiving estrogen therapy. On the vulvar surface the vestibular epithelium appears similar to the vaginal epithelium in women of reproductive age (Figures 39.3, 39.10). The hymenal ring contains some Merkel tactile disks for touch and moderate numbers of free nerve endings, which are pain receptors; the hymenal ring lacks other receptors that are present in the labia majora (51,52).

In rare cases of imperforate hymen, the hymen lacks its normal

opening. This leads to accumulation of menstrual exodus in the vagina, resulting in vaginal distension (1) with menstrual products, a condition referred to as hematocolpos. Coitus, or the routine use of intravaginal tampons, results in tears in the hymen, which result in small soft hymenal tags referred to as carunculae hymenales, or carunculae myrtiformes (34,53). On the external hymen and on the

vulvar vestibule, small papillae may be identified, which are referred to as vestibular papillae. Multiple papillae are seen in the condition known as vestibular papillomatosis (54). Such papillae within the vestibule are generally considered a variant of normal anatomy and are infrequently associated with human papillomavirus. Solitary or isolated asymptomatic papillae on the hymen usually represent a normal anatomic variant (55) (Figure 39.11).

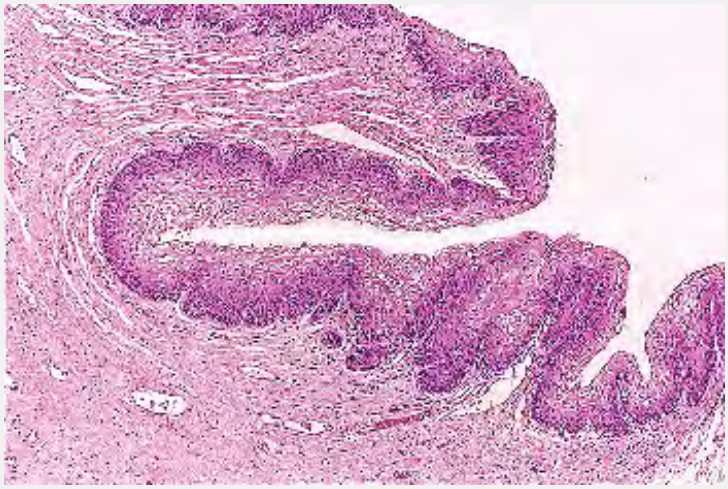

Figure 39.9 Vulvar vestibular cleft. The vulvar vestibular cleft has a stratified squamous epithelial lining, similar to the vulvar vestibule. These clefts appear to arise as a result of squamous metaplasia of vestibular glands.

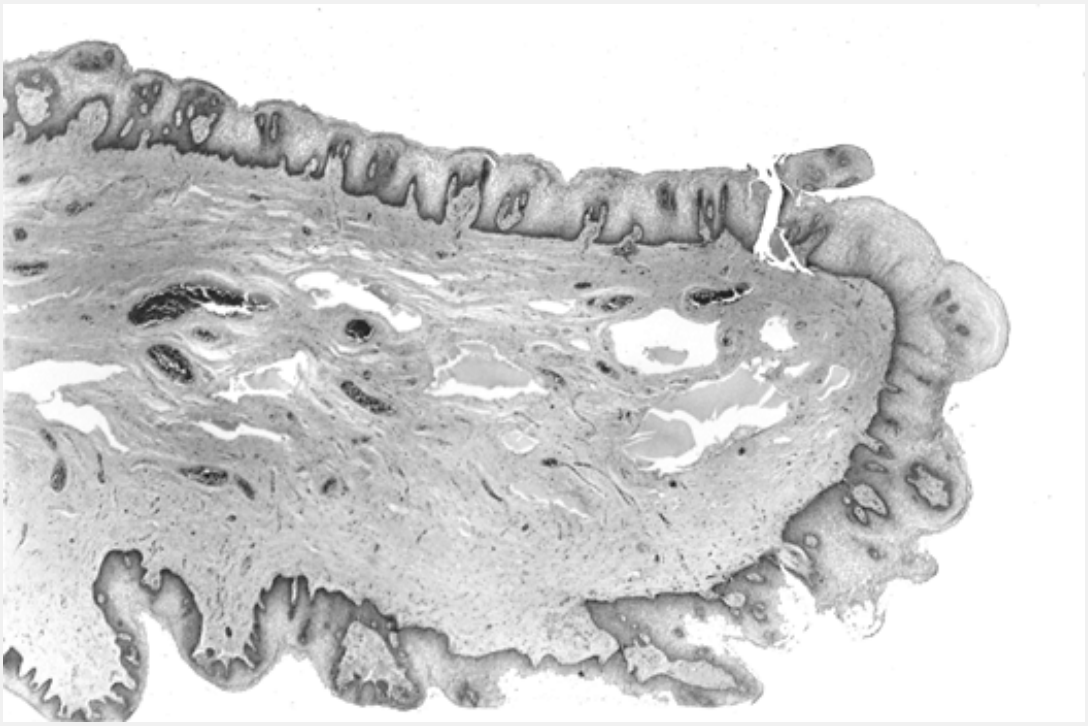

Figure 39.10 Cross section of the hymen of a 26-year-old woman. The epithelium of the vaginal (*upper*) and vestibular (*lower*) surfaces of the hymen is a stratified squamous epithelium, which is nonkeratinized and glycogen rich. The fibrovascular component of the hymen supports the epithelium.

Clitoris

The clitoris is the descendant of the embryonic phallus, homologous to the corpus cavernosum of the male penis. It is immediately anterior to the frenulum, at the junction of the labia minora, and it is enfolded by the prepuce. The clitoris measures approximately 2 cm in its long axis and consists of two crura and a glans clitoridis. The crura are composed of erectile tissue similar to that in the corpora cavernosa of the male (3,4). They consist of cavernous veins surrounded by longitudinal smooth muscle, as well as small centrally

placed muscular arteries, enveloped by the tunica albuginea. The tunica albuginea is composed of wavy collagen fibers and straight elastic fibers. Peripheral to the tunica albuginea is the loose connective tissue that supports the nerves and receptors of this area. The glans clitoridis is covered with squamous mucosa without glands, rete, or papillae (40,52,56). The cavernous tissue of the corpus spongiosum of the male does not have its counterpart in the clitoris; it is found instead in the vascular erectile tissue of the labia minora (Figure 39.12). The clitoris contains nerve endings in lesser amount than seen in the labia majora, although Pacinian corpuscles are abundant. Peritrichous nerve endings for touch reception are absent. The other receptors are present, although their distribution is highly variable (52). Other touch receptors, namely, Meissner's corpuscles and Merkel tactile disks, are present in reduced numbers in the clitoris, as compared with the labia majora or mons pubis. Pacinian corpuscles, for pressure reception, are present in large numbers (52). The free nerve endings for pain reception are found throughout the vulva and in relatively high concentrations in the clitoris, labia majora, and mons pubis (52). Ruffini's and Dogiel-Krause corpuscles, which may be associated with temperature or sexual sensation, are found throughout the vulva but not in the hymenal ring (52).

Figure 39.11 Vulvar vestibular papillae. The papillae have a stratified squamous epithelial surface and fibrovascular stalks.

Labia Minora

The bilateral labia minora derive from the embryonic medial folds (genital folds) and lie lateral to the vulvar vestibule and medial to the labia majora, bounded by the

intralabial sulcus. The epithelium of the labia minora is of ectodermal origin. The labia minora have their male embryologic counterpart in the penile corpus spongiosum (34). The minora measure approximately 5 cm in length and 0.5 cm in thickness; however, their length can vary considerably. The epithelium of the labia minora is of

the stratified squamous type; it is not keratinized on its vestibular surface but has a thin keratin layer lateral from Hart's line.

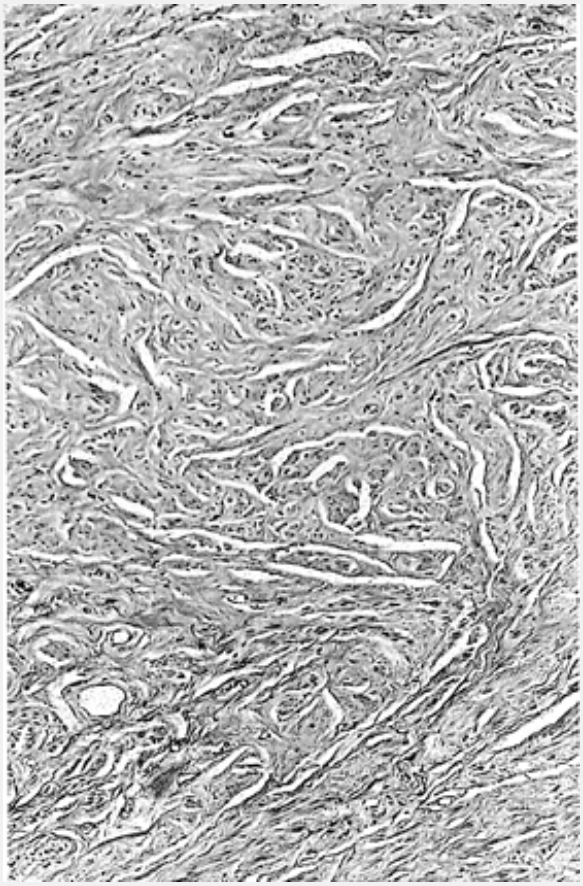

Figure 39.12 Erectile tissue of the labia minora.

Most of the epithelium of the labia minora does not contain skin appendages; however, in some individuals, the lateral labia minora may contain sweat and/or sebaceous glands (56). The epithelium of the labia minora may be somewhat pigmented, especially in lateral and posterior areas (Figure 39.13). Beneath the epithelium is highly vascular, loose connective tissue that is rich in elastic fibers.
Posterior and deep to the labia minora are the vestibular bulbs (bulbi vestibuli), which are composed of erectile tissue and are invested by

the bulbocavernous muscles. The labia minora contain erectile tissue and thus are highly vascular, yet they lack adipose tissue. The vessels and erectile tissue are supported by a rich elastic fiber component. The nerve endings within the labia majora are similar to those found within the clitoris, yet Meissner's corpuscles and Merkel tactile disks occur in larger numbers than usually identified within the clitoris (52).

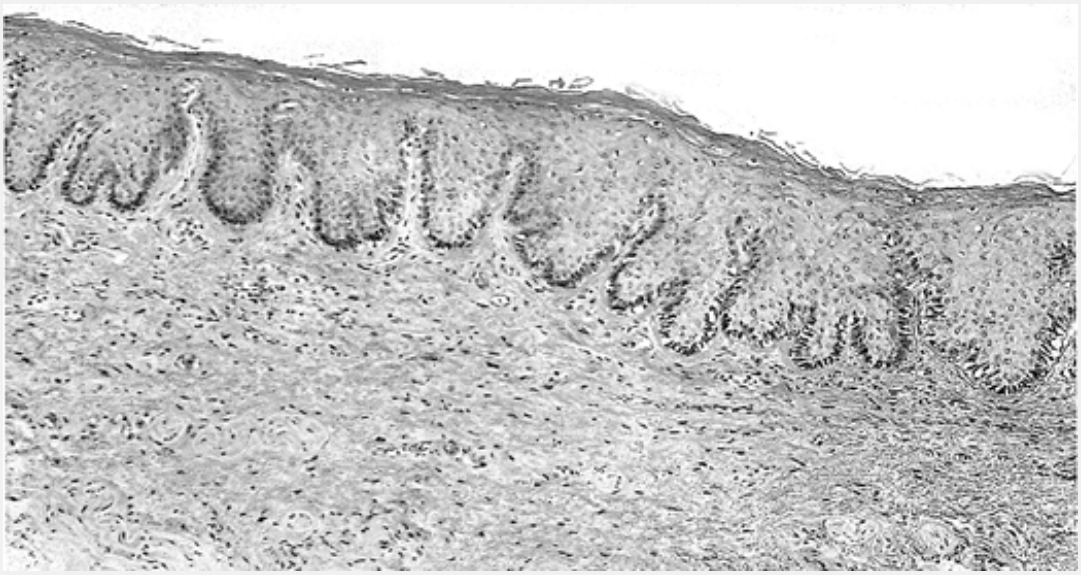

Figure 39.13 Lateral labia minora biopsy from a 27-year-old white woman. Within this area, the labia minora contain no skin appendages. The epithelium is pigmented, and melanocytes and pigmented basal epithelial cells are seen in the basal layer. The stratified squamous epithelium has a thinly keratinized surface. Beneath the epithelium, there is an elastic fiberâ€“rich stroma without fat or skin appendages. Moderate numbers of small vessels can be seen. Deeper tissue is demonstrated in Figure 39.12.

Congenital enlargement of the labia minora may occur and may be asymmetrical. Enlargement also may be secondary to irritation,

chronic edema or minor trauma. Surgical reduction of the labia minora or local excision for therapeutic reasons does not appear to impede normal sexual function or response; however, excision of the labia minora for female circumcision is associated with introital stenosis, vulvar keratinous cysts, and sexual and urinary dysfunction (8,57).

Labia Majora

The labia majora arise from the embryonic lateral folds (genital folds, labial folds), which arise lateral to the cloacal plate and do not fuse (39). The epithelium is ectodermally derived from the urogenital sinus. The endodermally derived epithelium of the vestibule joins with the ectodermally derived epithelium of the medial labial majora. This junction is apparently at Hart's line, where the epithelium of the medial (inner) labia majora joins the nonkeratinized squamous epithelium of the vestibule (29,30). In the male, the labial (scrotal) folds fuse to form the scrotum. This fusion usually occurs by 74 days of gestation (crown-rump length approximately 71 mm) (39). In the female, the labia

majora merge with the mons pubis anteriorly and with the perineal body posteriorly. The labia majora lie immediately lateral and parallel to the labia minora, separated by the intralabial sulcus. In the medial posterior positions, the labia majora are bounded by the vulvar vestibule. Laterally, they merge with the inguinal-gluteal folds, which separate the labia from the medial aspect of the thighs. Although minor asymmetry of the labia majora is considered to be normal, marked asymmetry may be early evidence of neurofibromatosis (58). Chronic inflammation, varicosities, edema, Bartholin's cysts, and benign or malignant tumors also may be associated with asymmetry of the labia majora.

Aging changes related to the labia majora include an increase in size of the labia with puberty, primarily related to increased fat within the

labia. In addition, there are dramatic changes in hair growth during puberty (see Mons Pubis discussion, below) (59). After menopause, there is a progressive loss of hair follicles and consequent loss of labial hair (60) as well as shrinkage of the labia majora. This is primarily related to loss of fat within the labia (34).

In addition to age-related changes, changes occur in the labia majora that are related to parity. During gestation, the influence of gestational hormones, especially progesterone, results in vascular dilation and stasis within the labia (52). These gestational changes may result in the development of vulvar venous varicosities (61).

Similar to other hair follicles, each follicle of the vulva has a hair root surrounded by the dermal root sheath, which invests the root sheath of the hair follicle. The inner root sheath is composed of an external clear epithelial cell layer (Henle's layer) and an inner granular epithelial cell layer (Huxley's layer). The hair matrix matures to the formed hair of the hair shaft, where the hair has an outer cuticle with a cortex and medulla. The hair papilla is found at the base of the hair root, protruding into and partially surrounded by the matrix of the hair. The papilla is supported by the dermal root sheath (40,56,62,63). Hair follicles are a portion of the pilosebaceous unit, which includes sebaceous glands.

In the labia majora, sebaceous glands can be found with and without associated hair follicles. The sebaceous glands are alveolar and arranged in a lobular manner, vested by collagen fibers. The cells of the sebaceous glands secrete in a holocrine manner, with the more mature cells accumulating sebaceous secretion (sebum) within their cytoplasm. The secretion is released as the cells undergo necrosis. The secretion may be released adjacent to the hair shaft in the pilosebaceous unit or directly to the surface when no hair shaft is present. There are two types of sweat gland: apocrine and merocrine (40,56,62,63). Apocrine glands are tubular and have a columnar secretory epithelium characterized by a prominent eosinophilic granular cytoplasm. These glands secrete by release of cytoplasmic

secretion and are associated with scent production. The scent associated with these sudoriferous glands is related to bacterial growth supported by the secretory products (56,62). Beneath the epithelial layer, myoepithelial cells are identified. These myoepithelial cells are arranged about the periphery of the gland, and their contraction promotes expression of the secretory contents from the gland lumen. The ducts of the apocrine glands are similar to those of the merocrine glands but may secrete into the upper hair follicle rather than to the skin surface when present in hair-bearing skin.

The merocrine glands are eccrine glands that produce clear watery sweat. The secretory cells have a pale, slightly granular cytoplasm and an outer layer of myoepithelial cells. The glands are simple and coiled and are found deep to the reticular dermis. The sweat duct is lined by cuboidal epithelium two-cells thick, and the double epithelial cell layer is lost as it joins with the stratified epithelial surface. Unlike sebaceous and apocrine glands, merocrine glands are not significantly stimulated by the sex hormones. [For further discussion on the histology of the skin elements, the reader is referred to Chapter 1 in this volume and to texts on histology (40,56,62,63).]

The epithelium of the posterolateral aspects of the labia majora, peripheral to Hart's line, is thinly keratinized and pigmented (Figure 39.14). At the posterior fourchette, the

retia are relatively deeper than in the posterior lateral area (Figure 39.15). Pigmented cells are seen at the basal layer in this area (Figure 39.16). A granular layer may be present immediately beneath the keratinized surface (stratum corneum). The granular layer arises from the underlying prickle cell (spinous cell) layer of the stratified squamous epithelium, with the stratum malpighii overlying the basal layer. The basal layer (stratum germinativum) is present immediately adjacent to the basement membrane (35,64). The medial hairless surfaces of the labia majora contain an abundance of sebaceous glands, which end at Hart's line. These glands are not associated

with hair-bearing pilosebaceous units and open directly onto the epithelial surface, with a short nonkeratinized epithelium-lined duct joining with the keratinized epithelial surface (Figure 39.17). Sebaceous glands within the labia majora may have a depth of up to 2.03 mm (65). Keratinous (epithelial) cysts may be associated with these sebaceous gland elements (3,57). Sebaceous glands are not found medial to Hart's line (Figure 39.2). At the midportion of the labia majora, hair follicles are associated with the sebaceous gland elements. Hair follicles within the labia majora may be as deep as 2.38 mm (65) (Figures 39.18,39.19). Apocrine and eccrine sweat glands are found associated with the hair-bearing areas of the vulva but are generally absent in the vestibule and medial nonâ€“hair-bearing areas of the medial labia majora (Figure 39.20). Deeper within the dermis of the labia majora, a delicate muscle layer (tunica dartos labialis) is present. Beneath this layer is a fascial layer that has a prominent elastic fiber component (52). The fascial layer is associated with a prominent adipose layer in women of reproductive age.

Figure 39.14 Posterior medial labia majora of a 27-year-old

white woman peripheral to Hart's line. This pigmented portion of the labia majora has a stratified squamous epithelium with a thin keratinized surface. The epithelium has deeper rete ridges than seen in the minora. The dermis is elastic fiber rich and moderately vascular. Sebaceous glandâ€“bearing skin was immediately adjacent to this area and has a moderately vascular dermis.

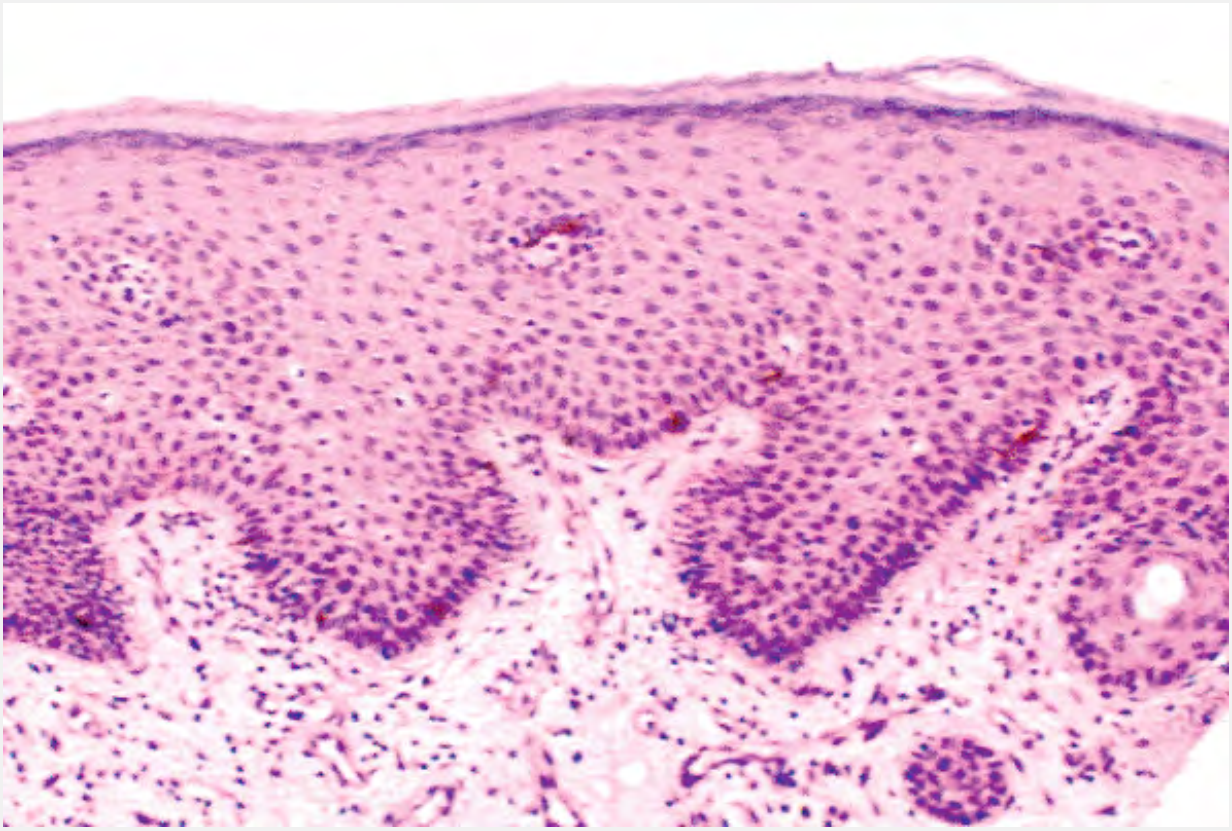

Figure 39.15 Posterior vulvar forchette. The epithelium has a thinly keratinized surface, moderately deep rete, and some melanin pigmentation within the basal cells.

Within the deep anterior labia majora, immediately adjacent to the

joins with the deep longitudinal smooth muscle layer (cremaster muscle) of the labia majora (52). The round ligament may include entrapped peritoneum (processus vaginalis), which can become cystically dilated and result in a cyst of the canal of Nuck (3). These peritoneum-lined cysts are typically encountered in the anterior portion of the labia majora, adjacent to or within the inguinal canal.

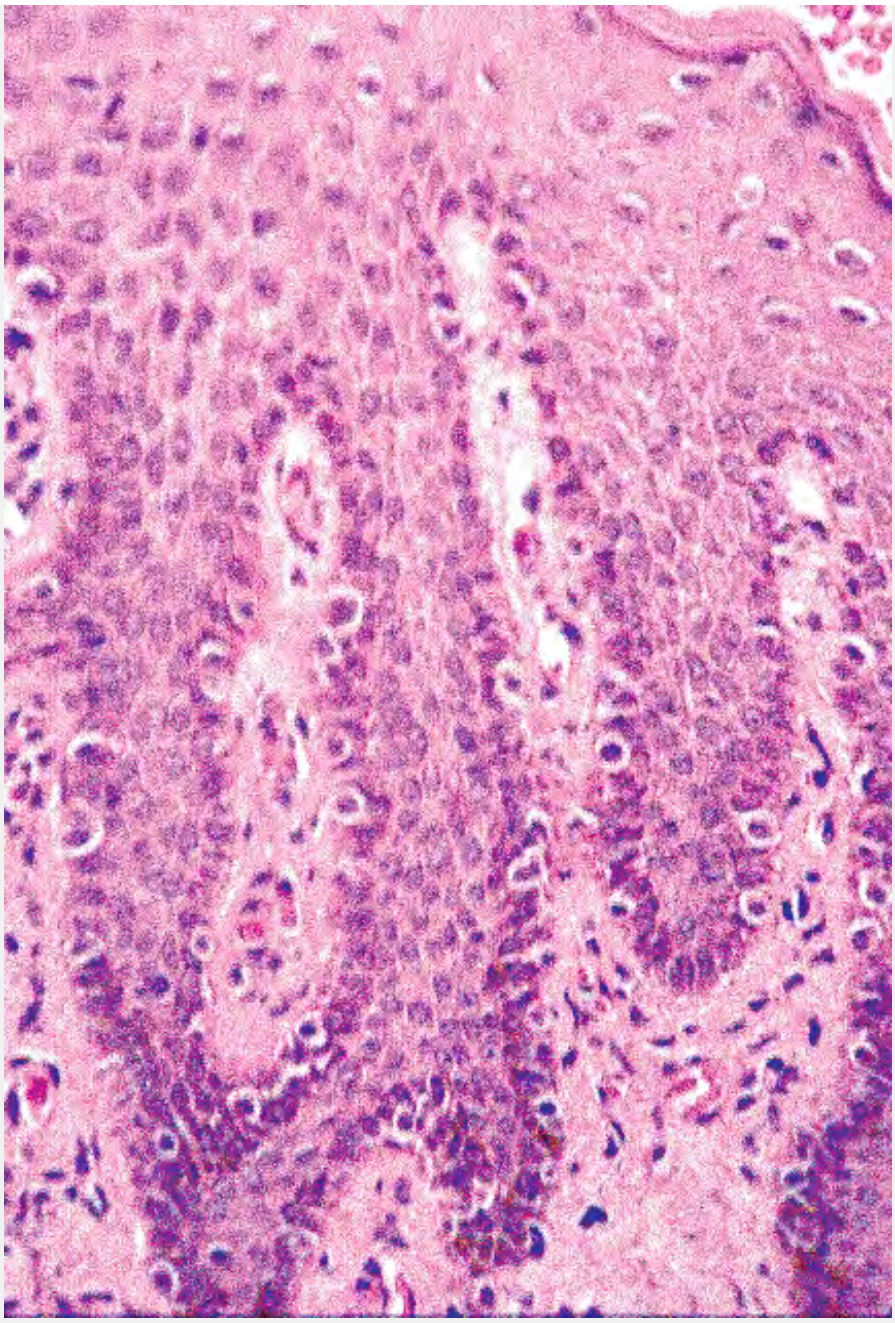

Figure 39.16 Posterior perineal body of a 27-year-old white woman. The skin at the perineal body is pigmented, and melanocytes and pigmented keratinocytes are present within the basal layer. The epithelium is stratified squamous epithelium, which has a thin keratin layer. The perinuclear halos present within the epithelial cells are normally seen and should not be

confused with koilocytosis. Small clear cells are seen in the epithelial stromal junction within many of the retia.

Figure 39.17 Labia majora, medial portion, with sebaceous gland elements exiting directly to the skin surface. The epithelium of the medial labia majora has a thin keratin and granular layer. The sebaceous glands may be seen clinically as Fordyce's spots.

The epithelium of the labia majora is rich in nerve endings and contains touch receptors, including Meissner's corpuscles, Merkel tactile disks, and peritrichous nerve endings (52). Pacinian corpuscles for pressure sensation are present within the fatty layer of the labia majora, as well as within the labia minora, clitoris, and mons pubis. Free nerve endings for pain reception are also present

within the epithelium, as well as within muscle cells and blood vessels (51,52). Ruffini's corpuscles are seen throughout the subcutaneous tissue of the labia majora, labia minora, clitoris, and mons pubis. They are absent in the hymen. Their exact function in the vulva is uncertain; however, they may be temperature receptors and/or receptors for sexual stimuli (52). Dogiel-Krause receptors have a distribution similar to that of Ruffini's corpuscles; however, they are present in a relatively smaller concentration in the mons pubis and labia majora (52).

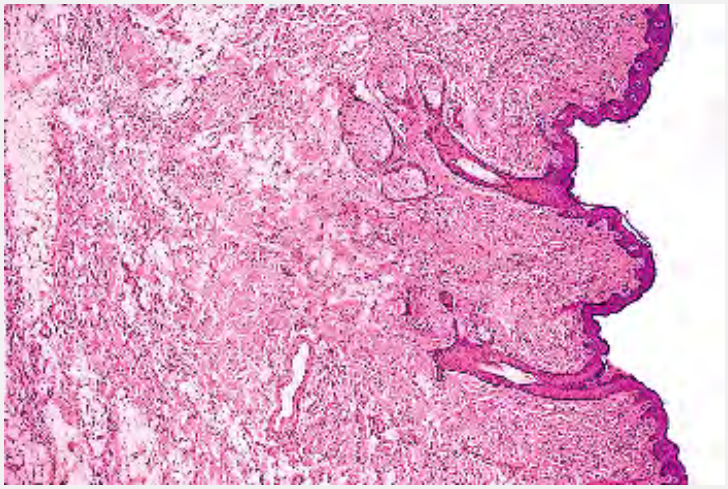

Figure 39.18 Labia majora, midportion, with underlying dermis and deep fatty tissue. The thickness of the dermis can be seen in this section of the labia majora. A few deep hair follicles can be seen within the elastic fiberâ€“rich dermis. The dermal junction with the deep fatty tissue is irregular.

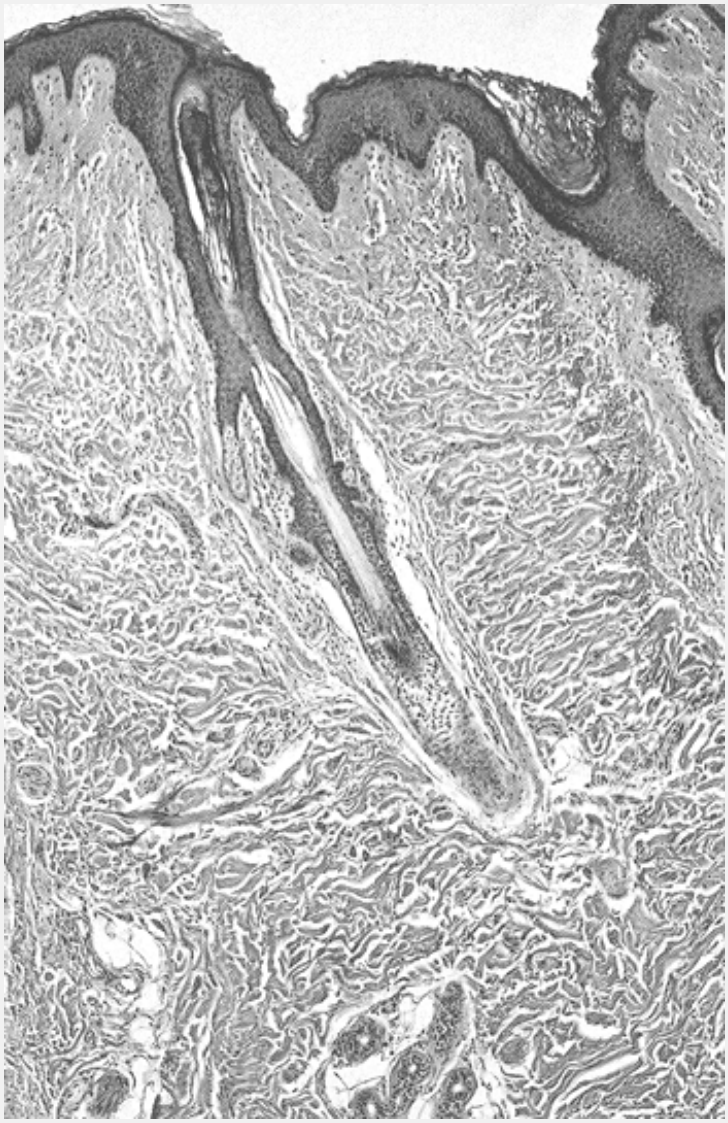

Figure 39.19 Labia majora, lateral, with hair follicle and sweat gland elements. The sweat gland duct is seen adjacent to the portion of the hair follicle.

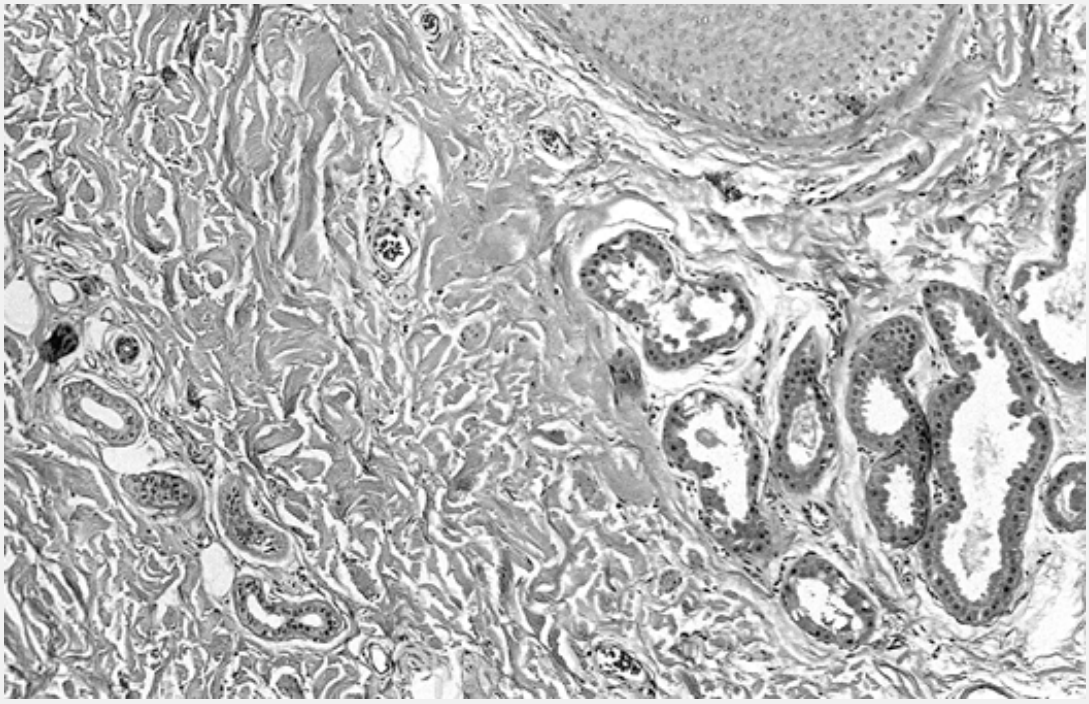

Figure 39.20 Labia majora with apocrine glands and sweat ducts adjacent to a hair follicle. Moderate vascularity of the collagen-rich dermis of the labia majora surrounds these sweat gland elements.

Medial to the labia majora, within the sulcus between the labia majora and minora (sulcus interlabialis), anogenital mammary-like glands are present that may give rise to cysts within the intralabial sulcus; they also may involve the medial aspect of the labia majora. These glands, and the cyst described, are lined with a cuboidal to columnar epithelium with an underlying myoepithelium. The myoepithelial cells are immunoreactive for smooth muscle actin and S-100 antigen, as well as low-molecular weight keratin. The superficial luminal epithelial cells are of an apocrine type, with visible â€œsnoutsâ€• (Figure 39.21). These cells are immunoreactive for low-molecular weight keratin and human milk fat globule antigen. Individual cells are also immunoreactive for carcinoembryonic

antigen and S-100 antigen. Estrogen and progesterone receptors have been detected in these cells. Mucus-containing or ciliated cells are not present, distinguishing the cysts of anogenital mammary-like glands from vestibular mucous cysts, MÃ¼llerian-related cysts or ciliated cysts, or Bartholin's gland. The lack of a stratified squamous epithelium or transitional epithelium distinguishes them from Bartholin's duct cysts, keratinous cysts, or vestibular glandular cysts that have undergone squamous metaplasia (66). There is evidence that these glands are the origin of fibroadenoma, hidradenoma papilliferum, milk cysts, and apparent ectopic breast tissue that have been described in the vulva (rather than being from true ectopic breast tissue) (67).

Mons Pubis (Mons Veneris)

The mons pubis has its origin in the embryonic genital medial cranial swellings (39). The subcutaneous tissue of mons pubis becomes more prominent with the onset of puberty, when there is a progressive increase in fat tissue beneath the mons. There is also a dramatic increase in hair growth of the mons pubis and labia majora.

Aging changes related to the mons pubis include hair growth changes that have been summarized and staged by Tanner in the following sequence (59). Stage 1 is characterized by no visible pubic hair growth. In stage 2, a small amount of pubic-type hair is seen on the midportion of the mons pubis, and some similar hair may be seen on the labia majora. In stage 3, the mons pubis hair growth is more prominent, both in the amount of hair and the coarseness of the hair. In stage 4, the hair growth over the mons pubis is similar to the adult, with the exception that the upper lateral corners of hair growth are lacking. Stage 5 characterizes the adult pubic hair pattern (59). The adult hair growth distribution is reached between the ages of 12 and 17 years (34). There can be substantial variability in the amount and character of the pubic hair (escutcheon) related to racial and genetic factors; however, pubic-type hair growth generally does

not extend above a horizontal line drawn between, and 2 cm above, the uppermost limits of the genitofemoral folds (60,68). Hair follicle depth within the vulva is greatest in the mons pubis, where hair follicle depth has been measured up to 2.72 mm (65). The mons pubis is richly endowed with nerve receptor types that were previously described for the labia majora (52).

Lymphatic Drainage

The vulvar tissues drain to lymph nodes in the femoral and inguinal lymph node chains. The anterior labia minora and clitoris drain through channels anterior and superior to these structures to join lymphatics from the prepuce and labia majora. These channels course laterally to inguinal and femoral nodes (69). In some cases, lymphatic channels from a lateral site may drain to the contralateral node group, which has clinical relevance in planning therapy for malignancies of the vulva. The most common site of metastasis from vulvar malignancies are the superficial inguinal nodes. In general 8 to 10 nodes are found in this area, with superior oblique (above the ligament of Poupart) and inferior ventral (between the ligament of Poupart and the saphenous vein and fascia lata) divisions. Midline structures, such as the

clitoris and the midline perineum, drain bilaterally. A second path of lymphatic drainage from the clitoris involves urethral lymphatics and lymphatics draining the dorsal vein of the clitoris. These channels lead inferior to the symphysis pubis through the anogenital diaphragm to join the lymphatic plexus of the anterior bladder surface. Ultimately, these channels terminate in the interiliac and obturator nodes or course superiorly to the femoral and internal iliac nodes. Deep pelvic nodes are not generally involved unless the superficial inguinal nodes are involved.

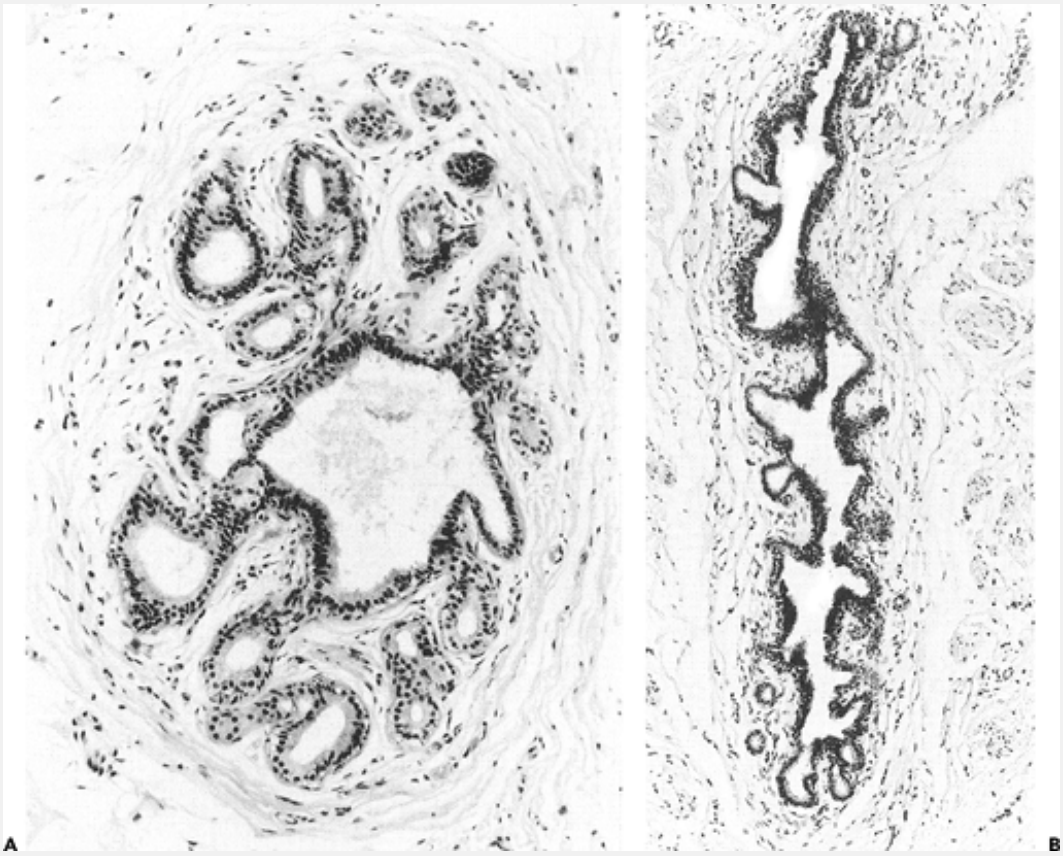

Figure 39.21 Mammary-like anogenital gland with main duct (A and B) and small acini (A). The epithelial lining is composed of a two-layered epithelium with underlying myoepithelial cell layer and a low columnar epithelial luminal epithelium. Reprinted with permission from:
van der Putte SC. Mammary-like glands of the vulva and their disorders. *Int J Gynecol Pathol* 1994;13:150â€“160.

Sentinel lymph node mapping in the assessment of vulvar carcinoma and melanoma, employing intraoperative lymphoscintigraphy (technetium-99mâ€“labelled nanocolloid) with or without blue dye (patent blue V) is gaining in application to assess inguinal lymph node status. Microscopic assessment of the lymph nodes picking up the colloid/dye is performed to plan appropriate lymph node

resection related to the vulvar surgery. When nodes are found to be negative by this technique, the patient may be spared radical inguinal-femoral lymphadenectomy (18).

Obstruction of vulvar lymphatics, related surgical interruption, or inflammation (such as secondary to Crohn's disease) may result in lymphangiectasia of the vulva. This condition may present with leakage of clear fluid from the vulva, associated with multiple small, glistening, superficial clustered vesicles on the vulvar skin, resembling frog spawn. Some degree of epithelial and dermal edema is also typically present (70).

Arterial Supply

The major arterial supply of the vulva originates with the superficial and deep external pudendal arteries (branching from the femoral artery) and the internal pudendal arteries

(branching from internal iliac arteries). The pudendal artery has anterior and posterior labial branches. Circulation to the clitoris is separate and emanates from the deep arteries of the clitoris. The anterior vaginal artery supplies the vestibule and Bartholin's gland areas (3).

Venous Supply

Major venous drainage of the vulva is primarily from the bilateral internal iliac veins, which drain into the external iliac venous system. The internal iliac veins drain both parietal and visceral venous systems. The parietal tributaries of the internal iliac vein include the internal obturator, internal pudendal veins, superior and inferior glutal veins, sciatic vein, and ascending lumbar veins. The visceral branches drain pelvic organs, including the uterine, ovarian, and vaginal venous systems. In a study of this drainage in 79 specimens, a single internal iliac vein was present on the side studied in 73% of

the cases; in 29% of the cases, two separate iliac veins drained into the external iliac vein; and, in one case, the internal iliac vein drained directly to the inferior vena cava (71). Vulvar varices are identified in approximately 2% of women seeking care in a vein clinic; such varices correlate with insufficiency of the internal iliac venous system and also involve the tributaries of the internal iliac vein as well as the saphenous vein (71).

Nerve Supply

The major nerves of the vulva are from the anterior and posterior labial nerves. The anterior nerve is a branch of the ilioinguinal nerve, and the posterior labial branch is from the pudendal nerve. The clitoral nerve supply is from the dorsal nerve of the clitoris and the cavernous nerves of the clitoris. Branches of the cavernous nerves, arising from the vaginal nerve plexus, join the clitoral dorsal nerve at the hilum of the clitoral bodies. The dorsal nerve of the clitoral bundle branches from the pudendal nerve. The two clitoral bodies, beneath the pubic arch, separate to form the two clitoral crura. Immunohistochemical studies have demonstrated that the dorsal nerves form two bundles that are extensively distributed along the lateral aspects of the clitoral bodies at the eleven and one o'clock positions but are sparse at the twelve o'clock position. These join distally to form a single clitoral body. The densest nerve groups that enter the glans clitoris are found on the dorsal aspect of the clitoris, with a concentration of nerves under the epithelium of the glans clitoris (72). The vestibule shares the clitoral nerve supply (3,52).

Vagina

Stanley J. Robboy
Rex C. Bentley

Introduction

Tissue from the vagina is infrequently examined via biopsy. Excluding the vaginal cuff removed for cervical disease, most biopsies and surgical operations are for infection, small intramural growths, intrauterine exposure to diethylstilbestrol (DES), or, in older women, squamous cell cancer and its precursors. This chapter addresses the gross, microscopic, and ultrastructural anatomy of the normal vagina. The embryologic discussion focuses on developmental perturbations, which provide insights into normal and microscopic anatomy.

Embryologic Changes

The paired mÃ¼llerian (paramesonephric) ducts appear about the thirty-seventh day postconception as funnel-shaped openings of celomic epithelium (1,2). These develop into paired, undifferentiated tubes that later grow caudally, using the already formed wolffian (mesonephric) ducts as a guidewire to reach the level of the future hymen (Figure 40.1). The absence of this occurrence, the incidence of which is about 1 in 5,000 newborn

girls, results in the Mayer-Rokitansky-Kuster-Hauser syndrome (absence of the vagina and cervix with usually only the remnants of the uterine horns) or complete absence of the mÃ¼llerian derivatives [vagina, uterus, and fallopian tubes] (3).

At about day 54, the paired mÃ¼llerian ducts fuse, becoming a straight uterovaginal canal (primordia of uterine corpus, cervix, and vagina), the lining of which is an immature columnar (MÃ¼llerian) epithelium (Figure 40.2) (4). The above changes occur in both female and male embryos. If the fetus is a male, the indifferent gonads become anatomically distinct testes at around day 44. The testis is important for two products it makes. One, mÃ¼llerian-inhibiting substance (MIS), affects the future of the mÃ¼llerian ducts. The other, testosterone, affects the future of the wolffian ducts. Shortly after the testes become distinct, Sertoli cells initiate MIS production, a protein in the large transforming growth factor-Î² family, in amounts effective to cause the mÃ¼llerian ducts to regress through a process of programmed cell death (5,6). If the embryo is female, testes do not develop. Because there is then no MIS, the mÃ¼llerian ducts are not inhibited from developing and thus grow without impedance to become the uterine tubes, uterus, and vagina.

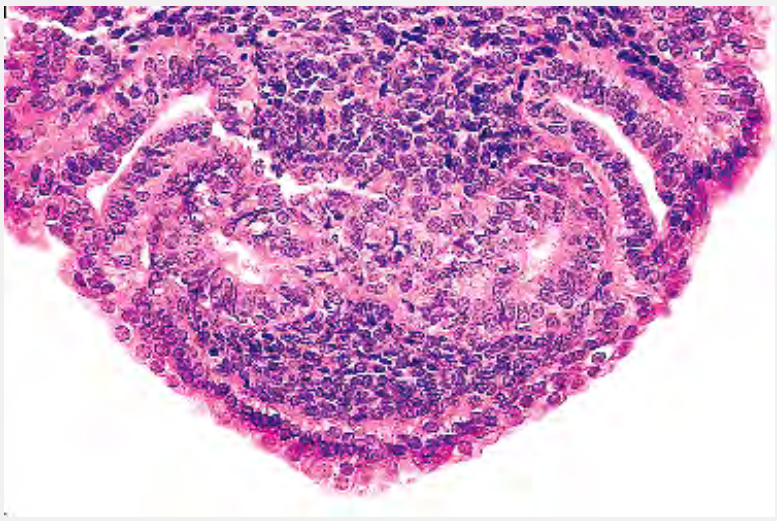

Figure 40.1 Region of urogenital sinus disclosing the tips of two central mÃ¼llerian ducts that have grown down the (outer) paired wolffian ducts (circa day 54). The cytologic features of the cells comprising both types of duct are indistinguishable on light microscopy at early stages of development. Reprinted with permission from: Robboy SJ, Ellington KS. *Pathology of the Female Genital Tract in Kodachrome Slides*. 2nd ed. Durham, NC: Gyn-Path Associates; 1996.

In contradistinction to MIS, which acts as an inhibitor, testosterone stimulates and is required to promote wolffian duct growth. In the male, the critical period for testosterone stimulation begins early in the tenth week (circa day 71) and causes the embryonic wolffian ducts to differentiate into epididymis, seminal vesicle, and ductus (vas) deferens. If there are no testes (as in the female) and testosterone stimulation has not occurred by the close of the critical window (circa day 84), the wolffian ducts wither and become vestigial remnants, which in the adult are found deep in the vaginal wall.

Until near the end of week 10 (to about day 66) the uterovaginal canal, with its solid tip already in contact with the urogenital sinus, continues to elongate caudally, still remaining as a simple tube lined by columnar epithelium (Figure 40.2). Beginning in the eleventh week, the epithelium stratifies, becoming several layers thick. Under one theory, the squamous cells are believed to derive from the urogenital sinus, invading the common tube from below and growing up the muscular scaffold to completely replace the mÃ¼llerian epithelium to the level of the external cervical os (7). The transition from mÃ¼llerian to squamous epithelium occurs at about the time when nuclear estrogen receptors appear in the vaginal stroma (8,9).

Stratification of the squamous epithelium lining the uterovaginal canal heralds formation of the so-called vaginal plate (circa the eleventh week). The proliferation progressively occludes the canal beginning caudally and extending cranially. Studies with latex-injected specimens indicate that even the lateral wings of the vaginal plate may become occluded, but a central lumen persists, especially in the upper vagina.

During the thirteenth week (91 days), cervical glands develop; they exhibit a wavy architectural appearance but cytologically are minimally differentiated. By the fourteenth week, the caudal vagina increases markedly in size (Figure 40.3). During the fifteenth week, the solid epithelial anlage of the anterior and posterior vaginal fornices appear. Starting with the sixteenth week, the squamous epithelium lining the vagina and the exocervix begins to mature, thus resembling the lining of the adult vagina. The epithelium thickens and glycogenates, features most likely related to increased maternal and hence fetal estrogen levels. As the cells mature, they lose cellular adhesiveness and desquamate, heralding the canalization of the vaginal plate and thus the onset of the final gross adult structure of the vagina. By the eighteenth to twentieth week, the development of the vagina is complete.

Why columnar epithelium with an embryonic appearance should initially line the mÃ¼llerian system and later be replaced by squamous epithelium remains of teleologic interest. The answer to the mechanism may lie in the vaginal wall stroma. Prior work in the mouse has shown that differentiation of the lower genital tract epithelium is dependent on the stroma on which it grows (10). For example, uterine epithelium, when grown intermingled with neonatal vaginal stroma, develops histotypic features of vagina. In contrast, vaginal epithelium, if grown with

neonatal uterine stroma, develops a uterine phenotype. The final

epithelium has cytosolic proteins characteristic of the induced rather than original epithelial source.

Robboy SJ, Ellington KS. *Pathology of the Female Genital Tract in Kodachrome Slides*. 2nd ed. Durham, NC: Gyn-Path Associates; 1996.

Additional evidence that the vaginal stroma plays a key role in epithelial differences comes from embryologic appearance of estrogen receptors. Among various body organs tested, the receptors are detected only in the genital tract. They appear in the mesenchyme at the tenth week, just before the mÃ¼llerian

epithelium is normally replaced by squamous epithelium of sinus origin (8). Epithelial labeling appears later (sixteenth week), at the time when the sinus (squamous) epithelium begins to mature and accumulate large quantities of glycogen. Interestingly, the stroma probably plays a key role in the action of MIS as well; the receptor for MIS is located in the stroma surrounding the mÃ¼llerian duct rather than in the mÃ¼llerian epithelium (11).

The developmental morphology of the vaginal mucosa and the inductive properties of the stroma supporting the vaginal mucosa are complex. For example, a hitherto unrecognized band of subepithelial stroma was described in 1973 that extended from the endocervix to the vulva (Figure 40.4) (12). It is 0.5 to 5 mm thick in mature females and most prominent in the endocervix. It is from this zone that fibroepithelial polyps seem to arise, an entity of no apparent physiologic function but which clinically should not be confused with malignant tumor (13,14).

Should the squamous epithelium described above fail during the critical weeks of embryonic life to replace the

original columnar cells lining the vagina, the columnar cells remain in an arrested state of development until sometime around puberty, when they may further differentiate into the adult-type epithelium usually seen in biopsy material. It is conjectured that the tuboendometrial type of epithelium is the basic form of epithelium supported by the vaginal mesenchyme. In fact, it may be that this type of epithelium is the basic type of mÃ¼llerian epithelium supported throughout the female genital tract, manifesting as serous cells in the uterine tube, endometrioid cells in the uterine corpus, and tuboendometrial cells in the vaginaâ€”cells that are quite similar. In the cervix, a tuboendometrial layer of epithelium also lies deep to and as a cuff about the luminal layer of mucinous epithelium (15); the tuboendometrial layer, which is continuous with the lining of the corpus, is readily observed in hysterectomy specimens but is

located too deep to be detected on biopsy. In fetuses where the vaginal lining has become squamous (older than 10 weeks), the inner stromal zone is obvious in the uterine tube, endometrium, and endocervix and tapers, appearing to end at the squamocolumnar junction of the cervix and vagina. Part of this layer may correspond to the most superficial stromal layer in the adult vagina described above. The original tuboendometrial layer is the origin of glandular remnants in the vagina of adults (adenosis).

Gross Features

The vagina (from the Latin for sheath) extends from the vestibule of the vulva to the uterus, lying posterior (dorsal) to the urinary bladder and anterior (ventral) to the rectum. It's axis averages 30 degrees with the vertical, arching slightly posteriocranially, and more than 90 degrees with the uterus (Figure 40.5). The anterior wall averages 8 cm in length and the posterior wall 11 cm, with the cervix filling the 3 cm difference. In early life, the vagina is constricted distally, dilated in the middle, and narrowed proximally. It surrounds the exocervix and forms vaultlike fornices between its cervical attachment and the lateral wall. In the adult, the anterior and posterior walls are slack and remain in contact with each other, whereas the lateral walls remain fairly rigid and separated. This is thought to give an H-shaped appearance to the vaginal canal on cross section (16), although with three-dimensional imaging with magnetic resonance imaging (MRI), a â€œWâ€• shape is now also recognized (1). During intercourse, the position of the uterus and bladder change relative to the vagina (17).

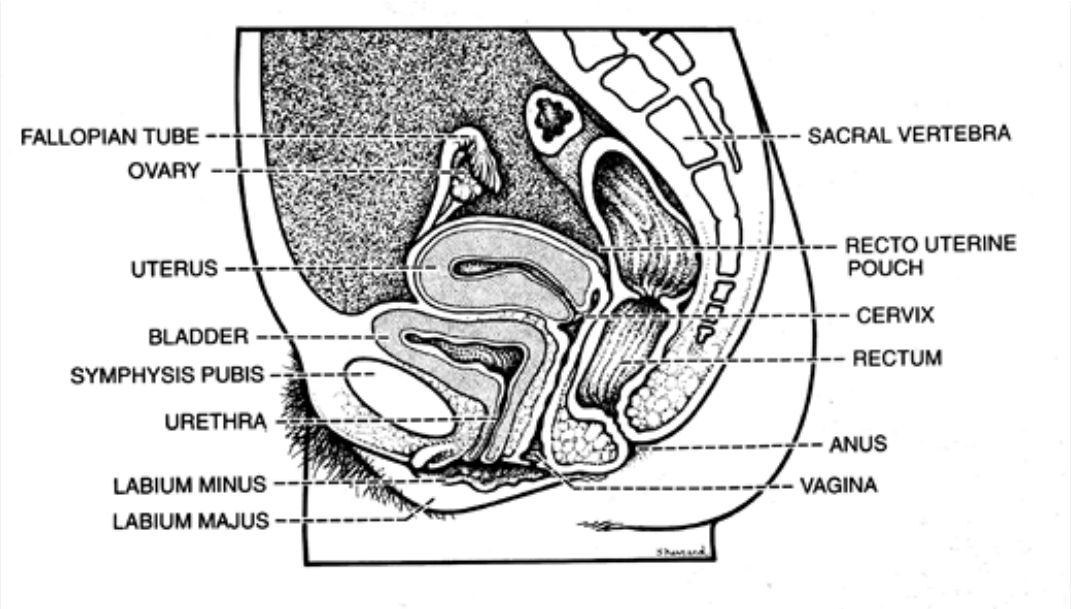

Figure 40.5 Structural relationships of the vagina. Its axis forms an angle of more than 90 degrees with the uterus. Reprinted with permission from:
Zaino R, Robboy SJ, Kurman RJ. Diseases of the vagina. In: Kurman RJ, ed. *Blaustein's Pathology of the Female Genital Tract*. New York: Springer-Verlag; 2002:151â€“206.

Posteriorly, the upper one-fourth of the vagina is related to the rectouterine space (i.e., the cul-de-sac or pouch of Douglas), which is covered with peritoneum. The middle half of the vagina is closely apposed to the rectum, separated only by fibrofatty adventitia and the rectovaginal septum. The lower one-fourth of the vagina is separated from the anal canal by anal and rectal sphincters, as well as the interposing perineal body, which contains the origin of the bulbocavernous and superficial transverse perineal muscles.

The urinary bladder and urethra lie anterior to the vagina. The urethra courses approximately one-third of its length on the vagina and then enters into the vaginal wall to become an

inseparable part of it, usually terminating with its external meatus at the introitus. Typically, the meatus is outwardly directed, but not uncommonly it is directed into the outermost vagina. The ureters course along both sides of the upper one-third of the vagina until entering the bladder wall.

The vagina opens into the vestibule formed from the urogenital sinus. The vestibule lies beneath the urethra and between the inner margins of the labia minora. The vagina, urethra, and ducts of Bartholin's glands open into the vestibule. The size and shape of the vaginal orifice are related to the state of the hymen. When the inner edges of

the hymen are apposed, the vaginal opening resembles a cleft. When stretched, the hymen may persist in the form of a ringlike structure about the readily recognized vaginal orifice. (See Chapter 39 for the anatomy of the hymenal region.)

Anatomy

Ligaments

The vaginal supports are intimately related to the uterus, urethra, bladder, and rectum (18). The lateral supports are called cardinal ligaments, the posterior supports sacrouterine ligaments. They originate where the isthmus of the uterine cervix and the uterine corpus meet and course outward, fanlike to the lateral and posterior pelvic walls. The isthmic fibers turn upward onto the uterus and downward onto the vagina. These ligaments, the connective tissues surrounding the vessels on the lateral vaginal walls, and the close proximity of the rectum, bladder, and urethra all contribute to support the vagina within the pelvis.

Blood Supply

The blood supply to the vagina is complex, with extensive anastomoses maintaining an adequate blood supply to all areas of the vagina in the event that injury restricts any single route of supply. The internal iliac (hypogastric) artery is the principal source of blood cranially as branches of the uterine arteries and caudally as branches of the middle hemorrhoidal arteries and pudendal arteries. Beginning cranially, the uterine artery gives off a descending branch, the cervicovaginal artery. Several branches supply the cervix. Lower branches supply the vagina. The vaginal arteries, which lie lateral to the vagina, send branches to both the anterior and posterior surfaces. The lower vagina receives its supply from ascending branches of the middle hemorrhoidal arteries and pudendal arteries, which also divide to send rami to the anterior and posterior vaginal walls. In toto, the extensive rami form a plexus around the vagina from which arise the median arteries, the azygos vaginal arteries on the anterior and posterior walls. A rich venous plexus also surrounds the vagina and communicates with the vesicle, pudendal, and hemorrhoidal venous plexuses, which empty into the internal iliac veins.

Nerves

The autonomic system of the pelvis originates in the superior hypogastric plexus. The middle hypogastric plexus, which passes into the pelvis, divides at the level of the S1 (sacral) vertebra into branches that pass to both sides of the pelvis and initiate the inferior hypogastric plexus. The inferior hypogastric plexus, a divided continuation of the middle hypogastric plexus, the superior hypogastric plexus, and the presacral nerve, descends into the pelvis in a position posterior to the common iliac artery and anterior to the sacral plexus; it curves laterally and finally enters the sacrouterine ligament. The medial segment of the primary division of the sacral nerves (S2â€“S5), as it sends fibers into the pelvic plexus located within the sacrouterine folds, appears to contain both sympathetic (inferior hypogastric plexus) and

parasympathetic (nervi erigentes) components. An extension of this plexus, located in the base of the broad ligament and supplied by the middle vesical artery, contains many ganglia. Most nerves enter the uterus near the isthmus. A lesser number descend along the lateral vagina, a pattern similar to the arteries that supply the vagina.

Lymphatic Drainage

The vaginal lymphatic system, despite the simplified view given here, is highly variable (Figure 40.6) (19). The lymphatics begin as a delicate plexus of small channels involving the entire mucosa and lamina propria and then drain into a deep muscular network. They terminate in a perivaginal plexus from which arise collecting trunks, which themselves coalesce into several larger channels.

The lymph drainage follows patterns that reflect functionally diverse geographic regions. The lymphatics of the upper anterior wall join those of the cervix, where they follow the cervical vessels to the uterine artery and accompany it to terminate in the medial chain of the external iliac

nodes. The lymph from the posterior vagina drains into deep pelvic, rectal, and aortic nodes. The lymphatics of the lower vagina, which also include the hymenal region, follow two distinct courses. One passes to the interiliac nodes in company with the upper vaginal discharge. The other traverses the paravesical space, carrying lymph to the deepest portions of the pelvis and draining into the inferior gluteal nodes near the origin of the vaginal or internal pudendal artery. The channels that anastomose with those of the vulva drain to the superficial iliac nodes. In summary, as a practical matter, one can generalize that tumors in the upper vagina will spread like cervical carcinoma to involve obturator and both internal and external iliac nodes. In contrast, tumors in the lower vagina will tend to involve superficial iliac

(inguinal) and deep pelvic nodes, similar to vulvar cancer.

Light Microscopy

Epithelium

The vaginal wall consists of three principal layers: mucosa (epithelial and submucosal stroma), muscle, and adventitia. The epithelium is about 0.4 mm thick and, on gross examination, exhibits a characteristic pattern of folds or rugae separated by furrows of variable depth. There are two longitudinal (anterior and posterior) and multiple transverse furrows. The rugal pattern of

the vaginal mucosa, which contributes to the organ's elasticity, produces an undulating appearance on microscopic examination in contrast to the flat surface of the cervix. The rugae, which are more prominent in nulliparous than multiparous women, reinforce the gripping effect of the levator ani and vaginal constrictor muscles during intercourse. Nonkeratinized glycogenated squamous epithelium lines the luminal surface in a manner similar to cervical epithelium. The normal vaginal mucosa lacks glands. Its surface is lubricated both by fluids that pass directly through the mucosa and by cervical mucus.

The mature, stratified squamous epithelium can be subdivided into several layers, typical of squamous epithelia elsewhere in the body (Figure 40.7). From the base to the surface, they are the deep, intermediate, and superficial zones. The deep zone contains the basal cell layer and, above this, the parabasal layer. Both are the active proliferative compartments or germinal beds, as shown by the Ki-67 antigen, which is demonstrable during late G1, G2, and M phases of the cell cycle (Figure 40.8). The basal cell layer consists of a single layer of columnar-like cells, approximately 10 Âµm thick, the long axis of which is vertically arranged. The cells have a basophilic cytoplasm and relatively large oval nuclei. Mitoses may be present. Occasional melanocytes also are found.

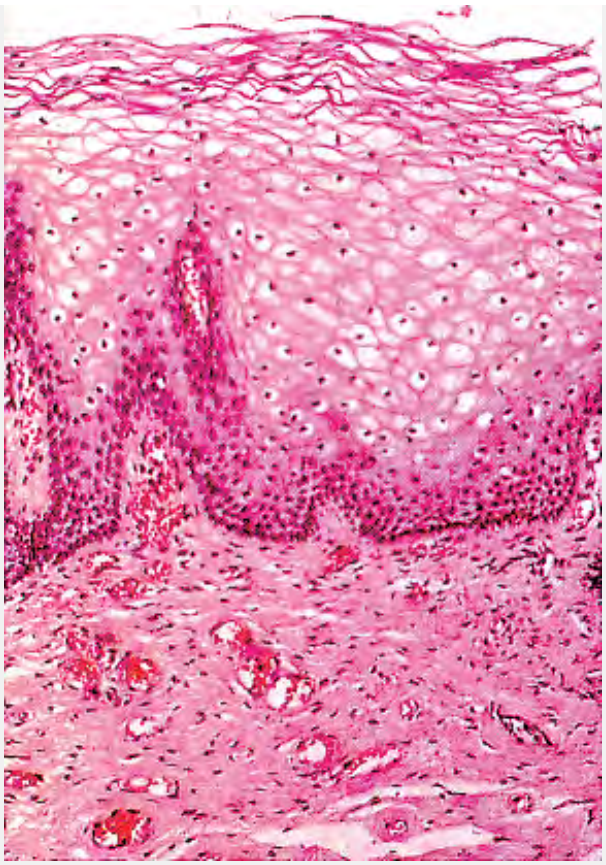

Figure 40.7 Mucosa of the adult vagina. Mature cells with glycogenic cytoplasm and pyknotic nuclei occupy most of the epithelial thickness. There is a single layer of dark basal cells and three to four layers of intermediate cells. Reprinted with permission from:
Robboy SJ, Ellington KS. *Pathology of the Female Genital Tract in Kodachrome Slides*. 2nd ed. Durham, NC: Gyn-Path Associates; 1996.

The parabasal layer is poorly demarcated from the overlying cell layers. It consists usually of about two layers of small polygonal cells, having a total 14 Âµm thickness, often with intercellular bridges. The cells have basophilic cytoplasm, a relatively large, centrally placed, round nucleus, and occasional mitoses.

The intermediate cell layer is of variable thickness. The cells have prominent intercellular bridges, a naviculate configuration, and a long cell axis paralleling the surface. The cytoplasm is basophilic, although some glycogen may be present. The nuclei are round, oval, or irregular, with finely granular chromatin. This layer of cells has about 10 rows of cells of about 100 Âµm thickness.

The superficial layer is also of variable thickness. The cells are polygonal when viewed from above and flattened when viewed in cross section. The cytoplasm is acidophilic, and the nuclei are centrally located, small, round, and pyknotic. Keratohyalin granules are sometimes seen in the cytoplasm. This layer also contains about 10 rows of squamous cells.

Relatively little is known about the normal components of the epithelium itself. The submucosa contains a variety of mononuclear cells demonstrable by immunocytochemical

methods. The dendritic processes of Langerhans cells (about 4 per high power field) are distributed throughout the mucosa (20). We have found them largely in the deeper layers, but they can extend into the superficial fields (Figure 40.9). Both T8 and, to a lesser degree, T4 lymphocytes are also frequently found, whereas macrophages and B lymphocytes are relatively uncommon.

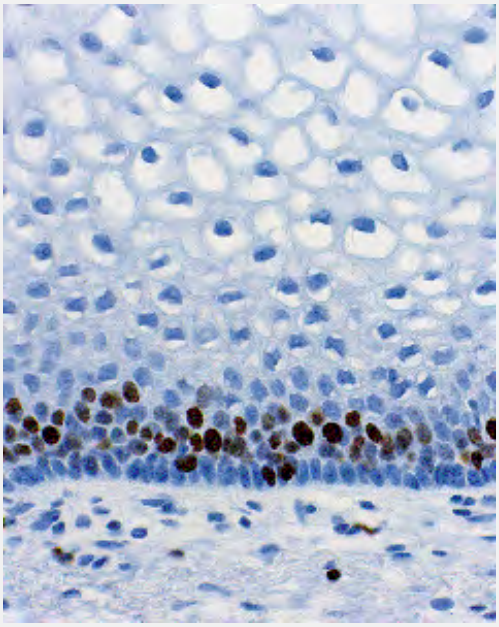

Figure 40.8 Ki-67 antigen, demonstrable during late G1, G2, and M phases of the cell cycle, in the basal and parabasal layers of the normal vaginal mucosa. Reprinted with permission from:
Robboy SJ, Ellington KS. *Pathology of the Female Genital Tract in Kodachrome Slides*. 2nd ed. Durham, NC: Gyn-Path Associates; 1996.

Epithelial Response to Hormones

Vaginal epithelial cells proliferate and mature in response to stimulation by ovarian or exogenous estrogenic hormones. Hence, it would seem that the total number of squamous cell layers would vary greatly during the normal menstrual cycle and as a woman passes through the various stages of the life cycle, that is, birth, childhood, reproduction, and the postmenopausal years. Earlier work indicated the high occurred at ovulation (average 45 layers). It built slowly during the proliferative phase and averaged 22 on

day 10. After ovulation, the number receded to 33 on day 19 and to 23 on day 24 (21,22). More recent workers found there was a statistically significant decrease from 27.8 on days 1 to 5 and 28.1 on days 7 to 12 to 26.0 on days 19 to 24, but clinically this appears to be of little import (20).

Without hormonal stimulation, the cells atrophy (Figure 40.10). At the peak of estrogenic activity (i.e., just before ovulation), the superficial cells with abundant intracytoplasmic glycogen predominate, both on histologic section and in smears (Figure 40.11). Lactobacilli metabolize the glycogen normally present in the vagina to lactic acid, which maintains an acid vaginal pH (about pH 4.4 during the late proliferative and secretory phases) (23).

Robboy SJ, Ellington KS. *Pathology of the Female Genital Tract in Kodachrome Slides*. 2nd ed. Durham, NC: Gyn-Path Associates; 1996.

Progesterone inhibits maturation of the vaginal epithelium. Consequently, intermediate cells predominate when the circulating levels of progesterone are high; for example, during the postovulatory phase of the menstrual cycle or during pregnancy. Estrogenic activity is low or absent before puberty and after the menopause; the vaginal

epithelium fails to mature and hence remains thin. Parabasal and intermediate cells predominate in the vaginal smear. In the newborn child, the vaginal epithelium is frequently mature because of the influence of placental estrogens (Figure 40.12). Quantitative studies measuring the rate of change in the maturation index in the infant's vagina from birth to the atrophic state indicate that vaginal cells replace themselves in less than two weeks; that is, the time required for basal cells to work their way up and become desquamated superficial cells. Studies of the exocervix indicate that turnover there is also rapid (24).

The submucosa, or lamina propria, lies beneath the squamous epithelium. It contains elastic fibers and a rich venous and lymphatic network. Sometimes the superficial lamina propria discloses a bandlike zone of loose connective tissue that contains atypical polygonal to stellate stromal cells with scant cytoplasm (Figure 40.4). Many cells are multinucleated or have multilobulated hyperchromatic nuclei. Few are mononucleate. Mitoses are not observed. These atypical stromal cells are thought to give rise to fibroepithelial polyps, which have been observed within the cervix, vagina, and vulva. They have been shown to be fibroblastic in origin.

Vaginal Wall and Adventitia

The vaginal musculature is continuous with that of the uterus. The outer layers in muscle of both the uterus and vagina run longitudinally to pass out onto the lateral pelvic wall to form the superior and inferior surfaces, respectively, of the cardinal ligaments. The longitudinal muscle fibers continue to course the length of the vagina to the region of the hymenal ring, where they gradually disappear in the connective tissue. On the anterior vaginal wall, the longitudinal muscle fibers are displaced by the urethra more than diminished in number. The inner muscle layer of the vagina forms a spiral-like course, appearing in microscopic sections as somewhat circular in direction.

The adventitia is a thin coat of dense connective tissue adjoining the muscularis. The connective tissue of the adventitia merges with the stroma, connecting the vagina to the adjacent structures. This layer contains the many veins, lymphatics, nerve bundles, and small groups of nerve cells.

Ultrastructure

On ultrastructural examination, the component layers are not sharply demarcated from each other. Rather, they may be somewhat difficult to distinguish because each layer has ill-defined limits and displays gradual changes in structure (25). In general the ultrastructural changes observed by transmission electron microscopy resemble those of the exocervix and mucosal squamous cells and are not further covered herein.

On scanning electron microscopic examination, the superficial cells appear large (50 Âµm in greatest dimension) and polygonal. The intercellular edges are narrow and dense and protrude slightly. The pattern of fine webbing and anastomotic intercellular bridges typifies nonkeratinized

squamous epithelium, such as that observed in buccal mucosa. The key structure on the cell surface is the microridge, or in reality myriad microridges, which are interanastomotic longitudinal elevations of the plasma membrane 0.2 nm long and 0.1 nm high (Figure 40.13). Arranged in dense convolutions, they tie one cell to another, operating in a zipper-fastener principle. They are thought to provide surface adhesion. Desmosomes are prominent in these areas.

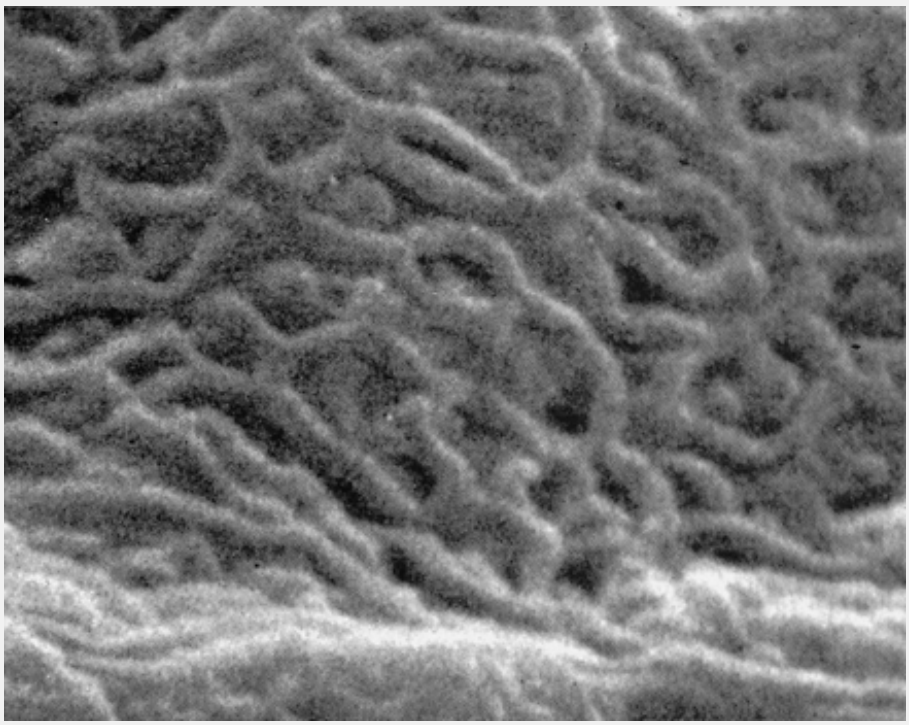

Figure 40.13 Intricate network of microridges on surface plasma membrane of most superficial squamous cells living in the normal vaginal lumen. Scanning electron microscopy (original magnification Ã—10,000). Reprinted with permission from:

Ferenczy A, Richart RM. *Female Reproductive System: Dynamics of Scan and Transmission Electron Microscopy*. New York: John Wiley; 1974.

Microridge formation depends on the topographic configuration of disulfide-rich keratin or keratin precursors, which are absent in immature precursor cells, such as intermediate cells and young metaplastic squamous cells. From midcycle and early in the luteal phase, intercellular grooves widen. Porelike widening (porosites) of the intercellular crevices takes place where several cells interconnect. This porosity is thought to enhance continuity of the intercellular space system of the vaginal epithelium and the vaginal surface, thus permitting free passage of vaginal lubricating fluid.

Information about changes at the biochemical and immunological levels is relatively little, but clearly the cells at various levels show dramatic differences. Part may reflect degrees of cellular maturity. Part may reflect subcellular specialization. Like other epithelia, both squamous and glandular alike, the pattern of cytokeratin expression reflects the state and nature of differentiation of the epithelial cells. The vaginal mucosa reflects that of other nonkeratinized squamous epithelium. Cytokeratin 14 (CK14) is demonstrable in the basal layer and CK13 in the parabasal layer, the latter supporting a subpopulation of cells that express CK10 (26). In ways uncertain, the differentiating cells show changes that have other effects. One is its influence on bacterial binding, such that cellular receptors that develop in the differentiated cells enhance adhesion of pathogenic bacteria. As one example, differentiated vaginal mucosal cells express receptors to *Escherichia coli* type 1 pili, which are surface-adhesive organelles (26). Such colonization where fecal *E. coli* are present in the vaginal introitus may be a key initial event leading to acute urinary infection. Another example is the presence of a surfactant protein (SP-A), which the human vaginal epithelial cells secrete. This factor, an important host defense, acts to facilitate micoorganism phagocytosis (27,28).

Differential Diagnosis and Special Anatomy

Wolffian Ducts

The wolffian duct, known otherwise as the mesonephric duct or Gartner's duct, is vestigial in the adult female (Figure 40.14). It begins to irreversibly wither if not stimulated to develop by testosterone before the thirteenth week postconception. This paired duct is most commonly situated in the lateral vaginal walls, although we have encountered it in all areas. Where encountered by chance in a radical vaginectomy specimen, the ducts are virtually always invisible grossly. Mitoses are absent. Usually it is a small duct or clusters of small glands about a duct. The lumen is filled frequently with a deeply eosinophilic, hyalinized secretion. The single layer of cells lining the duct is primarily composed of the cell nucleus. The cytoplasm is scant, relatively translucent, and lacks cilia. The nuclei frequently overlap. The chromatin is strikingly bland. On a

clinical basis, individual ducts occasionally become cystic and macroscopically visible. In the cervix, these ducts rarely appear diffusely throughout the wall and appear as mesonephric hyperplasia or even adenoma (29). We also have seen rare cases where the neoplasm present appeared to be a true wolffian duct carcinoma.

Remnants of MÃ¼llerian Duct Epithelium (Adenosis)

The DES story began in 1938 when this nonsteroidal estrogen was synthesized and then gained popularity for the treatment of high-risk pregnancy. By 1971, up to two million women had taken the drug, at which time it was linked to the extremely rare development of clear cell adenocarcinoma of the vagina in young female offspring. Subsequently, about one-third of the exposed young women were found to have adenosis (presence of glandular tissue in the vagina). Both retrospective and prospective studies have shown that adenosis can be found in nonexposed women

also, albeit rarely. In both exposed and nonexposed women, the adenosis is related to embryonic mÃ¼llerian tissue that has remained entrapped and not been replaced by squamous epithelium during fetal life.

Adenosis appears in three forms. One type, the embryonic form, is exceedingly rare. The other two are the adult and common forms. In adenosis found during fetal life and in stillborns, but only rarely in adults, the glands are embryonic in character (Figures 40.12, 40.15) (30). They are small, usually at the epithelialâ€“stromal interface, and are characterized by individual cells with small basal nuclei and copious bland cytoplasm that does not stain with either periodic acid-Schiff or mucicarmine.

It is believed that adenosis takes on its adult forms in women some time during puberty (31,32). Mucinous columnar cells, which by light and electron microscopy resemble those of the normal endocervical mucosa, comprise the glandular epithelium most frequently encountered as adenosis (62% of biopsy specimens with vaginal adenosis). This epithelium, because it frequently lines the surface of the vagina, is the type most commonly observed by colposcopy. Commonly, the mucinous columnar cells also line glands embedded in the lamina propria. This form of epithelium gives rise to the progestin-stimulated lesion, microglandular hyperplasia of the vagina (33).

Dark cells and light cells, often ciliated and resembling the lining cells of the uterine tube and endometrium, are found in 21% of specimens in the upper vagina with adenosis. This form of adenosis has been called tuboendometrial, although serous might be equally appropriate. The cells are usually found in glands in the lamina propria and not on the vaginal surface. Although adenosis

in the lower vagina is rare in absolute number, the percentage of biopsy specimens with adenosis that exhibits tuboendometrial rather than mucinous cells increases markedly in frequency in

comparison with the more cranial aspects of the vagina. The tuboendometrial cell, which is benign, is the cell that we believe is related to clear cell adenocarcinoma, possibly through atypical adenosis, a transitional form (15,34). Mucinous glands and mucinous pools or droplets are encountered frequently in the same biopsy specimen; mucinous and tuboendometrial cells are found together only occasionally in biopsy material. The tuboendometrial form of adenosis is the instrumental type of glandular cell induced by all regions of the mÃ¼llerian duct, be it uterine tube, uterus, or vagina, whereas the mucinous cell is generally specific to the endocervix or, after DES exposure, to the deformed region of the cervix, which becomes ill-defined and includes what appears to be the upper vagina.

Uterus and Fallopian Tubes

Michael R. Hendrickson
Kristen A. Atkins
Richard L. Kempson

Introduction

The fallopian tubes and uterus in many ways constitute a natural anatomic and functional unit. They both derive embryologically from the mÃ¼llerian duct. Taken together, they provide the locations for the fusion of the descending egg and the ascending spermatozoon, the implantation of the resulting blastocyst, the incubation of the developing gestation, and they ultimately provide the mechanism for the delivery of the conceptus at term. They have a common anatomic organization and share common responses to a changing steroidal milieu. Looking beyond normal structure and function to pathology, the fallopian tube and the uterus, together with the ovarian surface epithelium, comprise what has been termed the extended mÃ¼llerian system (1 ,2), which gives rise to a common set of neoplasms and nonneoplastic metaplastic epithelial changes.

This chapter emphasizes those aspects of normal histology and immunohistochemistry relevant to the diagnostic pathologist and

focuses on those features of the normal uterus and fallopian tubes that, because of their striking appearance or unfamiliarity, raise the issue of pathologic alterations.

Accounts of conventional light microscopic appearance of the fallopian tube and uterus have not changed substantially over the past several decades. This is in sharp contrast to the impressive gains in our knowledge of the biochemical and physiologic details of the normal function of these organs. Parallel advances have been made in microsurgery and radiologic imaging techniques. Increasing use of in vitro fertilization and embryo transfer technology has exploited these advances, and that in turn has prompted a return to many ancient questions: Why do women menstruate? What exactly does the endometrium do? Does it have an endocrine function? What are the functions of the many endometrial secretion products? Which of these endometrial contributions are essential to initiating and successfully sustaining a gestation? There has been an explosion of knowledge concerning the hormonal control of the reproductive system, fueled in large part by efforts to induce ovulation with pharmacologic agents. This has led in recent decades to a much more extensive knowledge of the neuroendocrine regulation of the menstrual cycle, the detailed anatomy and endocrinology of ovarian folliculogenesis, ovulation and corpus luteum function, the mechanism of action and genetics of steroid receptors, and the mechanisms responsible for normal menstrual bleeding. Paradoxically, most of this information is currently not of direct relevance to diagnostic pathologists. The practical orientation of this work notwithstanding, to ignore this knowledge would impart a distinctly dated character to this chapter. Therefore, we include a rough outline of some of this information and direct the interested reader to sources with a more detailed treatment of these issues.

This chapter first discusses the embryology and gross anatomy of the uterus and the fallopian tubes and then turns to the normal histology of the cervix, endometrium, myometrium, fallopian tube, and broad ligament.

Embryology

The uterus and fallopian tubes have a complex developmental history (3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11). For poorly understood reasons, precursors of both male and female internal genitalia are laid down early in each embryo in a manner analogous to the initial development of the bipotential gonad. This is known as the indifferent stage of genital development. Upon completion of this indifferent stage, definitive female differentiation is accompanied by regression of the male anlage, whereas male differentiation is accompanied by regression of the female anlage. Topographically, both of these systems are intimately related to the developing urinary tract, and, not surprisingly, anomalous development of the internal genitalia is often accompanied by anomalies of the urinary tract. Fetal sexual differentiation is completed during the first half of gestation; the last half is marked primarily by growth of the newly established genitalia. Relevant milestones have been summarized by Ramsey (12) (Figure 41.1).

The Indifferent Stage

By the 6th week of fetal life the urogenital sinus and the mesonephric (wolffian) ducts are well established. At this time the paired mÃ¼llerian (paramesonephric) ducts begin their development. These structures are formed by an invagination of the celomic epithelium adjacent to that investing each developing ovary. The mÃ¼llerian ducts are intimately related to the mesonephric ducts, and their normal formation appears in fact to be dependent on the presence of the mesonephros.

As the mÃ¼llerian ducts grow caudally, they approach the midline where the distal portions fuse. Shortly after this fusion, the apposed medial duct walls disappear, bringing the two lumina into continuity to form a single cavity. Further downward growth of the fused mÃ¼llerian structures (now termed the uterovaginal primordium)

brings them into contact with the urogenital sinus. At this stage both the mesonephric ducts and the mÃ¼llerian ducts are present in the fetus.

Female Differentiation

The differentiation of the indifferent internal genitalia into male or female structures depends on whether the fetus possesses ovaries or testes. In the male fetus, the Leydig cells and the Sertoli cells in the developing testes secrete testosterone and a nonsteroidal mÃ¼llerian inhibiting substance respectively; the latter, antimÃ¼llerian hormone (ATM) is a member of the transforming growth factor-Î² family of glycoprotein differentiation factors (13). The net effect of this secretory activity is to ensure the persistence, differentiation, and growth of the mesonephric ducts to form the male genital system and the regression of the mÃ¼llerian system. In the absence of a secreting testis (e.g., in a normal female fetus with ovaries or in a fetus with nonfunctioning gonads) the mÃ¼llerian structures persist, whereas the mesonephric ducts regress. The nonfused portions of the mÃ¼llerian ducts form the fallopian tubes; the fused segments develop into the uterus and probably the upper third of the vagina. Incomplete fusion of the caudal portion of the mÃ¼llerian ducts results in a spectrum of uterovaginal abnormalities (14).

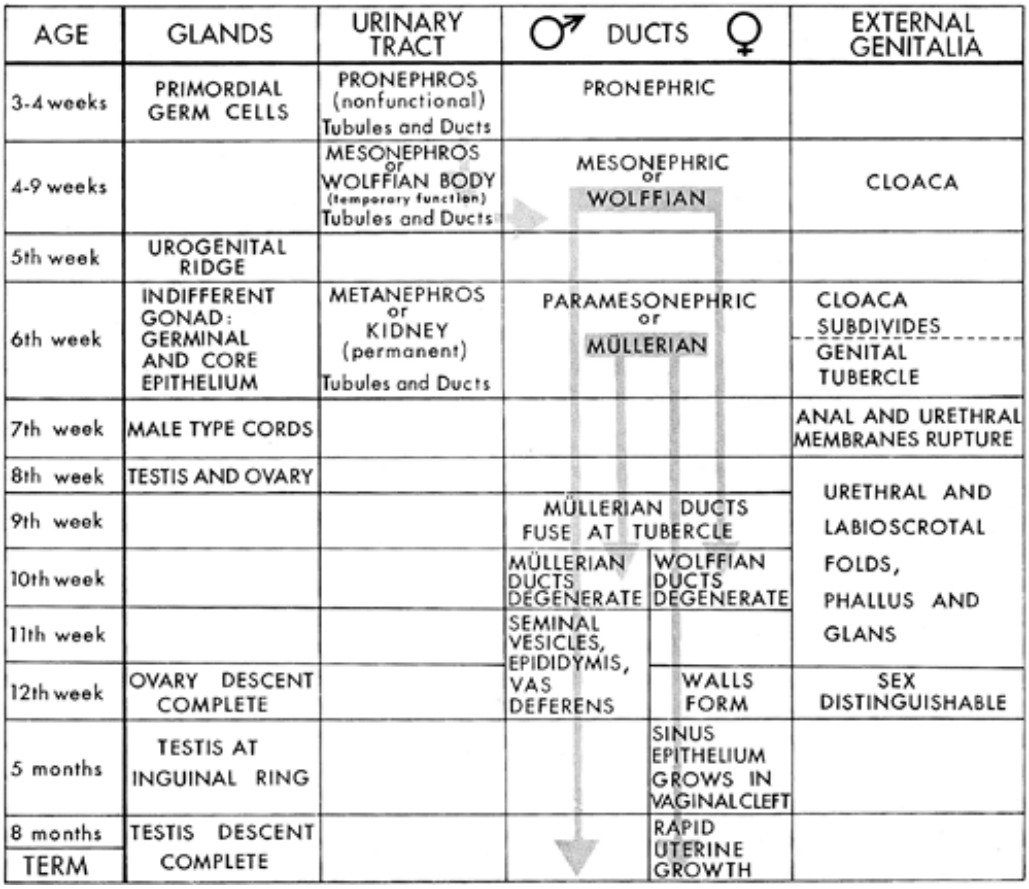

Figure 41.1 Chart showing interrelations and time sequence of events in the development of genitourinary system. Reprinted with permission from:

Ramsey E. Embryology and developmental defects of the female reproductive tract. In: Danforth DN, Scott JR, eds. *Obstetrics and Gynecology* . 5th ed. Philadelphia: JB Lippincott; 1986:106â€“119.

By the 21st week, the uterus and vagina are well formed. In contrast to the adult cervix, the cervix of the prenatal uterus is disproportionately large and makes up two thirds of the length of the organ. The second half of gestation is marked by uterine growth; from the 28th week to birth, a period of approximately 10 weeks, the fetal uterus doubles in size. However, the earlier cervicocorpus disproportion is maintained into childhood.

The events described above are driven, at least in part, by the

expression of secreted ligands of the wingless (WNT) gene family and transcriptional regulators of the homeobox (HOX) gene family (13 ,15).

Gross Anatomy

Premenarchal Uterus and Fallopian Tubes

Neonatal Period

At birth the uterus averages about 4 cm in length, and its bulk and shape are dominated by its disproportionately large cervix (the cervicofundal ratio is approximately 3â€“5:1) (Figure. 41.2). The impact of the maternal hormonal environment is reflected in the markedly thickened rugal vaginal mucosa typically present at birth and, to a certain extent, in the histologic appearance of the endometrium, which is most often proliferative or weakly secretory. Maternal estrogen also results in cervical squamous cell maturation with glycogen storage. These mucosal changes regress shortly after birth (16 ,17 ,18).

Infancy

Uterine growth continues into the second year of life, at which time it reaches a plateau that persists until the premenarchal growth spurt at about 9 years of age. Until approximately age 13, the cervix continues to account for greater than half of the uterine length.

Adult Uterus and Fallopian Tubes

General Relations and Attachments

The uterus is located anterior to the rectum and posterior to the bladder (Figure. 41.3). It is covered anteriorly and posteriorly by a reflection of pelvic peritoneum that continues laterally to form the anterior and posterior leaves of the broad

ligament. The posterior peritoneal reflection forms the uterine wall of the pouch of Douglas and covers a longer segment of the uterine isthmus than does the anterior peritoneal reflection. The tentlike broad ligaments house the major uterine vessels and the efferent lymphatic trunks; they also contain the fallopian tubes at their apices. Each ovary is attached to the ipsilateral uterine cornu by the utero-ovarian ligament, which is situated posterolateral and inferior to the uterine attachment of the fallopian tubes. The round ligaments arise anterolateral and inferior to the attachment of the fallopian tubes and pass anteriorly to insert into the canal of Nuck. These anatomic relations are of obvious importance

to the surgeon but also of value to the pathologist because they often enable proper orientation of the hysterectomy specimen. The anterior surface of the uterus is distinguished by its longer â€œbareâ€• region (i.e., lacking peritoneum) and the anteriorly directed stump of the round ligament. The posterior surface is more extensively covered by peritoneum, and the utero-ovarian ligament is attached to the posterior cornual aspect of the uterus. The uterus is anchored to its surroundings by a number of connective tissue bands; notable among them are the cardinal, uterosacral, and pubocervical ligaments (11 ,18 ,19 ,20).

Gross Anatomic Features of the Uterus

The adult nulliparous uterus is a hollow, pear-shaped muscular organ weighing 40 to 80 g and measuring approximately 7 to 8 cm along its long axis, 5.0 cm at its broadest extent (cornu to cornu), and 2.5 cm in anteroposterior dimension. These measurements vary considerably as a function of age, phase of the menstrual cycle, and parity. In general, high parity and youth are positively correlated

with increasing uterine size (21). The adult uterus consists of an expanded body, the corpus, and a smaller cervix. That portion of the corpus cephalad to a line connecting the origin of the two fallopian tubes is called the fundus. The cornua are the two lateral regions of the fundus associated with the intramural portion of the fallopian tubes. The remainder of the corpus tapers from the fundus into the isthmus or the lower uterine segment, which shares histologic features with both of the uterine segments that it bridges: the uterine corpus and the endocervix. The existence of an anatomically and functionally significant lower uterine segment has been disputed by some authorities (22). The uterine cavity has the approximate configuration of the uterus, but its internal dimensions are much smaller, reflecting the substantial thickness of the uterine wall. The cavity is triangular, and the apices of this potential space are continuous with the lumina of the fallopian tubes at the two cornua and with the endocervical canal at the internal os. The length of the cavity is approximately 6.0 cm. Again, these measurements vary considerably with the age and parity of the individual (23). The cervix is roughly cylindrical and normally measures approximately 3 to 4 cm in length (24). It is pierced through its center by the endocervical canal. Traditionally, the endocervical canal has been described as having an external os that opens onto the exocervix and an internal os that separates the endocervical canal from the endometrial cavity. Although the former is a reasonable anatomic landmark, the latter is not because grossly, the transition from endometrial cavity to endocervix is gradual, without abrupt anatomic demarcation between endocervix and endometrium. This is histologically mirrored by the gradual transition of the mucosa in this region from endocervical type to endometrial type. The mucosal surface of the endocervical canal is deeply clefted to form the plicae palmatae. The lateral connective tissue attachments of the uterus are referred to as the parametria; they contain vessels, nerves, lymphatics, and lymph nodes.

The normal myometrium consists of two strata: an outer

longitudinal muscle layer covering the fundus and an inner circular submucosal muscle layer extending to surround the internal os and the tubal ostia. There is an interposed thick middle layer, richly populated by vessels and composed of randomly interdigitating fibers (25). The magnetic resonance imaging (MRI) correlate of these layers is the outer zone and the submucosal low intensity halo â€œjunctional zoneâ€• (26 ,27). Functionally, the junctional zone appears to be more involved with menstruation while the outer zone assumes a prominent role in gestation and parturition.

Parenthetically, Toth has described two lateral subserosally situated longitudinal bands of distinctive muscle fibers, the fasciculus cervicoangularis (28 ,29). On occasion, epithelium that is immunohistochemically and histologically similar to cervical mesonephric remnants is present within this bundle, suggesting that these structures represent the vestiges of the wolffian (mesonephric) duct which is more commonly encountered in the cervical stroma (â€œmesonephric restsâ€•) and lateral vagina (Gardner's duct and derivative cysts).

Substantial deviations from the nulliparous adult uterus naturally occur throughout adult life. The uterus undergoes small-amplitude changes in size during the menstrual cycle, attaining its greatest volume during the secretory phase (27). During pregnancy, of course, the uterus enlarges much more dramatically to accommodate the growing conceptus. This growth is due largely to myocyte hypertrophy and hyperplasia, an increase in uterine vasculature, and in extracellular matrix; the net weight increases 10-fold during pregnancy. After delivery, uterine size rapidly decreases, and over the ensuing weeks a striking resorption of connective tissue occurs that is associated with a decrease in the size of individual myocytes (30). However, the uterus generally does not return completely to its nulliparous size and weight. Prior pregnancy (parity) can be deduced from several gross features. The multiparous nongravid uterus tends to weigh more in consequence of its thicker and more prominently layered muscular walls; this

increase in weight is proportional to the patient's parity (21). The vasculature of the multiparous uterus tends to be more prominent. The most suggestive changes of previous pregnancy, however, are seen in the cervix. The nulliparous circular small external os is transformed after pregnancy into a slit that forms prominent anterior and posterior lips. In addition, healed cervical lacerations may be pronounced, and enough endocervical tissue may reside on the exocervix to give it a red granular appearance near the os. With the waning of ovarian hormone synthesis during the menopausal years, the uterus involutes and atrophies. This is reflected by a decrease in its weight and its dimensions. On occasion the endocervical

canal is almost completely obliterated. Exogenous estrogens administered during this period sometimes maintain uterine weight artificially despite the loss of ovarian hormonal support.

Gross Anatomic Features of the Fallopian Tubes

The fallopian tubes are hollow, epithelium-lined muscular structures 11 to 12 cm in length that run through the apex of the broad ligament to span the uterine cornu medially and the ovary laterally. Each tube is divided into four anatomic segments. The intramural segment begins at the funnel-like uppermost recess of the uterine cornu and ends where the tube emerges from the uterine wall. The course of this 8-mm, pinpoint lumened segment varies from straight to highly convoluted (31). Beyond the uterine wall the proximal tube continues for 2 to 3 cm as the isthmus, a thick-walled, narrow-calibered segment that merges into a comparatively thin-walled expanded area, the ampulla. The distal tube ends in the trumpet-shaped infundibulum whose mouth opens into the peritoneal cavity and is fringed by approximately 25 fimbria. One of these, the ovarian fimbrium, attaches to the ovary. At the time of ovulation

the infundibulum forms a cap over the ovarian surface to create the ovarian bursa. The tubal mucosa and the underlying endosalpingeal stroma are thrown up into longitudinal, branching folds (the plicae) whose branches increase in complexity from the isthmus to the infundibulum. The plicae terminate in the fimbria. At the time of ovulation the fimbria sweep over the surface of the ovary to facilitate egg capture (13 ,32 ,33 ,34 ,35).

Uterine and Tubal Vasculature

The major arterial supply of the uterus derives from the right and left uterine arteries, which arise from the corresponding hypogastric (internal iliac) arteries. The uterine artery divides into ascending and descending branches laterally at the level of the uterine isthmus. The ascending uterine artery anastomoses freely with the ovarian artery (a branch of the aorta) in the mesosalpinx, whereas the descending branch anastomoses with the vaginal arterial supply. Both the ascending and descending uterine arteries give rise to a complex network of circumferentially arranged subserosal arteries: the arcuate arteries. These, in turn, give rise to a series of radial arteries that penetrate the myometrium. Each of these radial vessels branches, in the inner third of the myometrium, into straight arteries (supplying the basalis) and spiral arteries that become the spiral arteries of the endometrium (36 ,37 ,38).

A striking characteristic of the adult intramyometrial uterine arteries is their marked tortuosity. This, no doubt, has to do with the variation in uterine size during reproductive life. In the postmenopausal years, striking degenerative changes may be seen in the uterine arteries, including intimal proliferation, fibrosis, and medial calcification. The severity of these changes is typically out of proportion to degenerative changes in nonuterine arteries. The venous drainage of the uterus parallels its arterial supply.

Uterine and Tubal Lymphatics

Lymphatics are present in both the cervix and the corpus. In the endometrium these vessels are intimately associated with the glands of the functionalis. The myometrium and cervical stroma contain a complex labyrinth of lymphatics that course toward the subserosal plexus. The channels forming the latter ramify over the entire surface of the uterus, and the confluence of these channels forms the major efferent lymphatic trunks of the uterus. The chief interest in lymphatic drainage for the pathologist is as a guide to the dissemination of carcinoma. The major lymph node groups draining cervical and endometrial carcinoma are indicated in Figures 41.4 and 41.5 .

In both the mucosal and muscular layers, lymphatic anastomoses exist between the cervical and corpus systems, and on occasion cervical carcinomas may take advantage of this route to spread to the corpus. Whether the converse is true is unclear. Moreover, whether or not corpus carcinoma, once having invaded the cervix, then behaves like cervical carcinoma in terms of its lymphatic metastatic distribution is also unclear, even though this is a common clinical

assumption. Indeed, involvement of â€œcervical draining nodesâ€• by endometrial carcinoma does not necessarily imply cervical involvement. For further detail, the reader is referred to specialty works and textbooks of gynecologic oncology (39 ,40 ,41).

Tubal lymphatics accompany the ovarian vessels and drain into nodes near the right and left renal veins and the presacral and common iliac nodes. Lymphatic spread of tubal malignancy may reach extrapelvic sites early in its dissemination (42 ,43).

Uterine Cervix

The uterine cervix (or â€œneckâ€•) is the elongate fibromuscular

portion of the uterus that measures 2.5 to 3.0 cm. A part of this structure protrudes into the upper part of the vagina (vaginal part, portio vaginalis), whereas the remainder lies above the vaginal vault (supravaginal portion, portio supravaginalis). The outer surface of the vaginal portion of the cervix is known variously as the ectocervix or exocervix. It is covered, at least in part, by stratified squamous epithelium that is continuous with, and histologically identical to, the mucosa of the vaginal fornices. That portion of the cervix, in relation to the endocervical canal, is known as the anatomic endocervix. The endocervical canal, lined for the most part by mucin-secreting epithelium that blends at one end with the squamous epithelium of the exocervix and with the epithelium of the lower uterine segment at its other end, brings the vagina into communication with the endometrial cavity. The anatomic opening of the endocervical canal onto the exocervix is known as the external os. In parous women, this most often takes on a slitlike configuration that serves to divide the exocervix into anterior and posterior lips (18 ,44). This particular geometry is thought to be important in uterine function during gestation (45). The upper limit of the endocervical canal is known as the internal os. This is not a distinct orifice; rather, there is a gradual, funnel-shaped widening of the endocervical canal and a transition from endocervical epithelium into the endometrial epithelium of the lower uterine segment. The junction of the endocervical glandular mucosa with the squamous epithelium of the exocervix is known as the squamocolumnar junction. This junction does not always lie at the external os; in fact, the squamocolumnar junction typically is located on the exocervix, where it can easily be inspected with the culposcope. This is further discussed in the section devoted to the transformation zone.

The uterine cervix obviously plays an important role in the anatomic support of the internal genitalia and plays an active role in labor and delivery, but arguably its primary role is the production of cervical mucous. Cervical mucous acts as a functional gate that

prevents vaginal microorganisms from gaining access to the upper genital tract and (except for a small midcycle window before ovulation) denies sperm access to the uterus and fallopian tubes. At midcycle the chemical composition of the cervical mucous changes and its viscosity decreases. This has the effect of allowing the passage of sperm into the upper genital tract. These changes are the basis of the Spinnbarkeit and fern tests. In addition, the cervical mucous plays an important role in removing seminal plasma constituents (preventing sperm phagocytosis) and in providing a suitable environment for sperm storage, capacitation, and migration (46 ,47).

The following discussion first focuses on the epithelium of the exocervix, the endocervix, and the transformation zone and then turns to the stroma of the cervix and the changes that occur in the cervix during pregnancy.

Epithelium of the Exocervix

The squamous epithelium covering the exocervix is normally noncornified, and it grows, matures, and accumulates glycogen in its upper layers in response to circulating estrogens, most notably, estradiol (Figure 41.6). Because low blood levels of estrogen are the rule during childhood and the postmenopausal years, the squamous cells of the cervix do not proliferate or mature, and glycogen is not stored in the upper layers of the epithelium during these

periods unless estrogen is made available as a result of therapy or functioning ovarian tumors (18). In the immediate postnatal period, the squamous epithelium of the newborn cervix is fully mature due to maternal estrogen, but the epithelium quickly becomes atrophic and glycogen disappears as estrogen levels decrease.

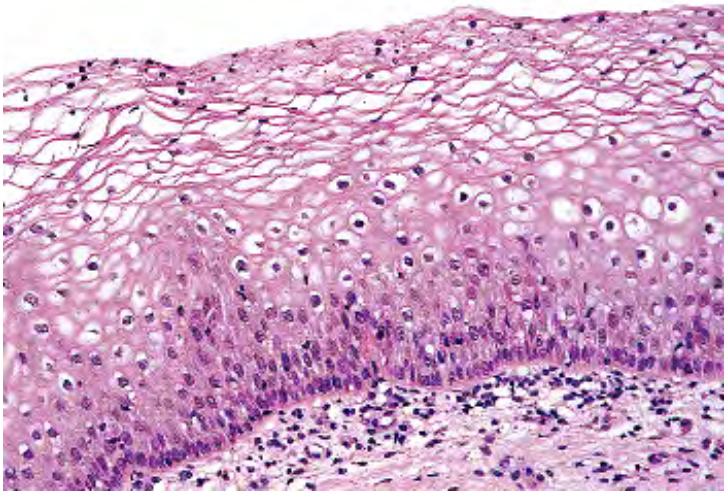

Figure 41.6 Mature squamous epithelium of the exocervix demonstrating a normal maturation sequence from basal cells to superficial cells. The cleared cytoplasm indicating glycogen storage should not be confused with koilocytosis.

The estrogenically stimulated cervical squamous epithelium of the sexually mature woman can be divided into three layers: the basal/parabasal cell layer, the midzone layer (or stratum spongiosum), and the superficial layer (Figure 41.6). The basal cell layer is composed of cells with scant cytoplasm and oval to cuboidal nuclei with dense chromatin. These cells are usually mitotically inactive and do not mark immunohistochemically with proliferation markers; for example, Ki-67 and proliferating cell nuclear antigen (PCNA) (48). The cells immediately above the basal layer comprise the lower portion of the midzone layer and are known as parabasal cells, a term often used in cytologic circles. The parabasal cells are somewhat larger than the basal cells due to their increased cytoplasm, and the nuclei have slightly less dense chromatin. In contrast to the basal layer, mitotic figures are usually present but are not abnormal or particularly numerous in the normal epithelium. This layer also displays proliferation markers (48). The midzone layer is composed of cells with even more abundant cytoplasm and somewhat smaller vesicular nuclei. These are known as intermediate

cells. Glycogen accumulates in most intermediate cells, and this imparts a finely granular or clear appearance to the cytoplasm. The superficial cells contain small, rounded, regular pyknotic nuclei, and their cytoplasm is abundant and clear as a result of even greater glycogen accumulation. Keratinization occurs in both the superficial and intermediate cells and renders them flat and platelike when they are spread on a slide. The cytoplasmic clearing characteristic of normal intermediate and superficial cells is often perinuclear. Because perinuclear clearing is also a feature of cells (koilocytes) infected by human papillomavirus (HPV), there is a potential for misinterpreting normal epithelial cells containing glycogen as abnormal. However, koilocytes not only feature perinuclear clearing of the cytoplasm, but their nuclei are larger, and these nuclei possess a more undulating nuclear membrane than do the nuclei found in intermediate and superficial cells (giving rise to the appearance of koilocytes sometimes described as â€œraisinoidâ€• or â€œpruneoidâ€•). Moreover, the nuclear chromatin of koilocytes has a ropy texture in contrast to the homogenous appearance of normal cells. The cervical squamous mucosa undergoes cyclic changes during the menstrual cycle similar to the estrogenâ€“progesterone-induced changes in the vaginal mucosa, although the cells composing the latter are a more liable index of hormonal status. During the luteal phase and pregnancy, when progesterone levels are high, there is a predominance of intermediate cells.

The exocervical epithelium in postmenopausal women (not receiving a supplement of estrogen therapy) is composed mainly of basal and parabasal cells that feature scant cytoplasm and little or no cytoplasmic glycogen (Figure 41.7). The cells may have the same degree of nucleus-to-cytoplasm ratio shift toward the nucleus as do the cells composing cervical intraepithelial neoplasia (CIN). Consequently, atrophic epithelium is a part of the differential diagnosis of CIN, and care should be taken when a diagnosis of CIN is contemplated in a postmenopausal woman. However, the basal

and parabasal cells in atrophic epithelia do not demonstrate the nuclear abnormalities and high mitotic index usually seen in the cells constituting the neoplastic epithelium in high grade CIN (high grade squamous intraepithelial lesionâ€”SIL).

Endocrine cells have been identified in the squamous epithelium of the exocervix by immunohistochemical techniques; their function is unknown, but they are thought to give rise to the rare cervical carcinoid tumors (49 ,50 ,51 ,52 ,53 ,54 ,55 ,56). Langerhans cells also are present in the ectocervical epithelium, as well as in the transformation zone (57 ,58 ,59). They

are involved in antigen presentation to T-lymphocytes. Melanin-containing cells have been reported in the cervical epithelium and provide a plausible cell of origin for the uncommon cervical melanoma and blue nevus (60).

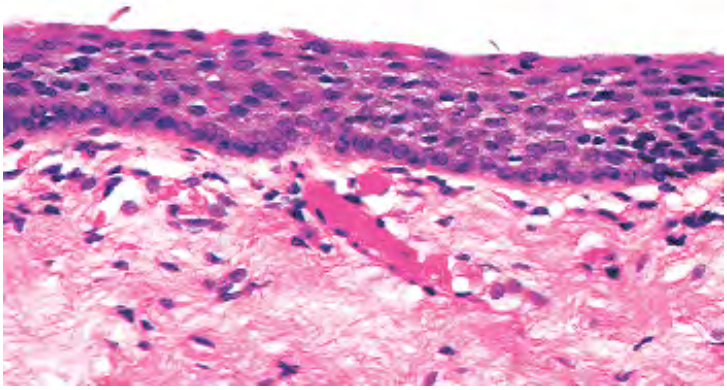

Figure 41.7 Postmenopausal atrophy of the cervical squamous epithelium. The immature cells can resemble the cells in high-grade squamous intraepithelial lesionâ€”SIL (cervical intraepithelial neoplasiaâ€”CIN).

Epithelium of the Endocervix

The anatomic endocervix extends from the external os to the internal os, but endocervical glandular epithelium is not exclusively limited to this anatomic area, particularly during the reproductive years. Rather, endocervical epithelium occupies significant regions of the anatomic exocervix during childhood and after the menarche. The shift of the endocervical epithelium out of the canal onto the exocervix is discussed in more detail below in the section devoted to the transformation zone.

The endocervix is lined by a single layer of mucin-secreting epithelium composed of cells with small, often basilar, nuclei above which is mucin-filled cytoplasm that imparts a â€œpicket fenceâ€• appearance (Figure 41.8). Goblet cells are sometimes encountered (Figure 41.9). The nuclei are generally small, elongate, and have rather dense chromatin. They tend to overlap one another. When the endocervical epithelium has been damaged and is regenerating, the nuclei may become larger and more rounded, but mitotic figures are difficult to find in nonneoplastic endocervical cells (61). If one encounters endocervical epithelium containing easily found mitotic figures, consideration should be given to the possibility of a pathologic process such as well-differentiated carcinoma or carcinoma in situ, particularly if the nuclei are enlarged and nucleoli are prominent. Nucleoli are usually not prominent in resting endocervical cells, but they may become so during regeneration, pregnancy, and neoplastic transformation. Mitotic figures may be found in the constituent glandular cells of cervical endometriosis.

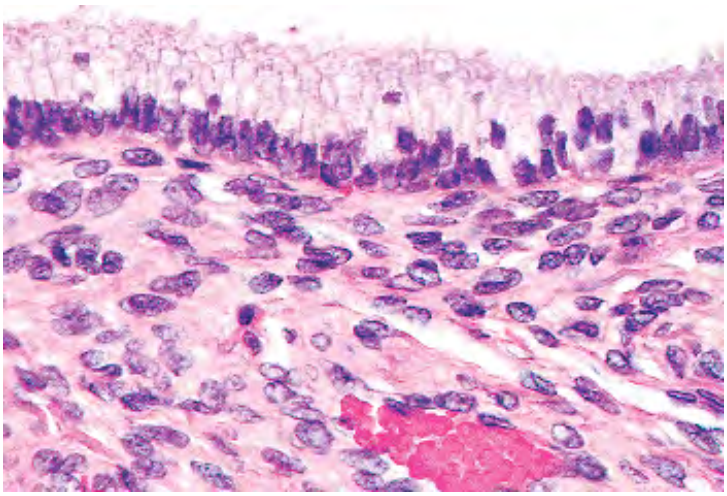

Figure 41.8 Normal endocervical mucosa with most nuclei in the characteristic basilar location. Enlargement of these nuclei and loss of apical mucin are features that should cause a closer inspection of the endocervical glands to ensure that neoplastic transformation is not present.

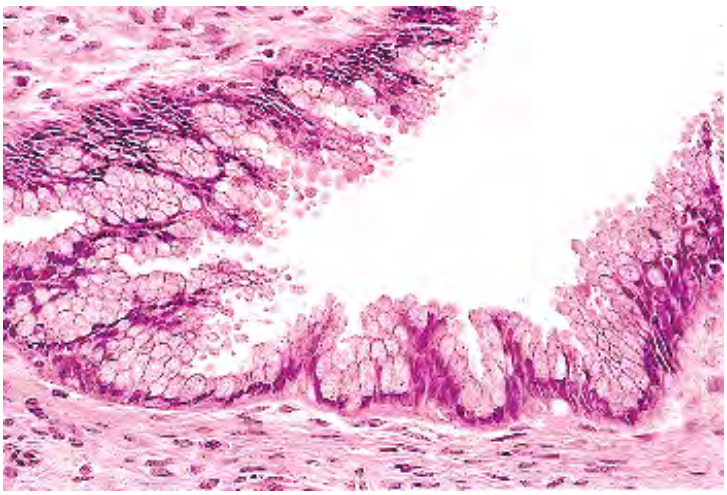

Figure 41.9 Goblet cells in the endocervix. Not infrequently, the nuclei of mucin-containing cells are displaced to the base of the cell and compressed by cytoplasmic mucin to produce a goblet cell. The presence of goblet cells and neuroendocrine cells in the normal endocervical mucosa tends to destabilize the conventional distinction in ovarian pathology between mÃ¼llerian (i.e., cervical) mucinous and intestinal mucinous differentiation.

Other types of cells may be identified in the endocervical epithelium. Ciliated cells are almost always present and can be a useful marker of a benign process when the appearance of the endocervical glandular epithelium raises concerns about well-differentiated adenocarcinoma (62). When ciliated cells are numerous, the term â€œciliary (or tubal) metaplasiaâ€• is often used (Figures 41.10A and 41.10B) (63,64,65,66,67,68,69). Ciliated cells themselves can develop enlarged dense nuclei and thus come to resemble neoplastic cells (Figure 41.10C). As a result, care should be taken to look for cilia before diagnosing in situ neoplastic transformation of the endocervix. Immunohistochemistry may be of aid in this distinction; Marques et al. found a combination of vimentin and carcinoembryonic antigen (CEA) helpful: adenocarcinoma in situ tended to be CEA positive and vimentin negative while the opposite was true for tubal metaplasia (70).

Subcolumnar reserve cells that have the potential to differentiate into ciliated and mucous secretory cells have been reported to populate the endocervix, even though there is evidence that the differentiated mucous cells are capable of division without the intercession of reserve cells (61,62). It is easy to confuse the lymphocytes that have populated the glandular epithelium with epithelial reserve cells (71).

Endocrine cells also are present within the endocervical epithelium. Their normal function is unclear, but it is generally held that they give rise to the endocrine neoplasms such as carcinoids and neuroendocrine carcinomas that occasionally are encountered in the cervix (49,54).

The endocervical epithelium not only lines the surface of the endocervical canal, it also dips, to a variable degree, into the underlying stroma to form elongate clefts (Figure 41.11A).

In histologic sections, these clefts typically are cut transversely,

imparting the false impression that true endocervical glands are present within the stroma. However, true glands have different epithelia lining their ductal and secretory portions. In contrast, the endocervical mucosa has a more or less uniform appearance whether it lines the surface or the deep-lying â€œglands.â€• Further evidence that these are not true glands was provided in an study conducted over 40 years ago by Fluhmann (72 ,73). He demonstrated, by means of serial sections and three-dimensional reconstructions, that what appeared to be endocervical glands within the stroma are actually complex protrusions of the endocervical lining that form clefts into the underlying stroma. When the endocervical epithelium lining the stromal clefts proliferates, side channels grow out from the clefts, giving rise to a histologic pattern that even more closely suggests acini of glands (Figure 41.11B). Fluhmann labeled these side channels â€œtunnel clustersâ€•; we also refer to them by a more euphonious designation: â€œFluhmann's lumens.â€• When secretion inspissates in tunnel clusters, either because of obstruction or because of the viscosity of the secretions, it appears as bright eosinophilic

material, an eye-catching pattern resembling the thyroid (see Figure 41.16). Having now discharged our obligation to anatomic accuracy, we shall continue to use the terms endocervical â€œgland(s)â€• and â€œcleft(s)â€• interchangeably.

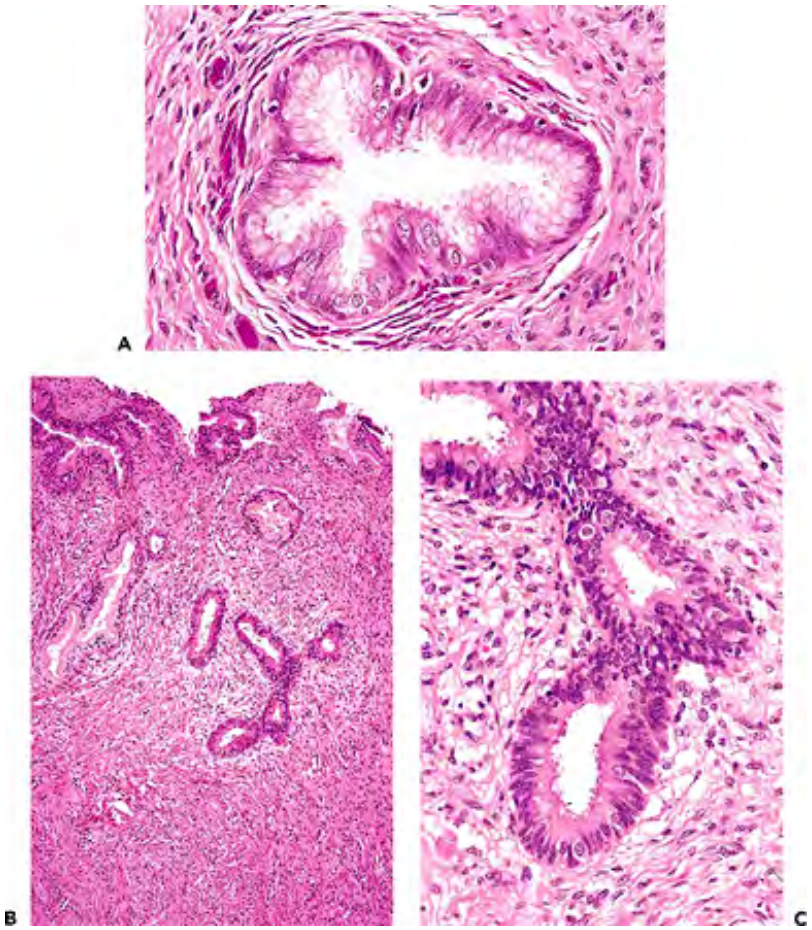

Figure 41.10 A . Ciliated cells in the endocervix. The normal cervical mucinous epithelium consists of an admixture of mucin-containing cells and a smaller population of ciliated cells. The population of ciliated cells undergoes cyclic variation with the menstrual cycle. B . Cervical tubal metaplasia. When ciliated cells are prominent they may simulate endocervical glandular dysplasia or carcinoma in situ. At low magnification the glands feature a prominence of nuclei, a feature shared with glandular dysplasia. C . Cervical tubal metaplasia. Higher magnification shows prominent cilia, the hallmark of ciliated cell metaplasia.

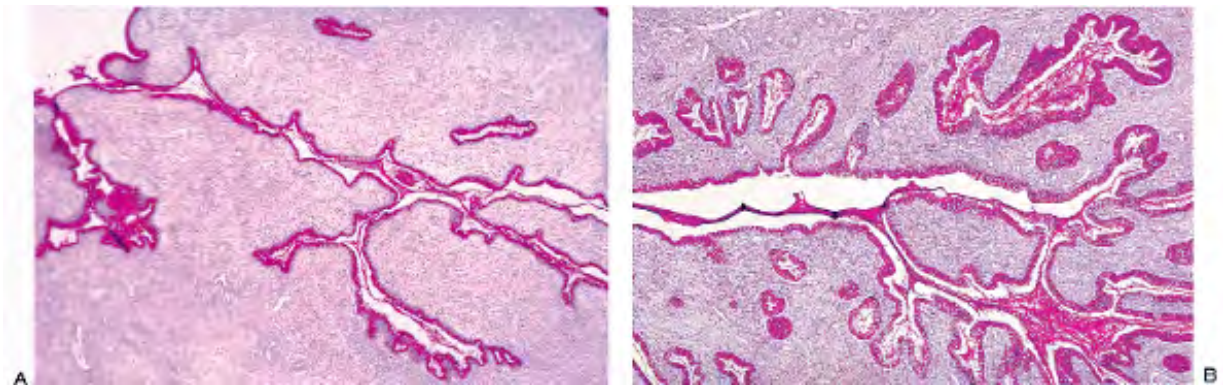

Figure 41.11 A . Tangential section of the endocervix stained with PAS to show how the gland clefts extend into the stroma and branch to form channels. B . When the endocervical mucosa undergoes hyperplasia and increases its surface area, as in pregnancy, the branches of the clefts proliferate and form even more collaterals (â€œtunnel clustersâ€•).

The depth to which benign endocervical glands can extend in the cervical stroma varies from cervix to cervix. They can be found as deep as 1 cm but usually are found at a depth of less than 5 mm (68 ,74 ,75). This anatomic variation becomes important when considering a diagnosis of â€œminimal deviation adenocarcinomaâ€• (76 ,77). In this form of adenocarcinoma, the cytologic features differ only minimally from normal endocervical epithelium and the diagnosis depends to a large extent on the identification of abnormally shaped glands at an inappropriate depth within the cervical stroma. The trick here is to compare the depth of the glands in question with noncontroversially benign glands in the immediate neighborhood. Additionally useful in establishing a diagnosis of malignancy is a search for glands around nerves or vessels, an irregular â€œlobster clawâ€• glandular configuration, and a granulation tissue stromal host response. We have not personally encountered a clinically malignant endocervical glandular proliferation that featured ciliated cells and, in our opinion, this finding argues strongly against a diagnosis of adenocarcinoma.

Endocervical cells show only minimal morphologic changes during the menstrual cycle, and even this amounts only to a shifting of the basally situated nuclei to a midcell position at the height of the proliferative phase. These minor cytologic changes are in contrast to the dramatic biochemical changes that occur within the endocervical cells during the menstrual cycle (46). Throughout the proliferative phase of the cycle, the endocervical cells secrete mucus of lower viscosity than at other times of the cycle. This is thought to aid penetration of the cervical canal by spermatozoa (46). When progesterone levels attain their zenith during the luteal phase, the endocervical glandular secretion becomes thick and scant. It is at this stage that the secretion may become inspissated and more visible in histologic sections. During pregnancy the number of tunnel clusters increases, and when this phenomena is extreme the term â€œcervical glandular hyperplasiaâ€• is often used (78). Pregnancy also causes the secretions of the endocervical cells to thicken and form a mucous plug that blocks the endocervical canal (47 ,79).

Epithelium of the Transformation Zone

The endocervical mucosa shifts over the various divisions of the anatomic cervix throughout life (18 ,44 ,80). At birth, the endocervical mucosa resides on the exocervix in two thirds of infants but it quickly moves back into the anatomic endocervical canal where in most girls it remains until near the menarche. After the onset of puberty, the endocervical mucosa again moves out onto the exocervix, usually more prominently on the anterior portion than on the posterior part (Figure 41.12A). The mechanism whereby endocervical mucosa changes location is apparently a mechanical one caused by swelling of the stroma of the cervical tissue in response to hormonal stimulation. As the lips of the cervix swell, they roll anteriorly and posteriorly, pulling the endocervical mucosa out of the canal onto the exocervix. The exposed endocervical tissue is often referred to as ectropion. Because the

exposed endocervical mucosa appears red and ulcerated to the naked eye, it also has been interpreted as an erosion. There is, in fact, no erosion of the mucosa, rather the process is one of physiologic ectopy. After menarchial ectropion occurs, the endocervical tissue is gradually replaced by squamous epithelium throughout the reproductive years. The area where the glandular tissue is being replaced by squamous epithelium is known as the transformation zone. The junction between the two types of epithelium is labeled the squamocolumnar junction (44 ,81).

Two squamocolumnar junctions are usually recognized (Figure 41.12B). The original squamocolumnar junction is the point where the native (original) exocervical squamous epithelium joins the endocervical glandular epithelium and is out on the exocervix during the reproductive years (80). This junction is usually sharply defined and it is anatomically fixed. After squamous metaplasia has replaced endocervical tissue, the original squamocolumnar junction is the fusion point between the new squamous epithelium laid down in the transformation zone and the native squamous epithelium (Figure 41.13). The functional squamocolumnar junction is the point of active replacement of columnar endocervical epithelium by squamous cells. This junction is often irregular and patchy, and it changes its contours and its locations during reproductive life. The functional squamocolumnar junction is usually implied when the term â€œsquamocolumnar junctionâ€• is used without a modifier and the area between the two squamocolumnar junctions is the transformation zone. During pregnancy, particularly the first pregnancy, even more endocervical tissue moves out onto the exocervix, enlarging the area of ectopic endocervical epithelium. This phenomenon also can occur during progestogen therapy.

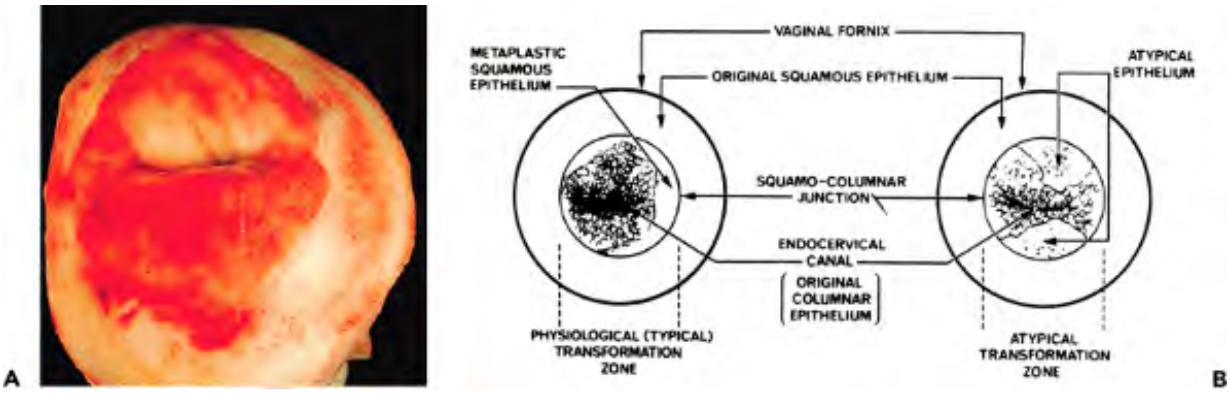

Figure 41.12 A . Multiparous cervix during the reproductive years. Note the slitlike configuration of the external os and the erythematous endocervical tissue out on the anatomic exocervix. This endocervical tissue undergoes conversion to squamous epithelium throughout the reproductive years. The squamocolumnar junction is visible as a sharp line between the white squamous epithelium and the erythematous glandular tissue. B . Diagram of the cervix demonstrating the transformation zone. On the left is a typical transformation zone in which metaplastic squamous epithelium is replacing endocervical columnar epithelium. â€œSquamocolumnar junctionâ€• refers to the original squamocolumnar junction. On the right is a nontypical transformation zone in which the metaplastic process is composed of dysplastic squamous cells and hence the process is cervical intraepithelial neoplasia. Reprinted with permission from: Fox H. *Haines and Taylor Obstetrical and Gynaecological Pathology* . 3rd ed. Philadelphia: WB Saunders; 1987.

Because endocervical glandular epithelium is present on the exocervix, the transformation zone can be visualized with the aid of a colposcope. This is fortunate because neoplastic change begins most commonly in the transformation zone, and neoplastic transformation is accompanied by structural alterations that can be recognized using the colposcope. The combination of papilloma virus detection, cytologic preparations, colposcopic examination, biopsy, and local destruction of intraepithelial abnormalities in the

transformation zone under colposcopic visualization is a powerful tool for the early detection and successful treatment of in situ neoplastic processes involving the cervix.

In the latter years of reproductive life the functional squamocolumnar junction reaches the area near the anatomic external os and, reversing its menarchal journey, begins to move up the anatomic endocervical canal. By the perimenopausal years, the squamocolumnar junction is usually concealed within the endocervical canal above the external os.

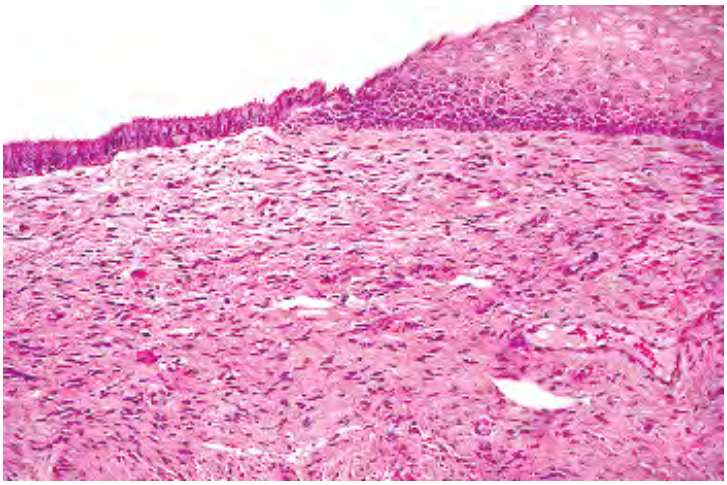

Figure 41.13 Squamocolumnar junction with a distinct transition from mature squamous epithelium on the right to endocervical glandular tissue on the left. Such a sharp change can be seen at the original squamocolumnar junction as well as the junction formed by squamous epithelium with endocervical tissue in the transformation zone when squamous epithelium is mature.

Two mechanisms are thought to be operative in transforming endocervical mucinous epithelium to squamous epithelium: squamous epithelialization and squamous metaplasia (3). The first involves the direct ingrowth of mature native squamous epithelium from the exocervix. This process is usually labeled â€œsquamous epithelialization.â€• During squamous epithelialization, mature

squamous cells come to lie beneath the endocervical glandular cells. They push the endocervical cells off the basement membrane, and gradually the columnar cells degenerate and are sloughed. Squamous epithelialization initially spares the openings of the underlying endocervical glands, and at this stage the openings to the glands have the appearance of pores when examined with the colposcope. Eventually, the ingrowth of squamous epithelium involves the orifices of the glandular clefts and then it can extend for varying distances down into the cleft spaces (Figures 41.14 and 41.15). When this process involves the orifice, it may plug the opening and if the mucinous epithelium below continues to secrete, a mucin-filled cyst (Nabothian cyst) or tunnel clusters filled with eosinophilic secretion result (Figure 41.16). If squamous epithelialization involves the cleft and its ramifying tunnels, squamous epithelium will be surrounded by endocervical stroma. Consequently, histologic sections taken in an area of squamous epithelialization may show Nabothian cysts, mucification of tunnel clusters, and/or islands of benign squamous epithelium in the stroma beneath the surface epithelium.

When the endocervical clefts undergo squamous epithelialization, care must be taken not to confuse the deep-lying benign squamous cells with invasive carcinoma. Although the cells in squamous epithelialization may have enlarged nuclei and prominent nucleoli, they do not demonstrate the anaplasia, the pleomorphism, the chromatin abnormalities, or the abnormal mitotic figures characteristic of invasive carcinoma. Moreover, the benign cells conform to the rounded configuration of the preexisting cleft and do not infiltrate the stroma irregularly. Typically there is no granulation tissue host response to squamous epithelialization, although chronic inflammation may be present. If squamous epithelialization involves tunnel clusters, small groups of squamous cells come to lie deep within the cervical stroma, imparting an architectural pattern that even more resembles infiltrating squamous cell carcinoma. Squamous epithelialization seems to be stimulated by chronic

inflammation and local trauma, including cauterization or laser surgery.

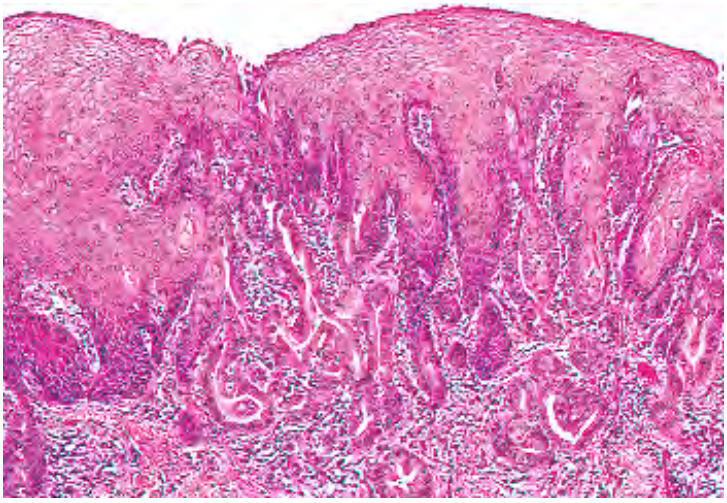

Figure 41.14 Squamous epithelialization of the endocervix. Note the mature squamous epithelium extending into endocervical gland clefts (PAS positive glandular structures surrounded by stroma). This process can mimic invasive carcinoma.

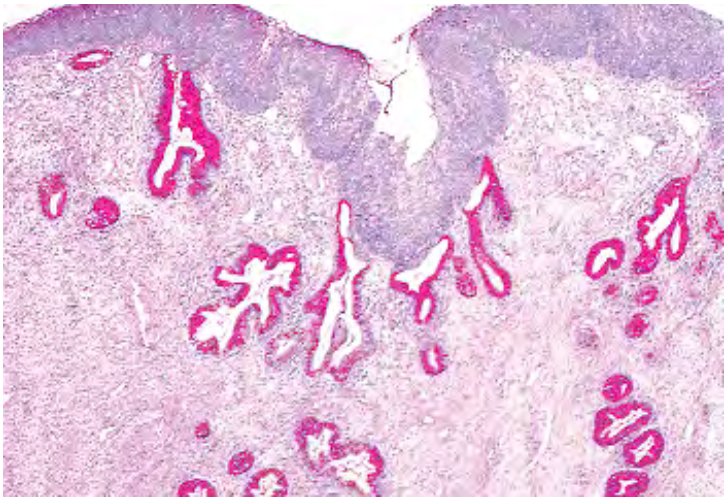

Figure 41.15 Conversion to squamous epithelium in the cervix may occur more rapidly on the surface than in the clefts, causing squamous epithelium to overlie endocervical gland clefts. When the newly laid down squamous epithelium blocks the orifices of the clefts, nabothian cysts or mucification of tunnel clusters, as seen in

Figure 41.16 , may result.

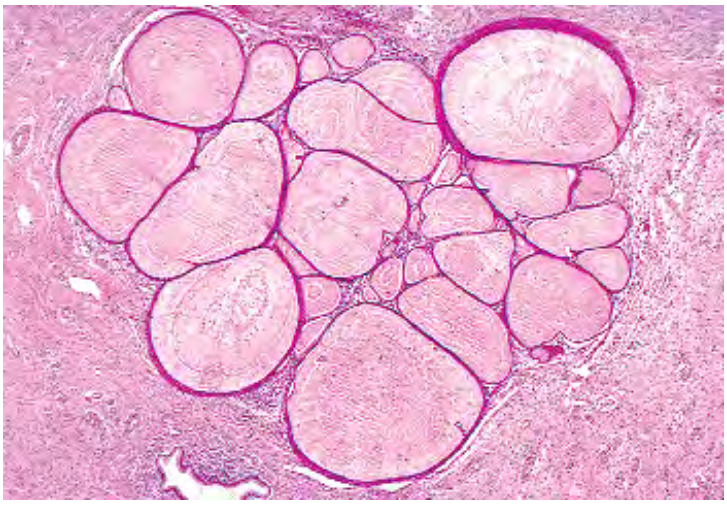

Figure 41.16 When the newly formed squamous epithelium in the transformation zone covers the endocervical gland cleft orifices and secretion continues, the tunnel clusters fill up with secretion that may become inspissated (â€œmucificationâ€•).

The second mechanism thought to contribute to the conversion of endocervical mucinous epithelium to squamous epithelium entails first the proliferation of endocervical â€œreserve cells,â€• and then the differentiation of these cells into squamous cells rather than mucin-producing cells (82). This process, known as squamous metaplasia or prosoplasia, can be distinguished from squamous epithelialization because, unlike the cells in squamous epithelialization, the reserve cells initially do not have squamous characteristics; rather, they appear as cuboidal cells with round nuclei growing beneath the mucinous epithelium (Figure 41.17). In fact, these cuboidal cells are identical in appearance to the basal or parabasal cells of the squamous epithelium. After the reserve cells proliferate and stratify, they differentiate into squamous cells that initially have only slightly increased amounts of cytoplasm (immature squamous metaplasia). Later the cells may fully mature

to glycogen-containing squamous cells indistinguishable from the superficial cells of the exocervix (see Figure 41.13). Confusingly, â€œsquamous metaplasiaâ€• is commonly used as a generic term for both metaplasia and squamous epithelialization.

Immature squamous metaplastic cells without fully developed squamous characteristics or glycogen accumulation can come to occupy most or all of the thickness of an epithelium (83 ,84) (Figure 41.18). Because fully mature squamous cells are not present toward the surface and because the cytoplasm of the immature cells is relatively scant and its nuclei often are elongate, immature squamous metaplasia can bear a close resemblance to high grade intraepithelial neoplasia (dysplasiaâ€“carcinoma in situ). However, the nuclei in immature squamous metaplasia are uniform, chromatin abnormalities are minimal at most, and nuclear contours are usually smooth. Although mitotic figures may be present, in immature squamous metaplasia abnormal forms are not found. The possibility of immature squamous metaplasia should be considered in each case where a diagnosis of intraepithelial neoplasia is contemplated.

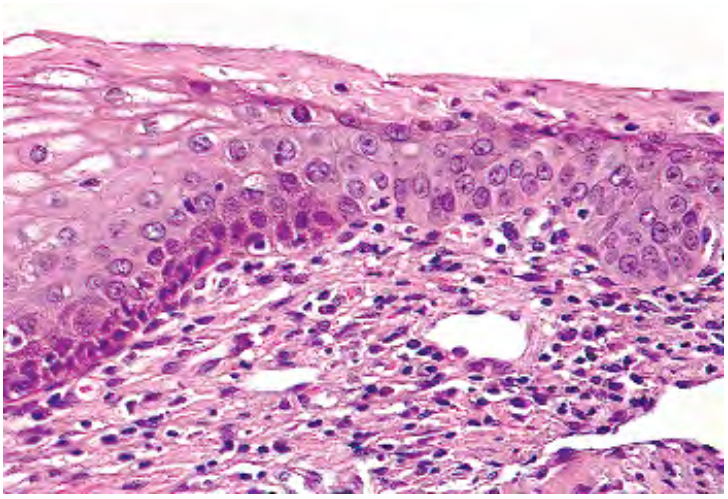

Figure 41.17 Functional squamocolumnar junction with metaplastic epithelium on the right. Note that in this example maturation has proceeded to the parabasal cell stage with abrupt keratinization rather than the normal maturation sequence to superficial cells as

seen on the left.

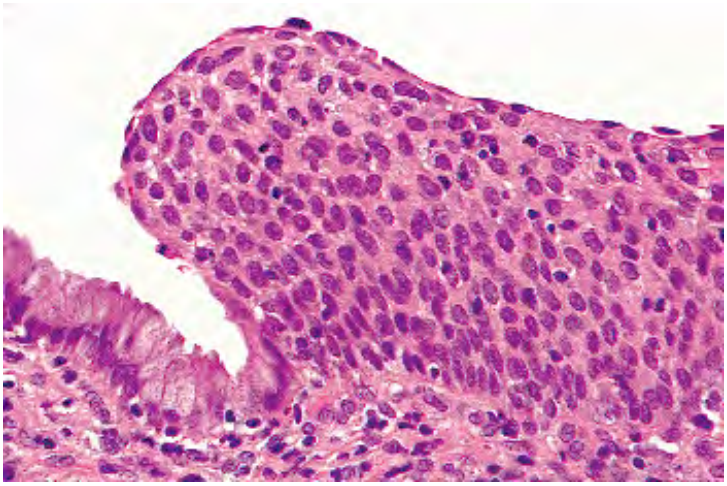

Figure 41.18 Immature squamous metaplasia on the right. The constituent cells do not demonstrate evidence of maturation and are similar to cells normally present in the basal layer of squamous epithelium. This type of metaplasia can be confused with high-grade squamous intraepithelial neoplasia.

Squamous metaplasia is usually patchy, giving rise to the characteristic irregularity of the functional squamocolumnar junction (Figures 41.19A, B). As squamous metaplasia proceeds, the islands of squamous cells form bridges to other centers of metaplasia, ultimately producing a solid area of squamous epithelium.

Whatever the mechanismâ€”either squamous epithelialization or squamous metaplasiaâ€”squamous replacement of mucinous epithelium on the exocervix is a normal process that must be distinguished from in situ and invasive neoplasms. Features that are often found in neoplasia but not in metaplasia or epithelialization are moderate to marked pleomorphism, lack of maturation sequence (this may be present in immature squamous metaplasia), irregular nuclear outlines, and abnormal mitotic figures. Nucleoli are usually inconspicuous in cervical intraepithelial neoplasia but are often prominent in metaplasia, and epithelialization (a notable exception

is immature squamous metaplasia), and reactive changes in response to cervicitis.

Cervical Stroma

In contrast to the wall of the uterine corpus, which is predominately muscular, the stroma of the exocervix is mainly fibrous tissue admixed with elastin through which run infrequent strands of smooth muscle (85 ,86 ,87 ,88). A large number of vessels course through the stroma. A rich capillary network interfaces with the epithelium at the stromalâ€“epithelial junction. This interface is irregular and features

fingers of connective tissue containing vessels overlain by a squamous cell mucosa of variable thickness. Much of the endocervical stroma is also fibroelastic tissue, but at the upper end of the endocervix the superficial fibrous stroma blends imperceptibly into the endometrial stroma of the lower uterine segment. Consequently, the superficial stroma of the upper endocervix and the stroma of the lower uterine segment has a hybrid endometrialâ€“cervical appearance. This can cause localization problems when it is important to determine whether a neoplastic process in a curettage specimen involves the endometrium or the endocervix, or both. We think the presence of unequivocal endometrial stroma, as determined by high cellularity (closely packed nuclei), should be present before interpreting tissue as originating from the endometrium on the basis of the stroma alone. Of course, if one type of normal glands is present, whether endocervical or endometrial, these glands can suggest the origin of the tissue, but both types of glands or even hybrid glands may be present in the transition area between the endocervix and the lower uterine segment. The endocervix contains a greater number of smooth muscle fibers in its deeper stroma than does the exocervix, and in the lower uterine segment these blend into the myometrium.

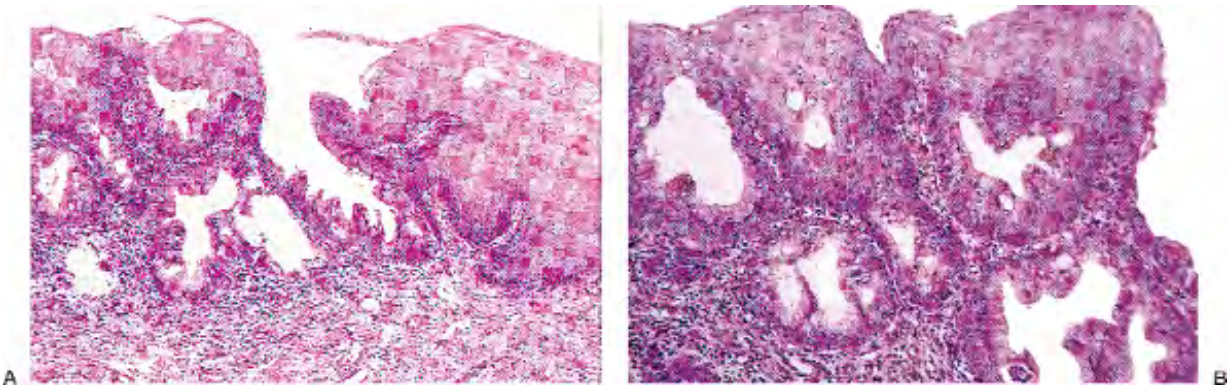

Figure 41.19 A . Islands of metaplastic squamous epithelium in the transformation zone at the functional squamocolumnar junction. These islands will eventually coalesce. B . Higher power photomicrograph of the area of squamous metaplasia demonstrated in A.

The cervix bridges the sterile environment of the uterine cavity and the microbiological jungle of the lower genital tract. It is not surprising that this important immunologic role (both humoral and cellular) would be marked by a conspicuous lymphoid presence (44). Thus, large numbers of T-lymphocytes normally populate the endocervical stroma (89). B-lineage lymphoid cells, manifest as either plasma cells or germinal centers, are also commonly encountered.

In addition, dendritic cells are numerous in the cervix; a subset of these are Langerhans cells (immature dendritic cells that express MHC class II antigens and the CD4 receptor on their surface) that are involved in internalizing antigen and presenting it to T-lymphocytes in the regional lymph nodes (58 ,90 ,91 ,92).

The relevance of these observations to the surgical pathologist is chiefly to discourage the overuse of â€œchronic cervicitisâ€• ; the presence of lymphoid tissue in the cervix is as normal as its presence in the small intestine.

In our opinion, a diagnosis of chronic cervicitis should be withheld unless the lymphoid infiltrate is very heavy and/or lymphoid nodules

are numerous. Particularly important for the diagnosis of chronic cervicitis are large numbers of plasma cells. Scattered plasma cells are normal in the cervix. Acute cervicitis is not uncommon, but true inflammatory erosion or microabscesses are rare in the cervix.

Lymphocytes also may migrate into the endocervical epithelium, and in this location they may assume the appearance of â€œcleared cells.â€• Such cells have been misconstrued as â€œreserveâ€• cells in the past (71).

Remnants of the wolffian ductâ€”commonly known as mesonephric restsâ€”can be found in the endocervical stroma of the lateral portions of the cervix in about a third of women (93) (Figure 41.20A, B). Usually these are deep in the stroma, but occasionally they are found near the surface and they can even blend with the endocervical gland clefts. Mesonephric rests are tubular structures lined by a single row of cuboidal cells with a central, round, cytologically bland nucleus. Typically the tubules form lumens that contain hyalin-like, eosinophilic secretions. Architecturally, there is usually a central elongate duct surrounded by smaller tubules. The combination of deep stromal location, the hyalin-like secretions, and the cuboidal cells usually serves to make identification of mesonephric rests straightforward. Even though tunnel clusters may ramify from a central cleft and contain eosinophilic secretion, they are lined by endocervical mucin-producing cells. The importance of this vestigial structure lies in its mimicry of

well-differentiated adenocarcinoma. Mitotic figures are usually absent in mesonephric rests and the chromatin of the cells is bland. Moreover, mesonephric rests do not exhibit the raggedly infiltrative growth of carcinoma even though they are located deep in the stroma. Rarely, atypical hyperplastic and neoplastic processes may involve mesonephric remnants (78 ,93 ,94). Mesonephric proliferations, benign and malignant, often express CD10 (95 ,96).

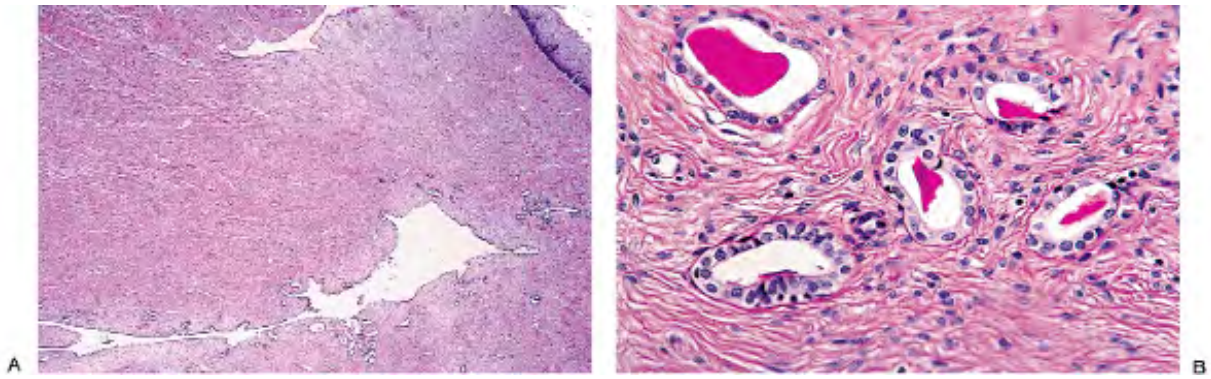

Figure 41.20 A . Mesonephric remnants in the cervix. A long cleftlike space deep in the stroma surrounded by tubules is the characteristic architectural finding. B . Ducts lined by bland cuboidal cells containing lumenal PAS-positive eosinophilic secretion are key features of mesonephric remnants. The blandness of the constituent cells and the organization around a central cleft are the most helpful features in distinguishing this from well-differentiated adenocarcinoma.

Multinucleated giant cells rarely are found in the normal superficial endocervical stroma. These cells have enlarged and sometimes bizarre-shaped nuclei with smudged chromatin similar to those seen in fibroepithelial stromal polyps (97). They should not be mistaken for a neoplasm (98 ,99 ,100).

Cervix During Pregnancy

During pregnancy the endocervical epithelium proliferates so that its mucus-secreting surface increases. This proliferation leads to both the formation of polypoid protrusions of endocervical epithelium into the endocervical canal and an increased number of tunnel clusters budding off preexisting clefts within the cervical stroma. The overall impression is one of an increase in the amount of endocervical tissue and, consequently, this normal process is often termed â€œendocervical glandular hyperplasia,â€• or when numerous small glands are packed together, â€œmicroglandular

hyperplasia.â€• Identical changes can be produced by artificial progestogens. The endocervical mucus during pregnancy is thick and functions as a plug to seal off the endometrial cavity from the vagina (22 ,101). Arias-Stella reaction may be seen in the endocervical glandular cells (102). As in the endometrium, the large cells with prominent nucleoli characteristic of the Arias-Stella reaction can raise concern about clear cell carcinoma, but the absence of mitotic figures and the gestational setting should quickly eliminate this possibility.

The stroma of the cervix undergoes a complex series of biochemical and biomechanical changes during pregnancy and parturition that taken together are known as cervical â€œripeningâ€• (103). The initial change seems to be extensive destruction of collagen fibers by various collagenases accompanied by the accumulation of gel-like acid mucopolysaccharides. This process causes the cervix to soften, a process that reaches its zenith immediately before parturition. As a result, the cervix is easily effaced by the presenting part of the emerging infant. Thus, the usually cylindrical cervix is transformed into a thin saccular structure. The increased fluid in the cervical stroma during pregnancy causes the cervical lips to roll further out into the vagina, everting more of the endocervical mucosa beyond the external os. Squamous epithelialization and metaplasia rapidly ensue, and at the time of delivery there is often considerable immature squamous epithelium in the transformation zone. As noted previously, the cells in immature squamous metaplasia can closely resemble those found in intraepithelial neoplasia, so caution should be exercised when examining cervical specimens taken from pregnant women.

The cervical stromal cells, particularly those near the surface of the endocervical canal, may undergo decidual change during pregnancy (Figure 41.21A, B). Cervical decidual reaction is typically patchy, and at low power this focal replacement of the cervical stroma by aggregates of epithelioid cells can resemble invasive large cell nonkeratinizing carcinoma. Awareness of this physiologic process

during pregnancy and close attention to the cytologic features of the suspect cells should avoid misdiagnosis (104).

Normal findings in the cervix that have relevance to histopathologic differential diagnosis are presented in Table 41.1 .

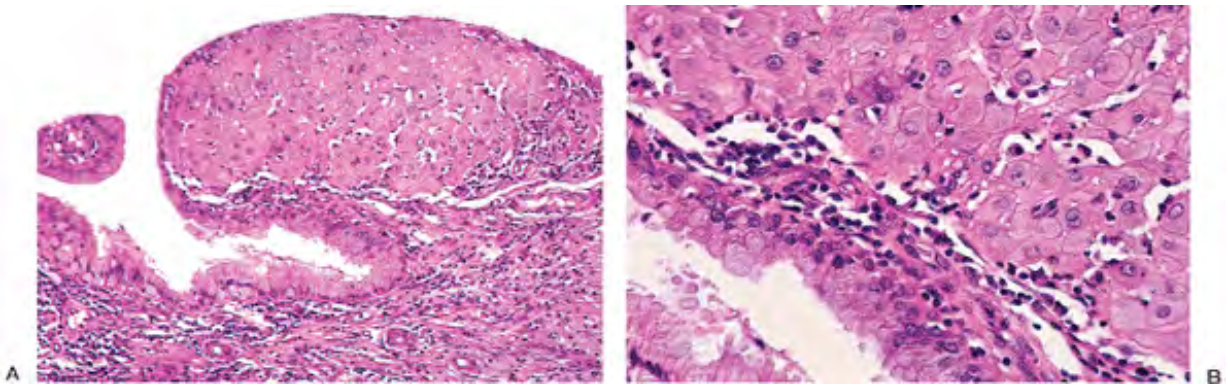

Figure 41.21 A. and B . Decidual reaction in the cervix. The sheetlike arrangement of the cells can mimic squamous cell carcinoma, but the nuclei are bland (see Figure 41.18).

Endometrium

Tissue Sampling and Associated Problems

A variety of endometrial tissue sampling techniques are available to the clinician. These techniques differ with respect to their indications, their limitations, and their associated complications (105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113). Endometrial curettage (cervical dilation and endometrial curettageâ€”D and C) entails the removal of most of the uterine mucosa by scraping with a sharp curette. Under ideal circumstances, the excision is complete or nearly complete. Endometrial biopsy (EMB) involves the removal of a more limited sample of tissue than does the complete curettage

and is performed with a smaller curette. Single strips of endometrium are usually taken from both the anterior and the posterior fundal surfaces. Even though the sample is limited, the accuracy of diagnosis approximates that of the D and C. The chief advantage of this technique is that it does not require cervical dilation (and hence does not require anesthesia). EMB thus combines convenience and low cost, with little sacrifice in diagnostic accuracy. The major limitation of EMB lies in its inherent potential to miss focal lesions, such as polyps and localized carcinomas. Accordingly, when carcinoma is suspected clinically, a negative biopsy must be followed by a complete D and C, because only this technique ensures the absence of carcinoma. Hysteroscopy in combination with endometrial sampling is thought by some to increase the detection rate of uterine abnormalities (114); others disagree (115). If EMB is performed as part of an infertility workup (but see below), tissue should be obtained well into the presumed secretory phase; that is, 2 to 3 days before the time of the next menstrual period as estimated by clinical and laboratory findings. Although principle biopsy in the late luteal phase might destroy an early gestation, in practice this seems not to be the case (116).

Three artifacts of sectioning and tissue preparation should be mentioned at this point. A frequent finding in endometrial curettings is the â€œtelescopedâ€• gland, which is characterized by an â€œinside-outâ€• gland within the lumen of a gland with a normal configuration. This artifact is seen when an intussuscepted or telescoped gland (produced by the traumatic removal of the tissue) is cross-sectioned, and it occurs most frequently in straight glands. Another artifact is the result of sectioning and involves the tangential cutting of a gland to produce a â€œpseudo-gland-within-glandâ€• pattern. Confusion with adenocarcinoma can be avoided by attention to cytologic detail, comparison with surrounding glands, knowledge that the gland-within-gland pattern in carcinoma is usually extensive, and awareness of this topologic problem. A third artifact involves tangential sectioning of the endometrial surface to

produce pseudocystic and pseudobudded glands. Poor fixation can sometimes result in the retraction of endometrial glands from their surrounding stromal envelope. Moreover, cytoplasmic vacuolization may be a result of autolysis and can simulate early secretory vacuolated epithelium.

Histology of the Normal Endometrium

The normal endometrium has a multiplicity of constantly changing normal patterns that depend on the nature and intensity of ovarian hormonal stimulation. The purpose of this section is to analyze the morphology of the normal nongravid endometrium in some detail from three points of view. First, we discuss regional variations, then the individual components of the endometrium; finally, using this background, we describe the temporal variations in the histology of the endometrium that occur throughout life.

Deeply situated normal endocervical gland clefts or Nabothian cysts
Minimal deviation adenocarcinoma (MDC)
Lobster claw configuration in MDC
Ciliated cells in benign proliferations and almost always absent in malignant cervical glandular proliferations
68 ,74 ,75 ,262
Easily found mitotic figures in endocervical epithelium
Adenocarcinoma: invasive or in situ
Cytologic atypia in carcinoma
Compare problematic epithelium with normal epithelium elsewhere

In normal endocervical epithelium mitotic figures are rare. In squamous metaplasia and regenerating cervical epithelium mitotic figures may be numerous but abnormal forms are not present.

Mesonephric remnants: mesonephric remnants, especially when florid, must be distinguished from invasive adenocarcinoma, especially minimal deviation adenocarcinoma.
Minimal deviation adenocarcinoma (MDC): mesonephric carcinoma
MDC often has an associated superficial component of ACIS
The glands of mesonephric remnants are rounded and smooth contoured; those of carcinoma are usually jagged and infiltrative; the glands of Mesonephric remnants branch of a central, elongate, ductal structure, those of invasive adenocarcinoma are haphazard and lack a central originating duct.
93
Decidual reaction
Large cell nonkeratinizing squamous cell carcinoma
Mitotic figures, cytologic atypia in carcinoma

Arias-Stella reaction
Clear cell carcinoma of the cervix/vagina
Arias-Stella reaction usually does not feature mitotic figures that are easily found in clear cell carcinoma.
Maternal DES therapy was discontinued in the 1960s
102 ,223
Lower uterine segment vs. endocervical fragments: can make a difference when carcinoma (endocervical vs. endometrial) is found in curettings.

Differential curettage; imaging studies.
Immunohistochemistry (stains for CEA and p16 often positive in endocervical carcinoma and negative in endometrial). Are not entirely reliable in the individual case but may be helpful.

Squamous metaplasia and epithelialization involving cervical gland clefts
Invasive carcinoma
Assess nuclear features and evaluation for the presence or absence

of infiltration

Endometriosis: benign endometrial glands and stroma
Adenocarcinoma: when stroma is inconspicuous
Adenosarcoma: look for stromal mitotic figures
Think of the possibility of endometriosis
Look for the missing component in additional levels
Cytologic atypia is usually minimal in endometriosis but mitotic figures may be present
263 ,264 ,265
Microglandular adenosis and endocervical glandular hyperplasia
Adenocarcinoma
Prominent nucleoli and abnormal division figures are features of carcinoma. Easily found mitotic figures almost always are a carcinoma feature.
266 ,267
Immature squamous metaplasia
High-grade SIL: may mimic because nuclei of the cells are large and cytoplasm is relatively scant.
Look for nucleoliâ€”often present in metaplasia, but often inconspicuous in CINâ€”and abnormal mitotic figures and abnormal chromatin patterns. Nucleoli may not be prominent *immature* squamous metaplasia
84
Glycogen storage in superficial squamous cells
Koilocytosis (HPV infection).
Koilocytic nuclei: (1) enlarged, (2) irregular nuclear membranes, (3) dense ropy chromatin.

Tubal metaplasia: endocervical pithelium lined by prominent and numerous ciliated cells may suggest adenocarcinoma in situ or endometrioid carcinoma
Cervical adenocarcinoma in situ
Numerous mitoticfigures and abnormal mitotic figures are features

for adeno CIS not tubal metaplasia. Look for ciliated cells; if numerous, the process is almost surely benign.
63 ,64 ,65 ,66 ,67 ,69
Multinucleated stromal giant cells: these may be a normal finding; probably myofibroblastic cells
Neoplasm, particularly sarcoma.
Granulomatous inflammation
Look for abnormal mitotic figures, high cellularity, and granulomas.

Finding	Diagnostic Confusion	Suggestions for Resolution	References

Table 41.1 Normal Findings in the Cervix that have Relevance to Histopathologic Differential Diagnosis *(see text for Additional Differential Diagnostic Clues)*

Regional Variations

The uterine lining can be divided into two regions on the basis of its morphology: the mucosa of the lower uterine segment and the mucosa of the corpus proper. The mucosa of the lower uterine segment (isthmus) is in general thinner than the fundal mucosa. The glands and stroma tend to be only sluggishly responsive to hormonal stimulation, and in consequence this portion of the endometrium most often lags behind the rest of the endometrium in its development. The morphologic transition from endocervical mucosa to lower uterine segment mucosa is gradual, and in fact the hybrid endocervicalâ€“endometrial appearance of both the glands and the stroma of the lower uterine segment serves to identify this

zone in endometrial curettings (Figures 41.22).

The major portion of the uterine lining, the corpus mucosa proper, is normally fully responsive to hormonal stimulation. Two layers can be readily identified within the endometrium throughout this region: the lowermost is labeled the basalis and the overlying one the functionalis. The basalis is that zone of weakly proliferative glands and associated dense-spindled stroma immediately adjacent to the myometrium (Figure 41.23A, B). Characteristically, the junction of the basalis and myometrium is irregular, and smooth muscle and endometrial stroma interdigitate and blend together at this point (Figure 41.24). When florid, this irregularity may give the false impression that endometrial tissue is pathologically isolated within the myometrium. This deception is particularly important when evaluating the presence or absence of superficial myometrial invasion

in patients with endometrial adenocarcinoma. Of less importance is the confusion it creates in the diagnosis of adenomyosis. The basalis, despite its unimpressive, inactive, and undifferentiated appearance, plays a crucial role in the endometrial economy because it constitutes the â€œreserve cell layerâ€• of the endometrium. After the bulk of the overlying functionalis is shed during menstruation, or after the functionalis is removed by curettage, the basalis and the residual deep functionalis are responsible for regenerating the endometrium. The remaining surface epithelium of the lower uterine segment also participates in this regeneration (117).

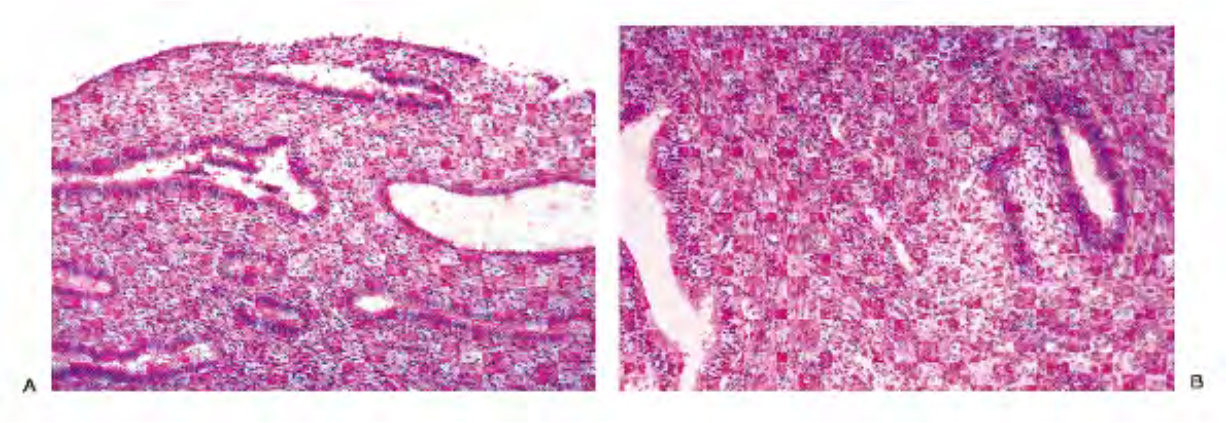

Figure 41.22 The lower uterine segment contains stroma and glands that are either hybrid between those seen in the endocervix and those in the fundus or a mixture of endometrial and endocervical glands and stroma. A . The stroma appears fibrous but more cellular than that typically found in the endocervix. B . An endometrial gland and an endocervical gland are found next to each other in this area of the lower uterine cervix.

The appearance of the basalis is relatively constant throughout the menstrual cycle. Specifically, the glands usually appear weakly proliferative; that is, they possess pseudostratified elongate nuclei, rare mitotic figures, and dense, intensely basophilic chromatin. Most importantly, they lack secretory change (see Figure 41.23), and the stroma is spindled and nondecidualized. A notable exception to this generalization is the basalis during the latter half of pregnancy, which usually exhibits secretory glandular changes and stromal decidualization. The importance of recognizing the basalis of the endometrium lies in not mistaking it for the functionalis in a curettage specimen. This confusion would result in an erroneous impression that this weakly proliferative appearance represented the fully developed state of the functionalis.

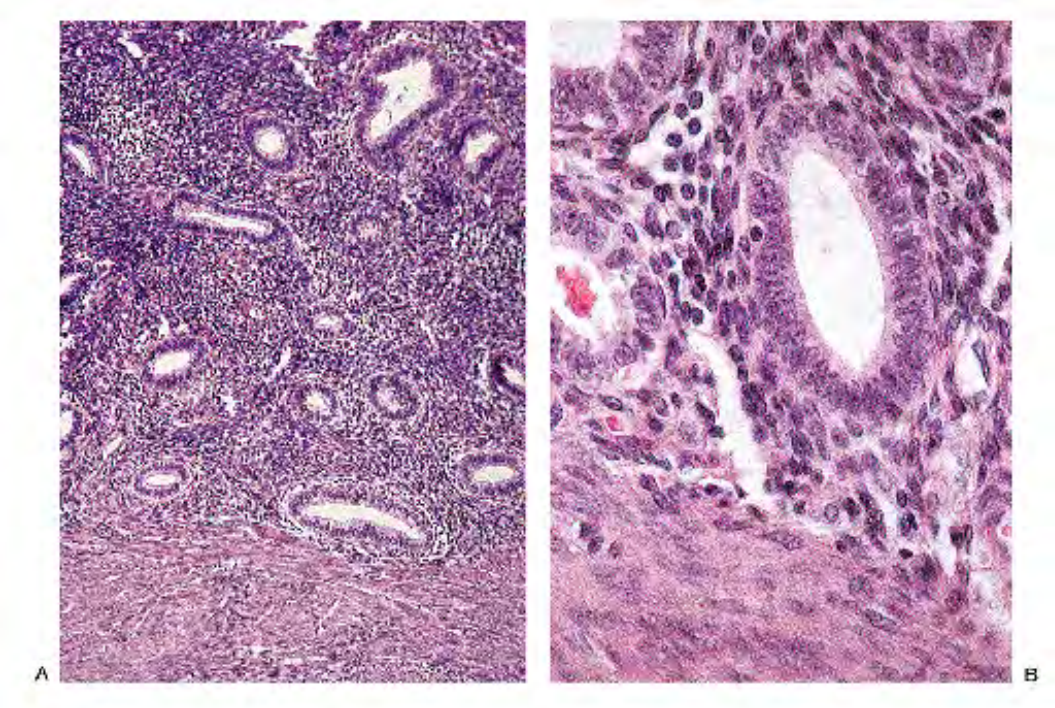

Figure 41.23 A . and B . The basalis of the endometrium is demonstrated. Throughout the menstrual cycle the basalis maintains a weakly proliferative appearance. As a result, dating of endometrium should be performed on fragments containing surface epithelium.

It is the functionalis that exhibits the protean changes so characteristic of the normal endometrium. This layer has been traditionally divided into two strataâ€”the compactum and the spongiosumâ€”based on the morphologic

appearances of each during the late secretory phase of the menstrual cycle and during pregnancy. Unless otherwise specified, the term â€œendometriumâ€• refers to the functionalis in the subsequent discussion.

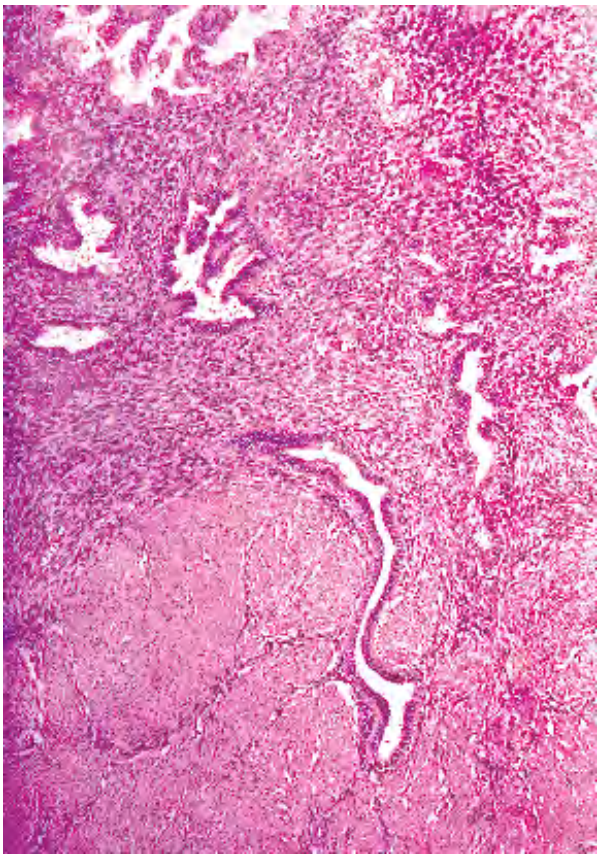

Figure 41.24 This is an example of an irregular endometrialâ€“myometrial junction. This phenomenon is important to think about when determining whether or not adenocarcinoma is superficially invading the myometrium.

Individual Components of the Endometrium

The normal endometrium consists of both epithelial (surface and glandular) and mesenchymal (stromal and vascular) elements, which during reproductive years first synchronously proliferate, then differentiate, and finally disintegrate at roughly monthly intervals.

Epithelial Elements

The endometrial glandular and surface epithelia are both composed of four morphologically distinct cells, two of which are functional

variants of the same cell.

Proliferative and Basalis-Type Cells.

The proliferative cells of the functionalis and the basalis-type cells are morphologically similar. These cells both have high nucleus-to-cytoplasm ratios and elongate sausage-shaped nuclei with dense chromatin and inconspicuous nucleoli. The cytoplasm is scant and generally basophilic to amphophilic (see Figure 41.33). Mitotic figures are common in the cells that compose the glands of the functionalis during the proliferative phase. When proliferative cells are the predominant cell type composing the epithelium (as in the proliferative endometrium), the nuclei appear pseudostratified.

Secretory Cells.

The characteristic cytoplasmic differentiation of the endometrial epithelial cell is nonmucinous secretion. Shortly after ovulation, secretory products accumulate in a subnuclear location in the proliferative cells; these products gradually shift to a supranuclear position and are ultimately discharged into the glandular lumens. This sequence of changes results in two easily recognizable secretory cell types: vacuolated and nonvacuolated secretory cells (see Figures 41.35B and 41.36C). Although vacuolated cells may have a nucleus similar to those seen in proliferative phase cells, the nonvacuolated secretory cells possess nuclei that are distinct from those seen in the undifferentiated proliferative phase cells. In contrast to the dense, intensely basophilic elongate nuclei of the proliferative cells, the nuclei of the nonvacuolated secretory cells are rounded and vesicular, they have uniformly dispersed chromatin, and occasionally nucleoli become prominent. The nonvacuolated secretory cells have uniform, moderately dense eosinophilic cytoplasm and often a frayed luminal border (see Figure 41.36C).

Another type of secretory cell is encountered, one that closely

resembles the secretory cell of the uterine (fallopian) tube. This cell has an elongate nucleus with coarse chromatin, a moderate amount of densely eosinophilic cytoplasm, and a rounded luminal bleb similar to those found in apocrine glands. These cells are common in the surface epithelium and occasionally may line an entire endometrial gland. Some of these cells may in fact represent â€œexhaustedâ€• ciliated cells.

Ciliated Cells.

The ciliated cells of the endometrium have received little emphasis in the past. However, they are consistently present in endometrial specimens and presumably represent one line of differentiation open to the basalis-type cell. These cells are more prominent near the uterine isthmus and during the proliferative phase (118 ,119).

Ciliated cells have distinctive round, smoothly contoured vesicular nuclei containing finely stippled chromatin (Figure 41.25). Although the nuclear features remain relatively unchanged throughout cell development, the configuration and location of ciliated cells vary as a function of the stage of ciliogenesis. The earliest identifiable ciliated cells are situated adjacent to the basal lamina of the gland and are roughly pyramidal in shape. They possess distinctively clear cytoplasm with central round nuclei. A rounded cytoplasmic zone containing eosinophilic fibrillary material can be identified with routine stains. This zone corresponds to the intracytoplasmic cilia seen with the electron microscope. When the growing ciliated cells reach the luminal surface, the cilia are exposed to the glandular lumen. Initially the

luminal surface of the ciliated cell is concave, but as the cell continues its development, this surface becomes convex, and ultimately the cilia may pinch off as a merocrine secretion. During this stage the cell has a characteristic fusiform-to-pear shape. Ciliated cells can come to predominate the cellular population of

glands, and when they do the term â€œciliary metaplasiaâ€• has been used.

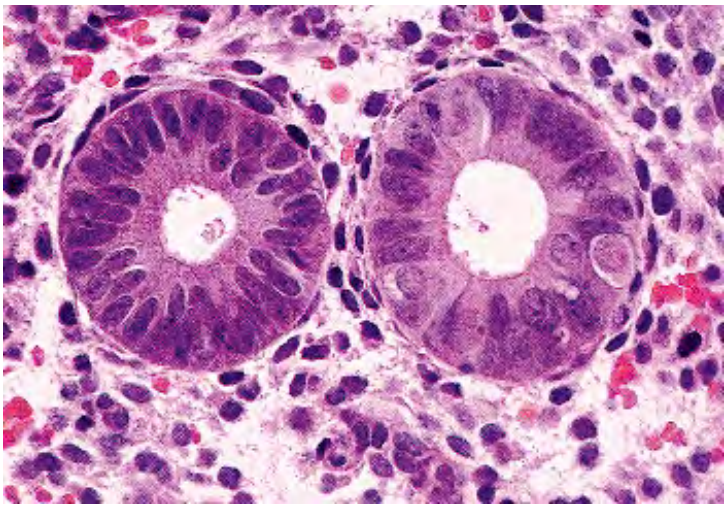

Figure 41.25 Proliferative phase glands with ciliated cells in the gland on the right. The round cell with clear cytoplasm at the 3-o'clock position has the characteristic appearance of ciliated cells before they have extruded their cilia into the glandular lumen. The other ciliated cells have a pyramidal shape.

The Gland as a Whole.

The normal endometrial gland is lined by the aforementioned cells arranged in a nonstratified cuboidal-to-columnar epithelium, which during the proliferative phase deceptively appears to be stratified (i.e., it is pseudostratified). During the early proliferative phase, the glands are straight and have narrow lumens (Figure 41.26). Beginning in the midproliferative period and lasting throughout the rest of the cycle, the glands exhibit increasing degrees of coiling, but not branching. This culminates in the serrated saw-toothed appearance of the glands in the late secretory and menstrual endometrium. The surface epithelium is composed predominantly of apocrine-like secretory cells and ciliated cells, and has a relatively constant appearance throughout the cycle.

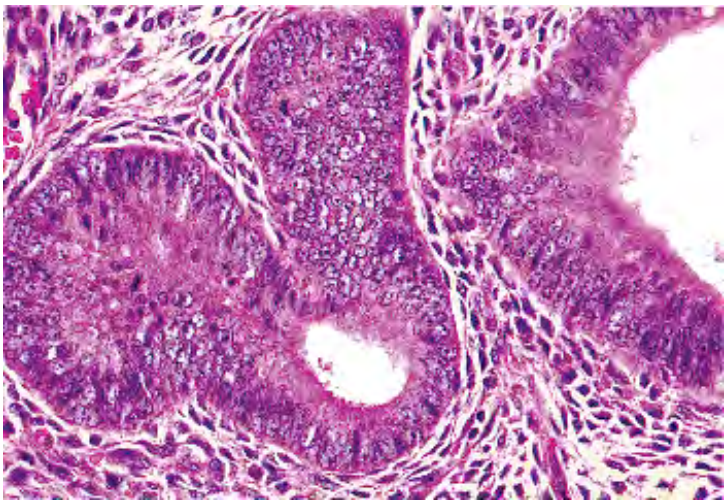

Figure 41.26 Proliferative phase glands and stroma. Note the elongate rather than rounded shape of the stromal cell nuclei. However, it is not uncommon for stromal cell nuclei to be elongate.

Mesenchymal Elements

Cellular Elements

Endometrial Stroma

The endometrial stromal cell is the predominant cellular component of the stroma, and its appearance varies greatly with the stage of the menstrual cycle. During the early proliferative phase these cells have scant indistinct cytoplasm and dense oval-to-fusiform nuclei (Figure 41.27). As the menstrual cycle proceeds, the stromal cells become more elongate and acquire more cytoplasm. During the late proliferative phase and well into the secretory phase, electron microscopy shows increasing amounts of rough endoplasmic reticulum and both intra- and extracytoplasmic collagen. Toward the end of the secretory phase, the perivascular stromal cells become rounded, acquire more cytoplasm, and develop vesicular nuclei with occasionally prominent nucleoli. Cytoplasmic borders become more

fully developed and gradually the entire endometrial stroma is transformed into sheets of cells, polygonal cells with sharp and distinct cytoplasmic borders, abundant cytoplasm, and centrally placed vesicular nuclei (Figure 41.28A, B).

This unique mÃ¼llerian stromal transformation is called decidualization when fully developed (e.g., during pregnancy) and predecidualization when partially developed (e.g., during the late secretory phase of the menstrual cycle) (120). Ultrastructurally, the abundant cytoplasm of the decidual cell is populated by dilated rough endoplasmic

reticulum, Golgi apparatus, and distinctly small mitochondria. Decidual cells form basal lamina and have complex intercellular interdigitations and tight junctions. The prominent intercellular borders are due to the accumulation of pericellular matrix (121).

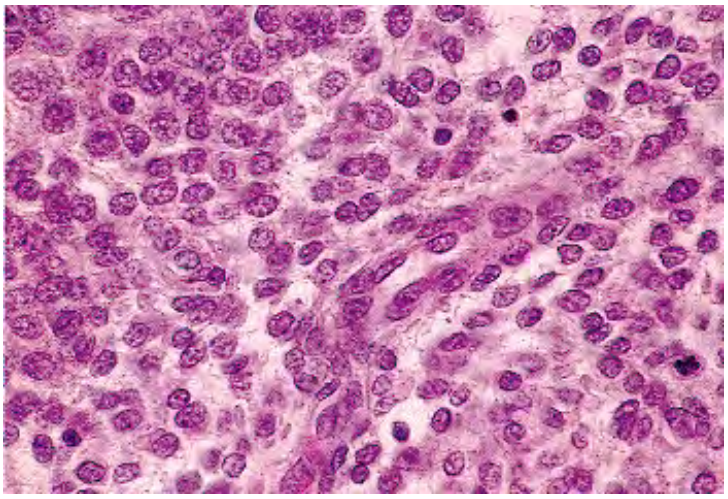

Figure 41.27 The proliferative phase endometrial stromal cells have scant, hard-to-discern cytoplasm and usually round nuclei (see Figure 41.26). Thin walled tubular blood vessels populate the endometrial stroma.

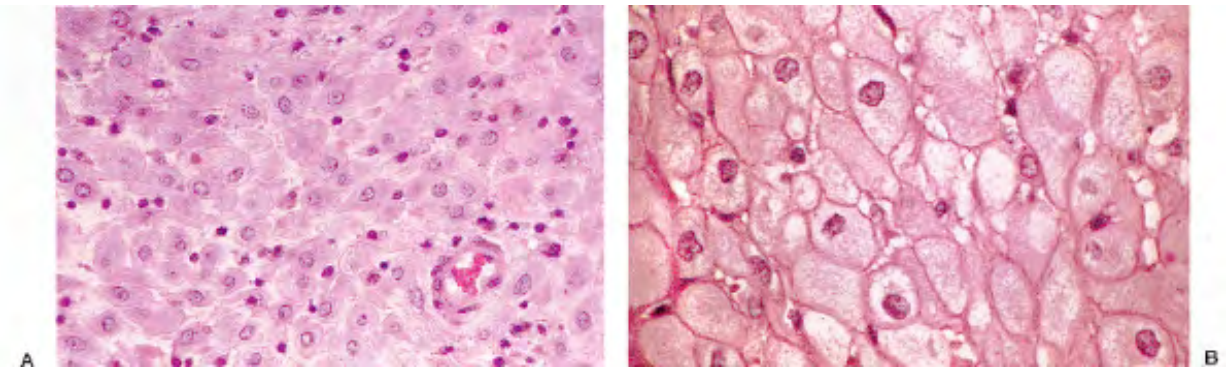

Figure 41.28 A . and B . These photomicrographs demonstrate decidual reaction during pregnancy. The cells have abundant cytoplasm and sharp cell margins.

Thus, the decidua is the specialized endometrium of pregnancy and plays an active role in implantation and in mediating the relationship between the fetoplacental unit and the mother. The decidua secretes a host of products (prolactin, relaxin, renin, insulin-like growth factors (IGFs) and insulin-like growth factor binding proteins (IGFBPs) involved in the paracrine and autocrine regulation of the feto-maternal interface (13 ,122). In short, the endometrium of pregnancy functions as an endocrine organ. In addition, decidual cells appear to be capable of phagocytosis and are thought to play a role dismantling the collagen scaffolding at the implantation site (106).

Hematolymphoid Cells

A second prominent cellular constituent, particularly in the late secretory phase and during pregnancy, is what historically has been referred to as the â€œstromal granulocyteâ€• but is now known to be a uterine natural killer (uNK) cell (123). These are rounded cells with bilobed nuclei, and have pale cytoplasm that contains eosinophilic granules. Their immunoprofile differs from that of blood natural killer (NK) cells. Their number appears to be positively correlated with the degree of predicidualization or decidualization in the surrounding endometrium; indeed, the number of such cells was

used by Noyes as a dating criterion. This close association has suggested to some workers that uNKs play a role in the control of trophoblast invasion and spiral artery remodelling in human pregnancy and suggest that uNK cells in the late secretory phase and in early decidua may be important in initiating and maintaining decidualization. Alternatively, the death of uNK cells might be an early event in the onset of endometrial breakdown at menstruation (124 ,125 ,126).

In addition to this unique uNK cell, the endometrium contains other leukocyte subsets whose precise composition is menstrual cycle-dependent. These subsets include neutrophils and eosinophils (both rare until the premenstrual phase); macrophages; mast cells, and T-lymphocyte populations (present throughout the cycle but increasing perimenstrually) (13 ,127 ,128). Lymphoid follicles are commonly seen in the basalis of normal endometria (Figure 41.29).

Plasma cells are routinely seen in postpartum endometrial samplings and as an associated feature in a variety of pathological settings (endometrial polyps, endometrial carcinoma, etc.) It has traditionally been held that, outside these settings, plasma cells are normally not present in the endometrium and when identified, suggest (usually subclinical) endometritis. Certainly this is plausible when large numbers are present, although recent studies have raised questions about the clinical relevance of scattered plasma cells (129 ,130). In fact, small numbers of

B-lymphocytes and plasma cells can be detected in endometrial samples using flow cytometry (127).

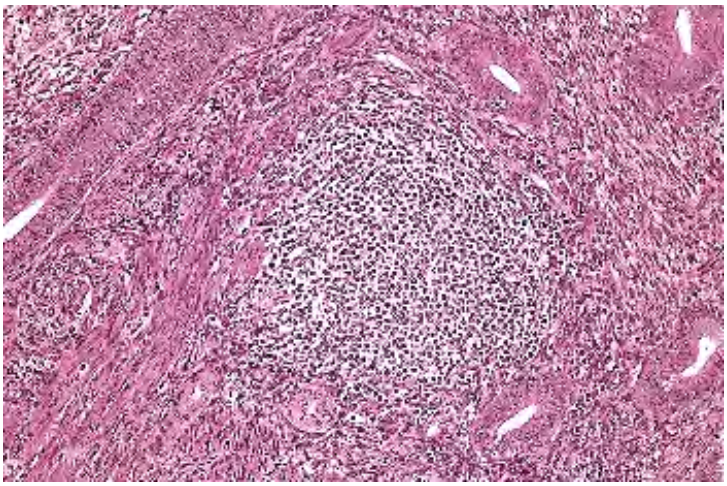

Figure 41.29 Lymphoid follicle. Scattered lymphoid follicles may be encountered in clinically normal women with otherwise unremarkable endometria. When present in large numbers and when associated with plasma cells, this finding is pathological.

Occasionally, cells with bean-shaped nuclei and abundant vacuolated lipid-containing cytoplasm are present in the stroma of endometria stimulated by estrogen. These are termed stromal foam cells and probably represent modifications of endometrial stromal cells (Figure 41.30). Similar appearing foam cells are seen as a component of an inflammatory infiltrate, particularly one produced by foreign material (e.g., keratin).

Reticulin Framework

The endometrial stromal cells elaborate a reticulin framework that becomes progressively denser as the endometrium develops during the menstrual cycle, so that by the late secretory phase each stromal cell is enmeshed in reticulin. This framework undergoes dissolution during menstruation. The stromal intercellular space is also rich in high-molecular-weight mucopolysaccharides during the midproliferative and late secretory phase.

Vascular Elements

The radial arteries of the endometrium derive from the myometrial arcuate system. As the radial arteries course toward the uterine cavity they give off basal branches and then continue as endometrial spiral arteries. The basal arteries are unresponsive to steroid hormones, whereas the spiral arteries respond to varying hormone levels both by proliferation and, during the luteal phase of the menstrual cycle, by intermittent contraction (131 ,132).

Angiogenesis, the formation of new vessels, is central to the menstrual cycle and to implantation and subsequent gestation. As concerns the menstrual cycle: there must be repair of the vessels ruptured during the menstrual phase, then rapid growth of vessels during the proliferative phase, further development of spiral arteries during the secretory phase and, to come full circle, the dismantling of the vasculature that leads into the menstrual phase (13). All these stages are closely monitored by activators and inhibitors (133 ,134 ,135 ,136).

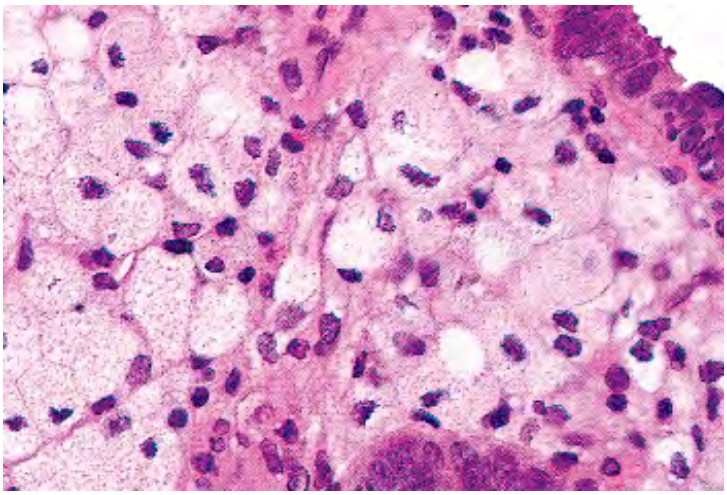

Figure 41.30 Stromal foam cells. Most likely these are modified endometrial stromal cells. In an inflammatory setting, stromal foam cells are probably macrophages.

During implantation and gestation, angiogenesis is again pivotal in negotiating the hookup of the feto-placental unit to the maternal

circulation. This entails an extensive remodelling of the placental bed spiral arteries to form the utero-placental vessels (137 ,138).

Ultrastructural Features and Immunohistochemistry

Both transmission and scanning electron microscopic study of the endometrium has produced an immense body of literature (109 ,139 ,140). Despite its scientific interest and the high aesthetic quality of many of the electron micrographs, little of this literature is currently of diagnostic relevance to the surgical pathologist. Mention should be made of two distinctive ultrastructural features found in the early secretory glandular cell: the giant mitochondrion complex (141) and the nucleolar channel system (142). These two features seem to be the earliest postovulatory morphologic change in the endometrial glandular cell.

Normal endometrial and endocervical epithelium have some differences in their immunohistochemical profile. Endometrial glands are positive for low and high molecular weight cytokeratins, vimentin, and occasionally CEA while endocervical epithelium expresses CEA but is negative for vimentin and low-molecular-weight cytokeratin (96). The endometrial stroma and mesonephric remnants are typically strongly positive for CD10 while the endometrial and endocervical glands are not. Occasionally normal smooth muscle cells express CD10 and about 40% of leiomyomas contain CD10 positive cells usually focally. Both the endometrial stroma and smooth muscle express vimentin, muscle specific actin, smooth muscle actin, and Bcl-2. Smooth muscle cells typically express desmin and caldesmon, whereas endometrial stromal cells do not. The combination of desmin (or caldesmon) and CD10 can be helpful in distinguishing smooth muscle tumors from endometrial stromal sarcoma.

The endometrium produces many secreted proteins that serve local cell signaling functions important for the developing endometrium

and embryo. There is a large and growing body of literature concerning these products of endometrium, a topic beyond the scope of this chapter. However, there have been a number of excellent recent reviews of this subject (13 ,107 ,143 ,144 ,145 ,146).

Temporal Variations

Unlike morphologically unchanging epithelia, such as vaginal or gastrointestinal mucosa, that have an essentially constant appearance throughout the cell's lifetime, the

endometrium undergoes dramatic temporal morphologic changes. The changes are cyclic and particularly striking during the reproductive years. These changes can be conveniently considered under six headings: newborn, premenarchal, perimenarchal, reproductive, perimenopausal, and postmenopausal years (107 ,147 ,148).

Newborn

The genitalia of the newborn girl respond to the high levels of circulating maternal and placental steroids by a transient burst of precocious development. The endometrium may be well developed and have either a proliferative or, less commonly, a secretory appearance. Within 2 weeks these changes have regressed, and the long hormonal quiescence of the premenarchal years begins. This quiescent period is characterized by a thin endometrium populated by inactive glands set within a spindled inactive stroma. Rarely, estrogen-secreting lesions of the ovary (follicular cysts, sex cord gonadal stromal tumors) may cause abnormal endometrial growth, with resulting abnormal bleeding as part of the syndrome of precocious pseudopuberty. The endometrium under these circumstances is proliferative or hyperplastic. That this phenomenon occurs suggests that the inactive appearance of the normal

endometrium during this period results from an absence of hormonal stimulation rather than from transient end-organ unresponsiveness (10).

Menarche

The onset of uterine bleeding (menarche) is one of the many changes that signal the maturation of the reproductive system. In the United States, this usually occurs between 12 and 15 years of age. Characteristically, the perimenarchal period is marked by greater variability in the length of individual cycles than is seen in the reproductive years and by the occurrence of anovulatory cycles (148). Disordered proliferative endometria are commonly encountered in this setting (see section â€œDisordered Proliferative Endometrium â€•).

Reproductive Years

The reproductive years are characterized by regularly occurring, roughly monthly, cycles, the end of which is signaled by menstrual bleeding (149 ,150). The dominant ovarian steroid secreted during the first half of the menstrual cycle is estradiol (E2), which induces endometrial proliferation. The second half of the cycle (beginning after ovulation) is hormonally dominated by both progesterone and estradiol, and this combination of hormones induces endometrial glandular secretion and stromal predecidualization. With the withdrawal of corpus luteum steroidal support, the endometrium is shed, setting the stage for the next cycle. These regularly recurring cycles may be interrupted by pregnancies, but after the termination of pregnancy, cycling is soon restored.

The biochemistry of the steroid molecules and their receptors that are responsible for the remarkable morphologic changes of the menstrual cycle have been the subject of intense study (151 ,152 ,153). Steroid molecules are hydrophobic and easily diffuse through cell membranes and freely enter all cells. The endometrium, vaginal

mucosa, and other steroid-sensitive tissues are target organs by virtue of the presence of high-affinity, high-specificity, low-capacity saturable receptors for E2 and progesterone. These nucleus-based receptors are absent in nonresponsive cells. In addition to being highly responsive to circulating hormones, the endometrium also synthesizes substances such as glycoproteins that affect the hypothalamic-pituitary-ovary axis and the endometrium itself (see above). A detailed description of hormone regulation is beyond the scope of this chapter, but several excellent reviews on the topic have been published and can be found in the general references listed at the end of the chapter. In broad terms, the steroid molecule combines with the appropriate receptor, and the steroidâ€“receptor complex becomes associated with a nonhistone nucleoprotein. The net effect of this linkage is to alter both qualitatively and quantitatively DNA-dependent RNA transcription. The consequence is an altered profile of protein biosynthesis. Furthermore, the unique response of a particular target cell type depends on what specific growth and differentiation program is initiated by the steroidal signal. The endometrium is a major target organ for this continual barrage of steroidal information. It responds by undergoing the dramatic morphologic alterations that constitute the normal menstrual cycle as well as producing proteins important for hypothalamic feedback, modulation of placental hormone secretion, regulation of macrophages, and regeneration after menses.

Morphology of the Normal Menstrual Cycle Endometrium

The first day of the menstrual cycle has conventionally been identified as the first day of menstrual flow. Menses usually lasts for less than 5 days and is followed by the endometrial proliferative phase, the length of which exhibits great variation (9â€“20 days), but on average it lasts for 10 days. After ovulation, the coordinated

and highly predictable series of stromal and glandular changes characteristic of the secretory (luteal) phase takes place. The traditional view is that the length of this phase is constant (14 days), and it is this alleged constancy that provides the basis for endometrial dating. Due to the sensitivity and specificity of serum hormonal studies, it is now uncommon for the surgical pathologist to be called upon to date the endometrium for infertility purposes. However, given the prevalence of polycystic ovarian disease, dysfunctional uterine bleeding, and iatrogenic hormonal use and because some gynecologists want endometrial dating it remains important for the surgical pathologist

to recognize when ovulation has occurred and the normal responses of the endometrium to various hormonal stimuli. The following discussion is a concise description of the normal menstrual cycle with more detailed information in the accompanying figures. (Figures 41.31 and 41.32 , Table 41.2) (106 ,107 ,117 ,154 ,155 ,156).

Proliferative Endometrial Phase (Ovarian Follicular Phase)

The proliferative phase spans the time from the previous menstrual period to ovulation. The endometrium responds to rising estrogen levels by synchronous proliferation of glands, stroma, and vessels. During the first third of the proliferative phase (early proliferative), the rate of growth of all three of these elements is coordinated, and as a consequence both vessels and glands are noncoiled. After a few days the growth of both glands and vessels outstrips that of the stroma; as a result, these tubular structures become coiled (mid- and late proliferative) (Figure 41.33).

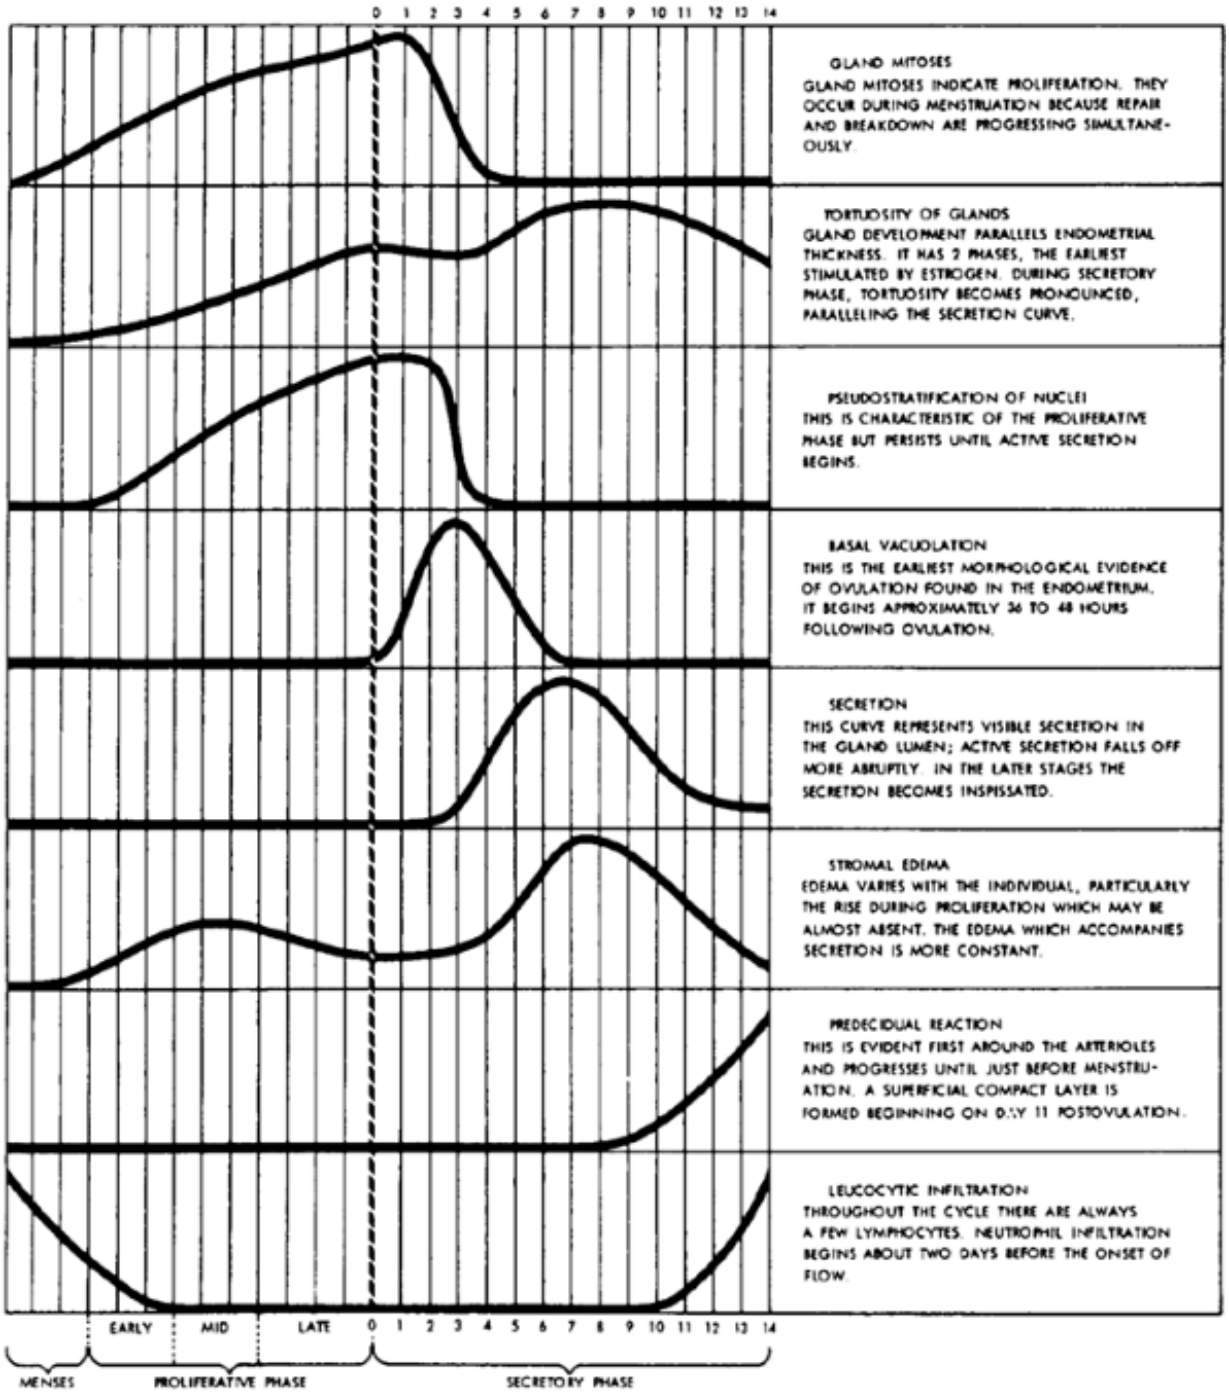

Figure 41.31 Approximate qualitative changes in eight morphologic criteria found to be most useful in dating human endometrium.

Noyes R. Normal phases of the endometrium. In: Hertig A, Norris H, Abell M, eds. *The Uterus* . Baltimore: Williams & Wilkins;

1973:110â€“135.

The glands are lined by mitotically active pseudostratified columnar cells with high nuclear to cytoplasmic ratios and dense chromatin (Figure 41.34). Mitotic figures are almost always easy to find. These cells are present throughout the proliferative phase and even into early secretion. After about 10 to 11 days, irregular subnuclear vacuoles begin to appear. During the last 2 days mitotic activity decreases, glandular coiling becomes more prominent, and vacuoles are easily found.

The interval period is the 48 hours between ovulation and the presence of uniformly vacuolated cells indicative of postovulatory day 2. Mitotic figures are present during this period, and the cells retain their proliferative nuclear features.

Endometrial Secretory Phase (Ovarian Luteal Phase)

Ovulation is mediated by the luteinizing hormone (LH) surge, a synchronous burst of LH and follicle-stimulating hormone secretion that peaks on the 14th day of the ideal 28-day cycle. Ovulation occurs roughly 10 to 12 hours after this peak. The length of time

from the last menstrual period to the day of ovulation for an individual woman is the length of her follicular phase. This surge of pituitary hormones initiates a complex series of events that results in the expulsion of the oocyte from the developed tertiary follicle and the transformation of the follicle into a corpus luteum. As a consequence of this transformation, the biosynthetic profile of the follicle changes, and both estradiol and large quantities of progesterone, are secreted. The biosynthetic lifetime of the corpus luteum defines the ovarian luteal phase that corresponds to endometrial secretory development. Both ovarian and endometrial luteal phases last 14 days on average, but this can be highly variable (see section â€œRelevance of Endometrial Dating to Diagnostic Surgical Pathologists â€•).

The endometrium, which has proliferated and has been primed by estrogen, responds to the simultaneous stimulation of estrogen and progesterone by differentiating in a distinctive fashion. The morphologic changes can be divided into four periods: interval, early secretory, midsecretory, and late secretory (see Figure 41.32). The first 24 to 36 hours of the secretory phase are morphologically silent because the endometrium, for the most part, retains its late proliferative appearance, although scattered nonuniform subnuclear vacuoles may appear. This morphologically indeterminate endometrium is termed â€œinterval.â€• The first unequivocal light microscopic indication that ovulation has occurred is the presence of uniform subnuclear vacuoles involving more than 50% of the endometrial glands. Over the next few days these vacuoles shift from a subnuclear to a supranuclear location. By the fifth postovulatory day, most of the secretion has been discharged into the gland lumen. The morphologic hallmark then of the early secretory phase (postovulatory days 2 to 5) is the vacuolated gland (Figure 41.35A, B).

The midsecretory phase lasts from postovulatory days (PODs) 5 to 9 and is characterized by nonvacuolated, prominently coiled secretory glands set within a spindled edematous stroma. Luminal secretion is

most prominent during this period, and the overall appearance is one of

glandular crowding (157). The secretory cells usually have round somewhat vesicular nuclei. This serves to separate them from the nuclei found in early secretory phase cells (Figure 41.36A, B, C). The distinctive feature of the late secretory endometrium (PODs 10â€“14) is stromal predecidualization. This diagnostic stromal change is heralded by an increased prominence of the spiral arteries. By the 10th postovulatory day, cuffs of predecidual cells are present around these arteries, initially involving the part of the vessel adjacent to the surface of the endometrium (Figure 41.37A, B). Subsequently, islands of predecidual cells appear in the superficial compactum. By POD 13 these islands become confluent. The extent of predecidualization is roughly paralleled by the degree of stromal infiltration by stromal granulocytes, although some investigators have suggested that the intensity of this infiltration is more closely correlated with the time of onset of menses (158). The appearance of the glands during the late secretory phase is not significantly different from their appearance during the midsecretory phase. They are lined by nonvacuolated secretory cells with round vesicular nuclei, and during the later days of this period, the glands typically have the saw-toothed appearance sometimes referred to as secretory exhaustion. As the late secretory phase progresses, increasing numbers of secretory cells exhibit apoptosis and apoptotic bodies accumulate within stromal macrophages.

What type of gland is present?

A. Proliferative Gland (Early proliferative, midproliferative, late proliferative, interval)

Is the gland straight or coiled?

Straight: early proliferative

Coiled: midproliferative, late proliferative, interval

Is there stromal edema?

Yes: midproliferative

No: late proliferative, interval

Are there scattered subnuclear vacuoles present, but with less than 50% of the glands exhibiting uniform subnuclear vacuolization?

No: late proliferative

Yes: intervalâ€”consistent with but not diagnostic of POD 1

B. Secretory Glandâ€“Vacuolated (Early secretory)

POD 2: Subnuclear vacuolization uniformly present, leading to exaggerated nuclear pseudo-stratification (greater than 50% of the glands exhibit uniform subnuclear vacuolization); mitotic figures frequent

POD 3: Subnuclear vacuoles and nuclei uniformly aligned; scattered mitotic figures

POD 4: Vacuoles assume luminal position; mitotic figures rare

POD 5: Vacuoles infrequent; secretion in lumen of gland; cells have a nonvacuolated secretory appearance

C. Secretory Glandâ€“Nonvacuolated (Midsecretory, late secretory, menstrual)

Is there stromal predecidualization?

No: midsecretory

POD 6: Secretion prominent

POD 7: Beginning stromal edema

POD 8: Maximal stromal edema

Yes: late secretory, menstrual

Is there crumbling of the stroma?

No: late secretory

POD 9: Spiral arteries first prominent

POD 10: Thick periarterial cuffs of predecidual

POD 11: Islands of predecidual in superficial compactum

POD 12: Beginning coalescence of islands of predecidual

POD 13: Confluence of surface islands; stromal granulocytes prominent

POD 14: Extravasation of red cells in stroma; prominence of stromal granulocytes

Yes: menstrual

crumbling stroma, hemorrhage
intravascular fibrin thrombi
stromal granulocytes prominent
polymorphs present
late menstrual: regenerative changes prominent

Table 41.2 Decision Tree for Endometrial Dating

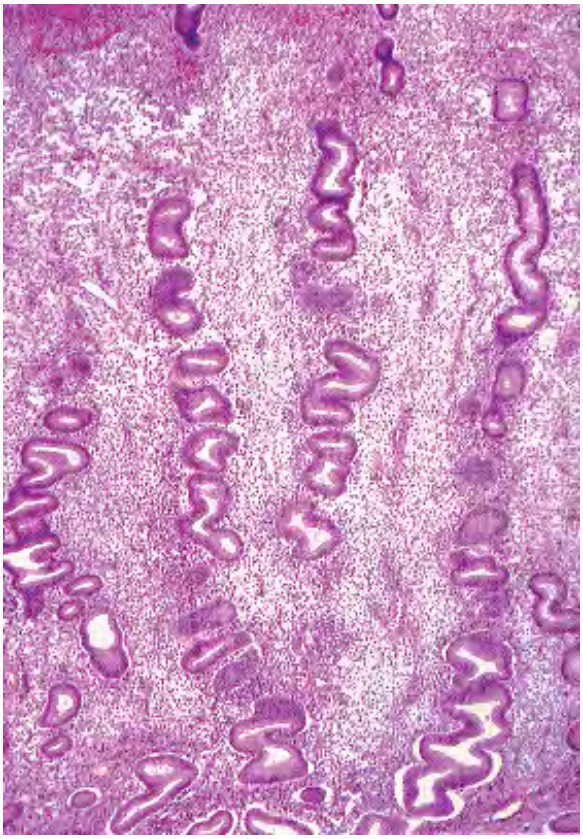

Figure 41.33 Midproliferative endometrium. Note the early coiling and synchronously developed glands.

Menstruation

Menstrual Phase (cycle days 1â€“4).

The abrupt withdrawal of both estrogen and progesterone accompanying the demise of the corpus luteum initiates menstrual bleeding. The molecular events initiating and guiding the controlled bleeding of menstruation are bewilderingly complex in contrast to the relatively straighforward light microscopic picture (159). The endometrium on the first day of menstrual bleeding (cycle day 1) is thin and compact. It is composed of the basalis andâ€”relative to the fully developed secretory endometriumâ€”a substantially shrunken, dense functionalis. The basalis maintains the relatively constant histologic appearance it has throughout the endometrial cycle. The shrinkage of the functionalis is largely due to â€œdeflationâ€• consequent on the withdrawal of interstitial fluid. The constituent glands and stroma of the functionalis fragment and crumble. Fibrin thrombi appears in vessels and within the

stroma. As the stroma disintegrates, the endometrial glands are randomly arranged and may artificially crowd together (Figure 41.38). The degenerative atypia of these glands, the necrotic background, and the close approximation of glands may suggest a diagnosis of malignancy. The general strategy of not making a diagnosis of malignancy when well-preserved glands and stroma are absent, should prevent such a mistake (Figure 41.39).

Figure 41.34 High-power view of a proliferative phase gland. The constituent cells are pseudostratified, and the characteristically elongate glandular nuclei have dense chromatin.

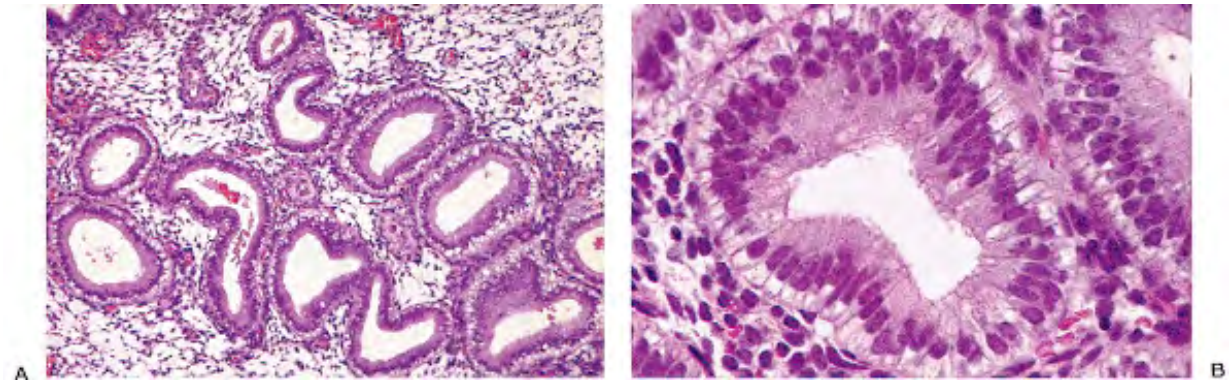

Figure 41.35 A . and B . Early secretory endometrium with subnuclear vacuoles. The nuclei retain the dense chromatin of the proliferative phase. Uniformly present cytoplasmic vacuoles are the most useful marker of the first third of the secretory phase.

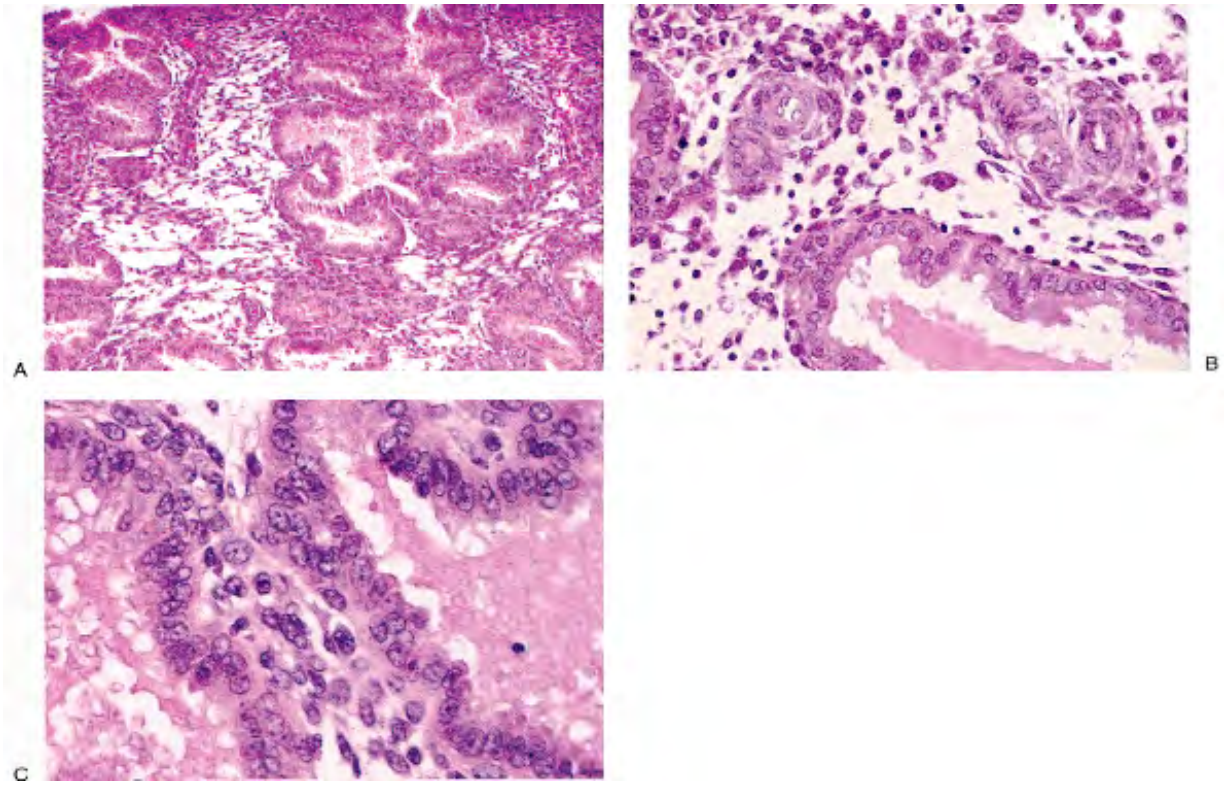

Figure 41.36 Midsecretory endometrium. The hallmarks of this period can be seen in these three photomicrographs. At low magnification (A), extreme glandular coiling and stromal edema are apparent. At a somewhat higher magnification (B), the coiled spiral arteries are seen within an edematous stroma. Perivascular predecidual reaction has not occurred. At yet higher magnification (C), the characteristically round vesicular nuclei of the midsecretory endometrium are apparent (contrast with proliferative phase nuclei in Figure 41.26).

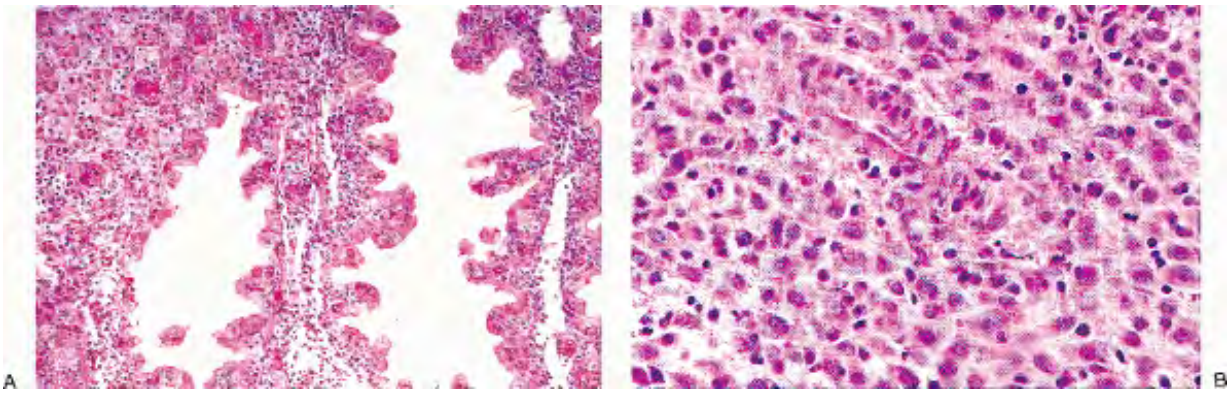

Figure 41.37 Late secretory endometrium. At low magnification (A), the serrated appearance of the gland reflects their coiled state. The stroma cells have undergone predecidual reaction (B). Predecidual reaction begins around the spiral arteries, and this reaction serves to distinguish midsecretory endometria from late secretory endometria.

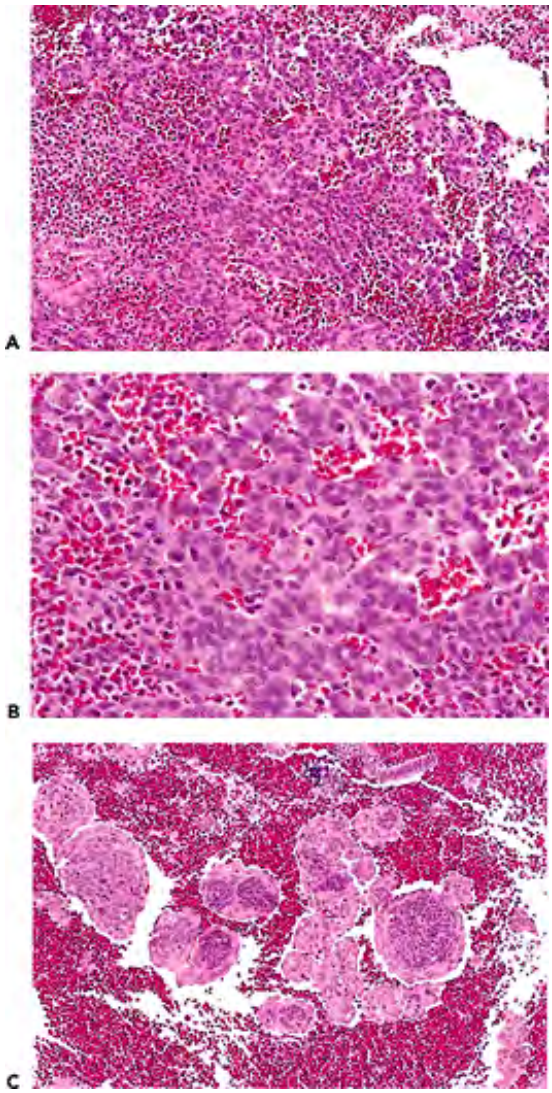

Figure 41.38 Stromal breakdown. Disintegrating endometrium may simulate endometrial malignancy. A . Sheets of disintegrating stromal cells may simulate an endometrial stromal neoplasm. B . Higher magnification shows individual cell necrosis and inflammation, findings that should raise the possibility of disintegrating nonneoplastic endometrium. C . Confirmation of this possibility is made by finding inflamed epithelium associated with degenerating stromal cells. In this case, characteristic epithelium-covered spherules are produced.

There is rapid onset of endometrial repair during this time. Numerous studies have demonstrated the outgrowth of epithelium

from the stumps of the disrupted endometrial glands and ingrowth from the intact areas of the cornual and isthmic endometrium. This process begins during the 2nd or 3rd day and is completed by the 4th or 5th day. This early repair phase is thought by some to be estrogen independent as is the initial regrowth of the vasculature (160). In normal women, almost 50% of menstrual blood loss occurs on the first day (106 ,161 ,162).

Endometrial Morphology During the Luteal Phase of the Cycle of Conception

If implantation of a blastocyst occurs, it will be during the midsecretory phase (PODs 6â€“8), and this event is associated with a resurgence of glandular secretion and a persistence of stromal edema. After this time, biopsy findings will

feature prominent glandular secretion (which in a nongravid cycle would have subsided), stromal edema, and stromal predecidualization (Figure 41.40) (163 ,164).

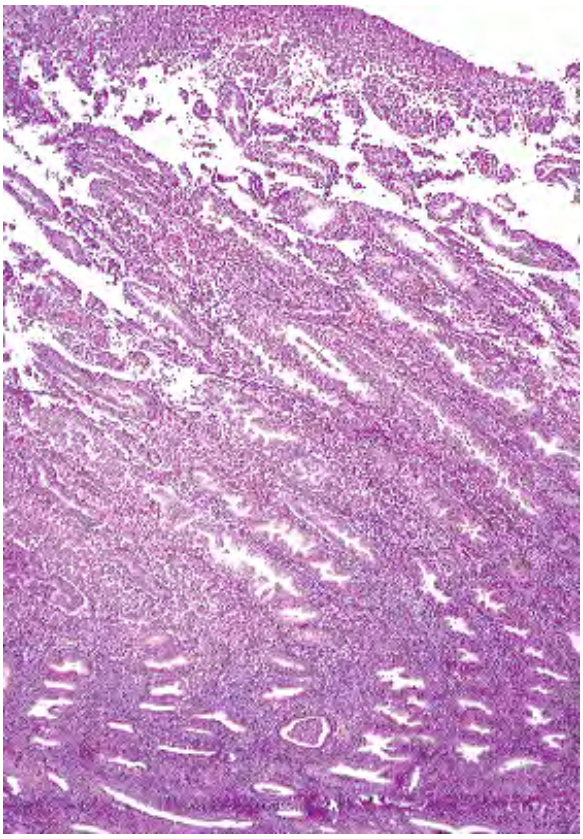

Figure 41.39 A low-power view of a menstrual endometrium showing the unresponsive basalis in the lower part of the photomicrograph and the functionalis disintegrating near the surface.

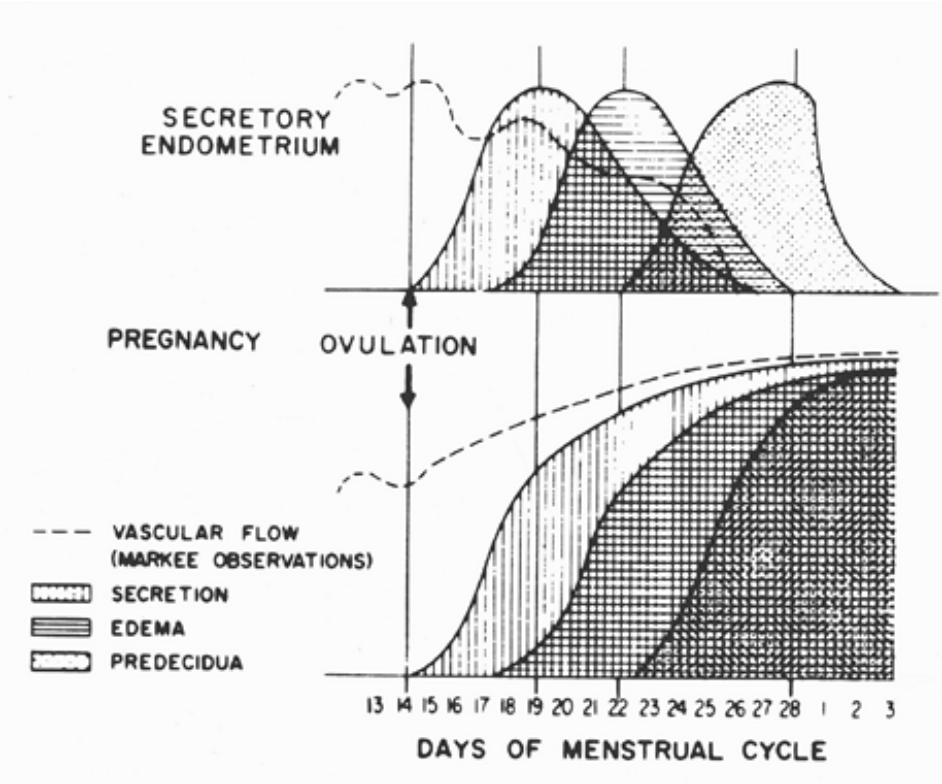

Figure 41.40 The transition from secretory to gestational endometrium is shown. The simultaneous occurrence of intense secretion, edema, and predecidual reaction and maintained vascular flow characterizes the early endometrial gestational responses. Reprinted with permission from:
Arias-Stella J. Gestational endometrium. In: Hertig A, Norris H, Abell M, eds. *The Uterus* . Baltimore: Williams & Wilkins; 1973:185â€“212.

The developing predecidua is gradually converted to decidua after POD 14 of the luteal phase of conception. This transformation is complete by the end of the first month of gestation. The fully developed decidual reaction is distinctive. Almost all of the endometrial stroma is converted into pavementlike sheets of epithelioid cells with prominent cytoplasmic margins and central vesicular nuclei (see Figure 41.28). In the superficial portion of the functionalis, the glands are compressed and their lining becomes flattened and endothelium-like. This compact sheetlike zone, the

zona compactum, overlies saw-toothed scalloped glands, the zona spongiosum, which continue to exhibit secretory features. Many of the glands in the spongiosum are lined by cells with enlarged nuclei that often have atypical nuclear features approaching those of the Arias-Stella reaction (Figure 41.41). Scattered â€˜stromal granulocytesâ€™ (uterine NK cells) are present. Decidual cells may exhibit substantial nuclear pleomorphism and cytologic atypia. This is particularly prominent in the region of the implantation site. In addition, this region is also infiltrated by intermediate trophoblastic cells, which normally have a bizarre cytologic appearance. These cells are positive for both keratin and hPL. The infiltration of decidua and the underlying myometrium by trophoblasts in the past has been termed â€œsyncytial metritis,â€• not a particularly felicitous label because the process has little to do with inflammation (Figure 41.42). Accordingly, the current term for this process is â€œimplantation site reactionâ€• and is diagnostic of intrauterine pregnancy (165). Both placental site reaction and decidual atypia may incorrectly suggest malignancy, but confusion with adenocarcinoma is avoided by noting the secretory setting of these findings as well as the clinical history.

Although a fully developed decidual reaction is a constant feature of intrauterine pregnancy, it is by no means a diagnostic finding. An identical decidual reaction may be seen in extrauterine (ectopic) pregnancy; also, it can be produced by progestational agents or can be associated with persistence of the corpus luteum unassociated with pregnancy (e.g., corpus luteum cyst). For this reason, intrauterine implantation should only be diagnosed in the presence

of chorionic villi or the presence of intermediate trophoblasts associated with enlarged vessels replaced by hyalin, or with fragments of fibrinoid matrix (165).

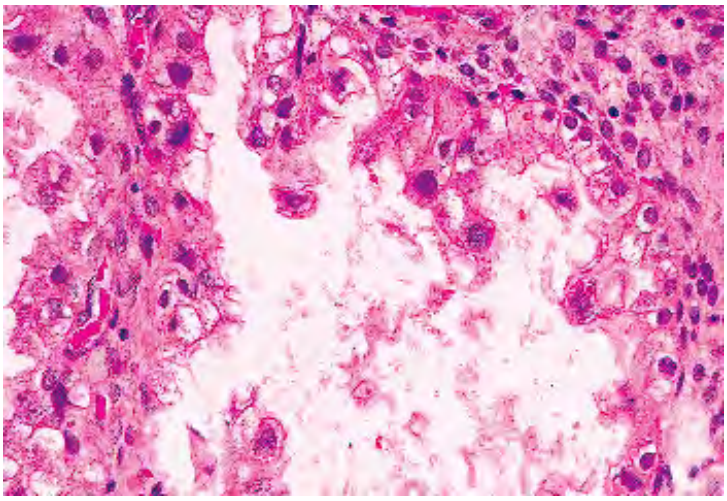

Figure 41.41 Gestational endometrium. This gland is lined by cells with enlarged dense nuclei characteristic of the Arias-Stella reaction.

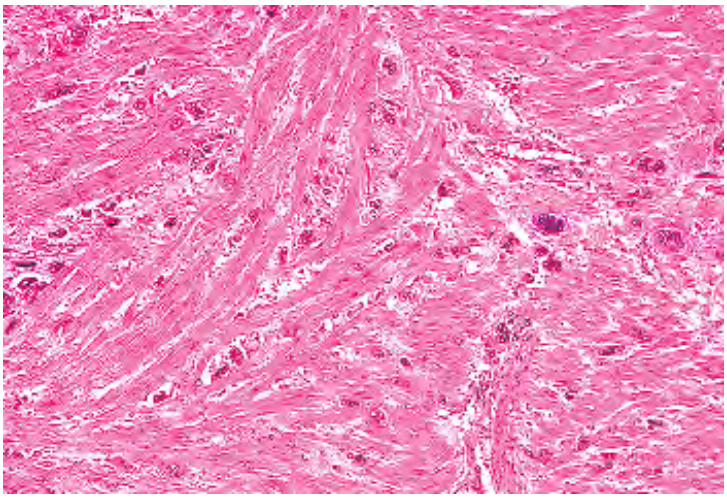

Figure 41.42 Myometrium beneath an implantation site containing infiltrating trophoblasts. This must not be misinterpreted as evidence of gestational trophoblastic disease.

Distressingly, on rare occasions, the finding of trophoblastic tissue in a curetting does not exclude an ectopic gestation and suggests that when clinical suspicion is high, the presence of either chorionic villi or an implantation site should not preclude further workup of a

possible ectopic pregnancy (166).

Previous intrauterine pregnancy is strongly suggested in the postpartum endometrium by the presence of cuffs of hyalinized decidua around sclerotic ectatic spiral arteries. The decidual cells composing this cuff often have hyperchromatic smudged and degenerate nuclei, and the vessels are often thrombosed. These findings have been referred to as subinvolution of the placental site and can be responsible for postpartum hemorrhage (167). This presumably occurs because these severely altered vessels are incapable of contraction. With time, the foci of hyalinization shrink and the nuclei may disappear, leaving a small pink scar resembling an ovarian corpus atreticum. These distinctive foci have been referred to as pregnancy plaques, and they may persist in the basalis for many years. Similar lesions featuring intermediate trophoblasts have been termed placental site nodule and placental site plaque (167). Occasionally, a placental site nodule (PSN) or exaggerated placental site can be confused for a gestational trophoblastic tumor such as placental site trophoblastic tumor (PSTT) or epithelioid trophoblastic tumor (ETT). While conventional H&E morphology is still very useful in distinguishing placental site nodules and plaques, immunohistochemical profiles can also be helpful. Studies over the last decade have shown that there are a variety of intermediate trophoblasts involved in implantation and establishing vascular connections to the maternal blood flow. These trophoblasts seem to have distinct immunohistochemical properties, some of which are shared with the cells of gestational trophoblastic tumors (GTTs). An exaggerated placental site is characterized by infiltration of individual cells with preservation of normal structures and mitoses essentially absent. Plancetal site trophoblastic tumors are characterized by mitotically active confluent masses of cells that disrupt normal architectures. All trophoblasts express pancytokeratins, so while this may be helpful in highlighting the trophoblasts it does little to predict the aggressive potential of the proliferation. Kurman et al. have established algorithms for

evaluating placental site nodules and trophoblastic tumors, using a combination of human placental lactogen (hPL), p63 and Ki67. Briefly, the intermediate trophoblasts of an exaggerated placental site is hPL positive, p63 negative, and has a Ki67 activity of less than 1%. A PTT will have the same immunohistochemical profile except the Ki67 is much greater. The intermediate trophoblasts in a placental site nodule are hPL negative, p63 positive and have a Ki67 activity of less than 10%. Epitheloid trophoblastic tumor can sometimes be confused with a placental site nodule but has a Ki67 activity of greater than 10%. Occasionally, the diagnostic dilemma is between placental site nodule and squamous cell carcinoma; in this scenario, inhibin and cytokeratin 18 can be useful as PSNs are postitive for both of these antibodies while squamous cell carcinomas are negative (168 ,169 ,170).

Hyperprogestational states (particularly pregnancy) are sometimes associated with the distinctive glandular change to which Arias-Stella first drew attention in 1954 and that now bears his name (171 ,172). Most commonly this change is encountered in endometrial glands, but on occasion it may be present in foci of endometriosis or adenomyosis, in endocervical glands, in uterine (fallopian) tube epithelium, or in the glands within polyps. The Arias-Stella (AS) phenomenon characteristically involves a focus of tightly packed glands whose extreme coiling and collapse throw the lining epithelium into prominent papillary folds. This epithelium is composed of cells exhibiting marked nuclear pleomorphism and hyperchromatism. The nuclei typically have a smudged appearance. The cell cytoplasm may be strikingly hypervacuolated and cleared (clear cells) or densely eosinophilic (dark cells) (see Figure 41.41). One or the other cell type may predominate from area to area. Occasionally the eosinophilic cells may line the glands in a hobnail fashion. Mitotic figures only rarely are present. Elsewhere the endometrium usually exhibits the other changes one would anticipate with progestational stimulation, such as secretory glands and a stromal decidual reaction.

Less striking degrees of nuclear hyperchromasia, nuclear pleomorphism, and cytoplasmic vacuolization are, in our experience, constant features of the secretory glands of every pregnancy. The Arias-Stella reaction appears to represent the extreme end of the morphologic spectrum of the glandular epithelial changes seen in all pregnancies.

An endometrial Arias-Stella change may be present in a variety of clinical settings, including normal intrauterine

pregnancy, extrauterine pregnancy, gestational trophoblastic disease, and persistent corpus luteum. In a retrospective review of patients coded as having Arias-Stella reaction, 16% had an extrauterine gestation. It also may be produced by the administration of ovulation-inducing drugs or progestational agents (171).

Because of the marked nuclear atypia of the epithelium lining the closely packed glands, the Arias-Stella phenomenon can be confused with adenocarcinoma, particularly with the architectural and cytologic features of clear cell carcinoma. This difficulty largely can be avoided by remembering that the Arias-Stella phenomenon occurs in a secretory setting; that is, more conventional secretory glands and decidualized or predecidualized stroma are usually found elsewhere in the specimen and the patient is premenopausal. Moreover, glandular mitotic figures tend not to be a prominent feature, although they may occasionally be encountered (173). Clear cell carcinoma (like any carcinoma) is fundamentally a proliferative process, and the constituent cells not only possess malignant features but also exhibit mitotic activity. Most importantly, clear cell carcinoma of the endometrium develops almost exclusively in postmenopausal women. Immunochemistry has been useful in separating the two; p53 and Ki-67 staining are absent in Arias-Stella (AS) and are present in clear cell carcinoma (174).

Occasionally in a gestational setting glandular nuclei may exhibit marked nuclear clearing reminiscent of herpetic infections (Figure 41.43) (175).

Endometrial Vasculature

The transition from the endometrium of early gestation to that of fully developed pregnancy is marked by the accelerated development of the endometrial vasculature, resulting in increased thickness of the spiral arteries, as reflected in their mean cross-sectional diameter (176 ,177).

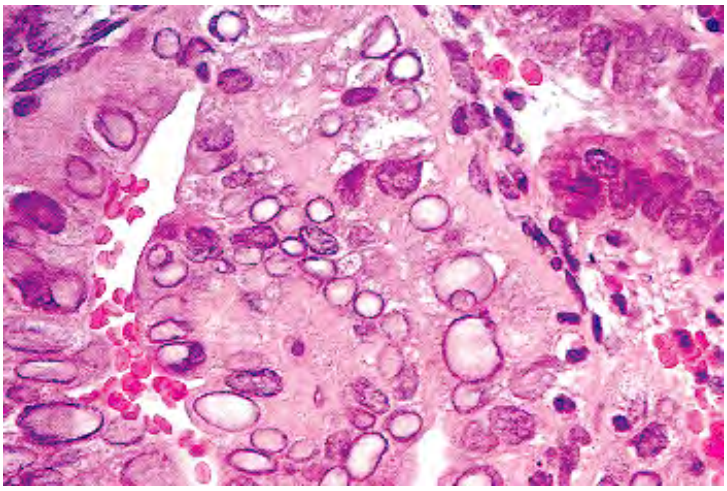

Figure 41.43 Nuclear clearing of the glandular cells in the endometrium may be seen in a gestational setting. This change should not be misconstrued as evidence of herpes virus infection.

Perimenopausal and Postmenopausal Years

With the waning of hormonal function in the fifth decade of life, a woman enters the perimenopause, during which time uterine bleeding characteristically again becomes erratic, and the length of time between bleeding episodes lengthens. Thus, both the perimenopause and the perimenarche may be marked by erratic ovarian function and consequent dysfunctional uterine bleeding (178

).

The end of ovarian follicular development and ovulation results in cessation of the menstrual periods and the menopause. Thereafter, the uterus enters a second inactive period, and the endometrial glandular epithelium, as in the premenarchal years, is typically atrophic. However, the glandular architecture and thickness of the endometrium may vary considerably. Several different patterns may be seen in the peri- and postmenopausal endometrium, which are described in the following sections.

Atrophic Endometrium

Atrophic epithelium is nonstratified and composed of a single layer of flattened to cuboidal cells. Mitotic figures are not present, the nucleus-to-cytoplasm ratio is high, and there is usually no specific cytoplasmic differentiation, although cilia may be present occasionally. The defining and only constant feature of atrophic endometria is the atrophic epithelial lining of its constituent glands, which may have any configuration, including cystic dilatation and glandular crowding. The stroma is spindled and is neither predecidualized nor decidualized. The nuclei may be densely pyknotic (as in postmenopausal endometria or endometrial polyps) or plump (as in endometria associated with oral contraceptives). Stromal disintegration may be present (Figure 41.44) (179 ,180 ,181).

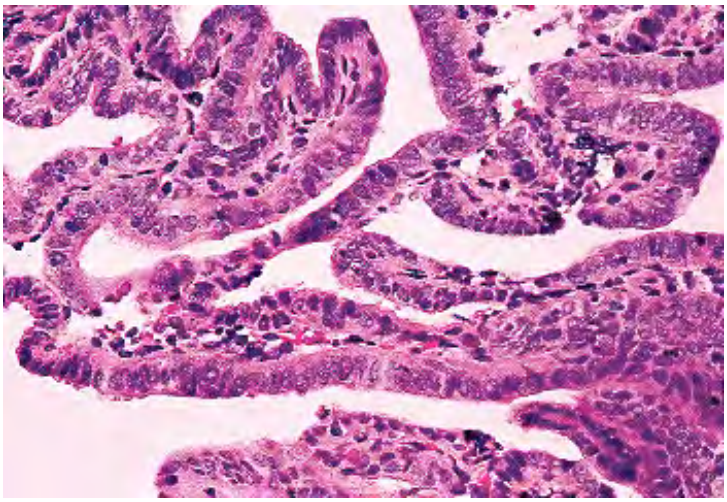

Figure 41.44 Endometrial atrophy as seen in an endometrial sampling. On occasion, atrophic surface epithelium may be removed in coiled masses and simulate hyperplasia because the glands are closely approximated. Reprinted with permission from: Hendrickson M, Kempson R. The uterine corpus. In: Sternberg S, ed. *Diagnostic Surgical Pathology* . New York: Raven; 1994:2091â€“2193.

Atrophic endometria can occur in a variety of clinical settings. It is the normal state during the premenarchal and later postmenopausal years. During the reproductive years, atrophic patterns may be seen in association with premature ovarian failure or, more commonly, in patients taking oral contraceptives.

Weakly Proliferative Endometrium

Weakly proliferative epithelium is nonstratified, although some degree of nuclear pseudostratification may be present, and its constituent cells are thin (pencil shape). This epithelium differs from the normal proliferative epithelium in the paucity of mitotic figures, the greater density of the nuclear chromatin, and, in the usual case, the overall lack of organization of the glands. The glands may be of any configuration, but the glands-to-stroma ratio is almost always

near unity or there can be a slight stromal predominance. The stroma is spindled; stromal cell nuclei may be densely pyknotic or plump.

The morphologic variability of the weakly proliferative endometrium parallels that of the atrophic endometrium. The difference between them is solely based on the appearance of the epithelial cells: weakly proliferative rather than flattened or cuboidal. The clinical settings in which these two endometria occur overlap considerably. It is conceptually convenient to regard the weakly proliferative endometrium as lying on a continuum between normal and atrophic endometrium; the weakly proliferative patterns may then be conceived of as representing a transition between normal proliferation and atrophy. Weakly proliferative endometria are most often encountered in patients in the peri- or postmenopausal years; these endometria appear to be poorly supported by low levels of endogenous or exogenous estrogen. This pattern is normal in the hormonally hyporesponsive lower uterine segment of the normally cycling premenopausal women.

During the perimenopausal period some women are prone to chronic stromal breakdown due to the inconsistent hormonal milieu and anovulatory cycles. This can result in surface metaplasias such as eosinophilic or papillary metaplasia. The former is characterized by enlarged cells with abundant pink cytoplasm and conspicuous necleoli. The latter often form small papillary aggregates which layer the surface epithelium but can be detached and free-floating in an endometrial sampling. When atypia is present in these cells, this benign process can be mistaken for serous papillary carcinoma or its precursor, endometrial intraepithelial neoplasia. In this setting Ki67 and p53 can be useful adjuvant tests as eosinophillic metaplasia has a low Ki67 index and is usually only weakly for p53 while EIC is often strongly positive for both. While this panel will not give a definitive answer, it can prove helpful in confirming the histologic impression (182).

Disordered Proliferative Endometrium

We regard â€œdisordered proliferationâ€• as the morphologic bridge spanning normaly proliferating endometrium and endometrial hyperplasia. It is the endometrial pattern encountered in women experiencing sporadic anovulatory cycles and thus is most commonly encountered in the perimenopausal and perimenarchal years. It is also commonly seen in women receiving estrogen therapy. Disordered proliferation differs from normal proliferation by virtue of a loss of synchrony of glandular development so that some glands are tubular, whereas others are cystically dilated or have complex shapes. Budding may be present so that there may be a shift in the glands-to-stroma ratio in favor of the glands, but this shift is never more than 2:1. When glandular predominance is so marked that there is a shift in the glands-to-stroma ratio of 3:1 in favor of the glands, a diagnosis of hyperplasia is warranted (Figure 41.45).

We think that disordered proliferation (in the sense above) represents the response of a normal endometrium to sporadic, unopposed estrogen stimulation. There is no evidence that this pattern is a marker for an increased risk for the subsequent development of endometrial carcinoma. Because the term â€œhyperplasiaâ€• connotes to many clinicians such an increased risk, we part company with those pathologists who include this pattern in the hyperplasia group.

Histologically, the variously shaped glands are lined by normal proliferative cells with elongate dense nuclei that are most often pseudostratified. Mitotic figures are usually present and may be numerous. Stromal cells are spindled with plump nuclei.

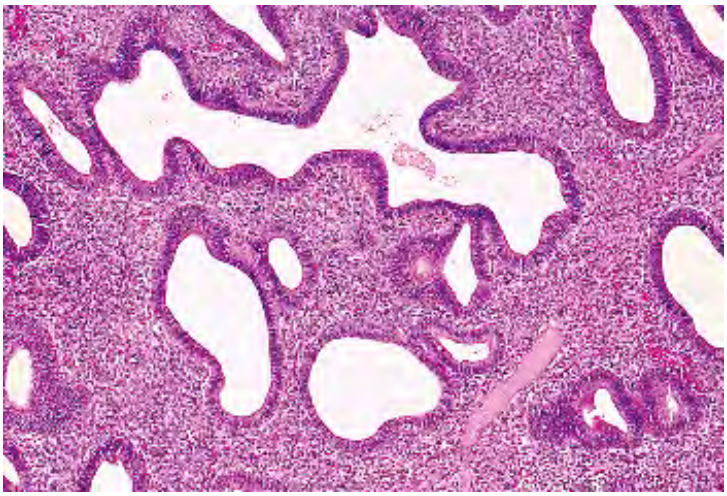

Figure 41.45 Disordered proliferation is the result of anovulatory cycles and is normal during the perimenopausal years. It is often found in the endometrium of women receiving estrogen therapy. Disordered proliferation is characterized by nonsynchronous growth of the glands including budding, but the glands-to-stroma ratio is unity or with a slight glandular predominance. This pattern of endometrial growth serves as a bridge between normal proliferation and hyperplasia.

Relevance of Endometrial Dating to Diagnostic Surgical Pathologists

The endometrial biopsy (EB) no longer plays the major role it used to play in the evaluation of the infertility patient for three reasons. First, historically, the EB's primary function was to serve as a bioassay for assessing a patient's endocrinological state; this role has been largely replaced by a variety of sophisticated and user-friendly direct methods of measuring circulating steroid and gonadotropin levels. Second, the EB's other function was to detect organic uterine disease. This role has been rendered irrelevant by the general availability of a large number of sophisticated imaging techniques. Finally, over recent years, many carefully controlled

studies have established that, as a screening test for distinguishing fertile from infertile couples, the endometrial biopsy has poor test characteristics. That is, setting aside organic causes of infertility, the endometrial biopsy, functioning as a bioassay, is unreliable in separating fertile from infertile women. This is due largely to the substantial morphologic heterogeneity of the normally functioning endometrium (183 ,184 ,185 ,186 ,187 ,188).

The latest edition of a widely used infertility text asserts: â€œTaken together, the body of available evidence supports the conclusion that traditional endometrial histologic dating is not a valid diagnostic tool. Consequently, endometrial dating cannot be used to guide the clinical management of women with reproductive failure and should no longer be regarded as an important element of their evaluationâ€• (189).

That said, the EB is still employed by some infertility specialists. In a recent survey of infertility physicians, 12% routinely ordered this test as part of the workup of the infertile couple, chiefly for its bioassay function (187 ,190).

Its deficiencies notwithstanding, the EB, when it is ordered for fertility evaluation, can provide much useful information. Its chief function is to determine whether ovulation has occurred and documenting anovulatory cycles points toward an ovarian factor in the patient's infertility. Again, organic reproductive tract disease may be detected on the endometrial biopsy; for example, endometrial poylps, leiomyomas, endometritis, hyperplasia, or carcinoma.

What modern studies *do* suggest is that the obsessive fine-tuning of the postovulatory morphologic date provides no useful clinical information. Historically, this fine-tuning of the postovulatory morphologic date was designed to detect luteal phase deficiency (LPD). Briefly, LPD can be thought of as a subtle form of ovulatory dysfunction manifested by a relatively short luteal phase. This results in low cumulative serum levels of progesterone in the luteal

phase of the cycle and a consequent underdevelopment of secretory endometrium. LPD is a relatively uncommon syndrome, that (like congestive heart failure) has many etiologies. LPD is thought by many experts to be responsible for some cases of infertility and to be remediable by using a variety of techniques, chiefly ovulation induction (13 ,189). Historically, LPD was defined in terms of a greater than 3-day disparity between the woman's *chronologic* date of ovulation and her endometrial *morphologic* date when this disparity occured more than sporadically. The diagnosis of this condition is now largely based on an assessment of the integrated luteal phase progesterone and not on a histological assessment of the endometrium (188 ,191 ,192).

What follows is a stripped down version of endometrial dating for those who are asked to provide a fine-tuned morphologic date (i.e., more than proliferative, early-, mid- or late-secretory); most endometrial biopsies do not require this.

The precise details of the morphologic patterns corresponding to standard cycle dates are presented in Table 41.2 and Figures 41.31 and 41.32 .

Some general points are important to keep in mind when using these aids:

1) *Morphologic dates and chronological dates*

In evaluating the endometrium, it is important to carefully distinguish between the morphologic postovulatory date assigned to a morphologically normal endometrium and the chronologic postovulatory date (POD) (106 ,147 ,193 ,194). The morphologic date is a summary characterization of the histologic development of the endometrium based on an assessment of glandular and stromal features. The morphologic findings may be summarized either in terms of postovulatory days, cycle days, or phases. For example, the morphologic pattern associated with a particular â€œstandardâ€• postovulatory day is assigned the number of that

day; for example, POD 12 refers to the pattern seen on POD 12 of the â€œstandardâ€• cycle. Equivalently, this morphologic information can be conveyed using cycle day or phase (e.g., late secretory).

2) *Endometrial dating should be reported as a range of 2 days*

Research in the last two decades has shown the fallacy in using a standard 28 day cycle for all women. It is now known that both the follicular and leuteal phases vary among women (195). Adding to this biological heterogeneity is the poor interobserver reproducibility of the conventional Noyes' dating.

Noyes and Haman reported that two observers agreed on the same morphologic date 29% of the time, were within one day of each other in 63% of the cases, and were within 2 days of one another in 82% of cases (196). These results have been duplicated in more recent studies (154 ,197 ,198 ,199). As a consequence, the results of endometrial dating should be reported as a range of 2 days to reflect this variability.

3) *Determining whether the patient has ovulated*

Deciding whether a woman has ovulated by examining an endometrial biopsy (EMB) taken in what is presumed to be her late luteal phase is usually a trivial matter; the

presence of a late secretory endometrium means ovulation. Deciding whether ovulation has occurred in the early luteal phase is more problematic. The characteristic light microscopic postovulatory secretory changes in the endometrium lag behind actual ovulation by at least 1 day. A biopsy on POD 2 usually reveals subnuclear vacuoles in the vast majority of glandular cells in the superficial functionalis but these may be spotty (interval pattern). Such vacuolization may be seen in late proliferative endometria as well as in other types of nonsecretory endometria and is, for this reason, not diagnostic of ovulation. Because of the ambiguous morphologic

picture in the early postovulatory period, endometrial biopsies are usually obtained well into the presumed luteal phase of the cycle, preferably on PODs 11 to 13. We require uniform subnuclear vacuolization in 50% of the glands before diagnosing the earliest morphologic evidence of ovulation; this usually is present by POD 3.

4) *Some practical details*

Accurate endometrial dating requires attention to a number of details (193). Dating features should be sought only in fragments of endometrial functionalis, which are lined by surface epithelium; fragments of basalis and lower uterine segment should be ignored. The assigned date should be of the most developed area and should be based on features near the surface epithelium (the â€œegg's eye viewâ€• of Noyes) (193).

The preconditions for assigning a morphologic date to an endometrium are described as follows. Assigning a date to an EMB is obviously not possible in the absence of an adequate specimen, in a noncycling endometrium (e.g., nonsecretory pattern other than proliferative), in a patient being treated with medication that alters the morphology of the endometrium, or in an endometrium that is inflamed or that houses an intrauterine device. Thus, a precondition for applying the dating criteria is that one is dealing with a roughly normal endometrial pattern. Scanning power examination should establish the presence of pattern uniformity (apart from the expected variation due to sectioning randomly oriented fragments and normal out of phase curettage inhabitants such as fragments of the lower uterine segment, cervical epithelium, and stratum basalis), the absence of significant budding and branching of glands, and the absence of necrosis and inflammation. Examination at higher power should exclude the presence of significant epithelial nuclear atypia and the absence of significant numbers of stromal plasma cells.

A checklist for the contents of the pathology report of endometrial biopsies is provided in Table 41.3 .

Endometrialâ€“Myometrial Junction

The endometrialâ€“myometrial junction is normally irregular, a phenomenon that must be kept in mind when assessing the presence or absence of myoinvasion by endometrial adenocarcinoma and in diagnosing superficial adenomyosis (see Figure 41.24).

Statement of the adequacy of the biopsy
Suggest re-biopsy if:
Sample is inadequate
The endometrium is disintegrating and not clearly menstrual (i.e., postovulatory)
The endometrium is disintegrating, postovulatory but otherwise undatable and the main concern is with the adequacy of the luteal phase
Statement about evidence of ovulation
Statement about pattern uniformity
An estimate of the endometrium's morphologic date (2-day interval)
Correlation with information about the chronological date
Statement about presence or absence of â€œorganic diseaseâ€•
Inflammation
Endometrial polyps
Submucous leiomyomas

Table 41.3 The Contents of the Pathology Report for an Infertility Endometrial Biopsy

Apoptosis and the Endometrium

The role of programmed cell death or apoptosis in the remodeling of the endometrium was mentioned earlier in this chapter. Apoptosis and its hormonal control in both human and animal endometrium is an area of active investigation by a number of groups (200 ,201 ,202 ,203).

Withdrawal of progesterone in the rabbit endometrium correlates with the development of apoptosis (204 ,205 ,206 ,207).

Bcl-2 is a protooncogene initially described in the (14 ,18) translocation in follicular lymphoma. It has been shown to prolong cell survival by preventing apoptosis. Gompel et al. studied Bcl-2 expression immunohistochemically in the normal endometrium (208). They found that Bcl-2 predominated in glandular cells and reached a maximum at the end of the follicular phase but disappeared at the onset of secretory activity. Maia et al. found a precipitous drop in Bcl-2 after ovulation, further supporting an increase in Bcl-2 in response to estrogen and a decrease in response to progesterone (209). In addition, this group found an elevated p53 expression in the proliferative phase but a drop in the late luteal phase. These results strongly suggest hormone-dependent regulation of Bcl-2 expression and cell cycling.

The role of tumor necrosis factor alpha (TNF-Î±) in the induction of apoptosis was explored by Tabibzadeh et al. (210). They found that the TNF receptor as well as Fas protein were expressed in endometrial epithelium throughout the entire menstrual cycle and were most prominent in the

basalis. They concluded that endometrial epithelium, by expressing receptors for TNF-Î± and Fas protein, can respond to ligands that regulate apoptosis.

Normal findings in the endometrium that have relevance to histopathologic differential diagnosis are shown in Table 41.4 .

Myometrium

The bulk of the myometrium comprises smooth muscle cells, but an important contribution is made by extracellular components such as collagen and elastin. The smooth muscle within the corpus is more concentrated relative to collagen and elastin than the muscle in

either the cervix or the lower uterine segment. This distribution of muscle is consistent with the passive role of the cervix during parturition; the uterine contents propelled by fundal contractions are thought to passively dilate a cervix previously softened by the action of collagenase. The uterine smooth muscle cells are spindled, with blunt-ended fusiform nuclei. Their cytoplasmic volume depends on whether the patient is pregnant (211 ,212 ,213 ,214). Scattered normal mitotic figures may be encountered, particularly during the secretory phase of the endometrial cycle (215). Characteristic ultrastructural features of smooth muscle include (a) numerous dense, 60- to 80-A myofilaments without cross striations, which almost fill the cytoplasm; (b) small round dense bodies along the trajectory of the filaments; (c) dense plaques arranged along the inner aspect of the plasma membrane; and (d) plasma membraneâ€“related vesicles that may play a role in ionized calcium movement across the plasma membrane during contraction. In addition, there is the usual complement of cytoplasmic organelles, including smooth and rough endoplasmic reticulum, mitochondria, and a Golgi apparatus. Typically these organelles arrange themselves around the nucleus, which often has an irregular shape. These ultrastructural features reflect the dual function of the uterine myocyte: muscular contraction and collagen and elastin synthesis. The ultrastructural appearance varies with the levels of circulating steroidal hormones. In particular, estrogen appears to sharply increase myocyte protein synthesis. This correlates morphologically in an increased volume of rough endoplasmic reticulum and increased numbers of cytoplasmic contractile elements. The biochemistry and electrophysiology of the myometrium have been extensively reviewed (214 ,216 ,217). The histologic and ultrastructural appearance of smooth muscle cells differ substantially from those of the endometrial stromal cell. These differences are set out in Table 41.5 . However, it should be noted that cells with a hybrid smooth muscleâ€“stromal phenotype occur normally at the endometrialâ€“myometrial junction and that this

phenotypic ambiguity is sometimes expressed by spindle cell neoplasms of the uterine corpus (218). Some uterine smooth muscle cells have been shown to express some classes of keratins (219 ,220 ,221 ,222). The immunohistochemical profile of myometrial cells is presented in Table 41.5 .

Pregnancy-Related Changes

To accommodate the growing fetus and to prepare for its role in fetal expulsion, the uterus undergoes a 10-fold increase in size and weight during pregnancy both by hypertrophy and, to a much lesser extent, by hyperplasia. Normal mitotic figures are often increased and may be present in large numbers. Uterine growth during pregnancy appears to be largely promoted by estradiol, whereas progesterone probably functions to inhibit uterine contractions during gestation. The light microscopic appearance of the hypertrophied uterine smooth muscle cells of pregnancy is distinctive. They are enlarged and have abundant, rather glassy cytoplasm and vesicular elongate nuclei with occasionally prominent nucleoli. Changes occur in the ultrastructural appearance of the smooth muscle cells as well. In addition to an increase in size and the number of myofilaments, there is a striking increase in the number of gap junctions (223 ,224). These establish the contact between cells required for the coordinated uterine contractions that expel the term infant (225). These myometrial changes are closely coordinated with the dramatic structural changes of cervical â€œripeningâ€• required for cervical effacement (see section â€œUterine Cervix â€•). In the postpartum period, the uterus undergoes an extraordinary 85% reduction in weight within 3 weeks of delivery (25). This weight loss is primarily due to a reduction in individual cell volume rather than a reduction in cell number. In addition, a large amount of collagen is degraded over this brief period. Complete return of the uterus to the nulliparous weight does not occur if gestation has proceeded beyond the second trimester.

The Fallopian Tube

Histology of the Fallopian Tube

The fallopian tube is lined by a nonstratified epithelium that is separated from the endosalpingeal stroma by a basement membrane. Each of the tubal segments is lined by a mixture of three basic cell types: ciliated cells, secretory cells, and intercalated (peg) cells (Figures 41.46A, B and 41.47). In recent years it has become apparent that the peg cell is, in reality, a stage in the cyclic variation during the menstrual cycle of the secretory cell (226). The relative number of these cells differs in each of the anatomic

P.1049

P.1050

P.1051

regions of the tube. In addition, many investigators believe that the numbers of the three types of cells within each of these anatomic regions undergo regular variations throughout the menstrual cycle (227 ,228 ,229 ,230 ,231 ,232). Ciliated cells are most prominent at the ovarian (distal) end of the tubeâ€”particularly in the fimbrial mucosaâ€”and predominate during midcycle; their numbers diminish progressively to achieve a nadir at the time of menstruation (Figure 41.47). In a gestational cycle the number of cilia continue to decrease. Ciliary movement rather than muscular contractions is chiefly responsible for the movement of the egg toward the site of fertilization: the ampulloisthmic junction.

â€œGlands within glandsâ€• can occur from trauma of D&C (telescoping) and tangential cutting
Endometrial hyperplasia: rolled up carpet effect may simulate the architectural complexity of hyperplasia or carcinoma
This artifact is usually only focal and often at the periphery or otherwise normal fragments of functionalis. Check that epithelium is identical to architecturally normal glands in the sample.

Strips of normal surface epithelium
Commonly seen with atrophic endometrium
Endometrial/hyperplasia/carcinoma : rolled up carpet effect may simulate the architectural complexity of hyperplasia or carcinoma
In contrast to hyperplasia and carcinoma, the rolled up atrophic endometrium is cytologically bland and mitotically inactive.
268
Lower uterine segment
Dating problem: the glands respond weakly at best to hormones and the stroma is often fibrous
Look for mucinous epithelial component. Unless the sample is inadequate for dating the endometrium, there will be other fragments around with an appearance more typical of functionalis.

Normal basalis
Dating problem: the glands respond weakly at best to hormones and the stroma is inactive
When assigning a morphologic date to an endometrial fragment, use only glands in close approximation to surface epithelium

Ciliated cells
Adenocarcinoma: intraepithelial ciliated cells have rounded pear-shaped contours and open, rounded nuclei with nucleoli
Look for cilia.
Endometria containing ciliated cells have a polymorphous appearance; the cytologic features are uniform within each subpopulation of cells.
268
Foam cells
Endometritis: foam cells are commonly encountered in hypoestrogenic settings and are thought to be one differentiated form of endometrial stromal cells

Look for plasma cells to establish the diagnosis of chronic endometritis. Macrophages (xanthoma cells) with foamy cytoplasm may occur in the endometrium as a component of a chronic inflammatory process. Commonly seen as a reaction to a foreign body or to keratin (e.g., in setting of proliferations shedding keratin).

269

Arias-Stella reaction

Adenocarcinoma: particularly clear cell carcinoma

Clear cell carcinoma is most frequently encountered in postmenopausal women.

Arias-Stella reaction usually does not feature mitotic figures, which are almost always easily found in clear cell carcinoma. A more difficult problem is distinguishing clear cell carcinoma from Arias-Stella reaction in a postmenopausal woman who is taking progestational medication.

171 ,173 ,174 ,223

Implantation site

Gestational trophoblastic disease: early gestations may mimic choriocarcinoma. The often bizarre shapes of trophoblastic cells may raise the possibility of choriocarcinoma a molar gestation, or PSTT

Clinical history to establish time course of gestation

Insistence on a bilaminar pattern of cytotrophoblast alternating with syncytiotrophoblast for choriocarcinoma, villi are not present in choriocarcinoma PSTT features.

Clinically relevant endometritis: a mixed plasmacyticâ€“lymphocytic infiltrate is a normal finding at the implantation site

Clinically relevant gestational endomyometritis can occur but only rarely is diagnosed initially on endometrial samplings. The vast majority of cases of â€œchronic endometritisâ€• seen in practice represent a clinically insignificant â€œphysiologicâ€• finding.

Irregular endometrialâ€“myometrial junction
Adenomyosis: glands and stroma surrounded by smooth muscle
Associated smooth muscle hypertrophy is a common feature of adenomyosis and not irregular junctions. Superficial myometrial location of suspected foci favors irregular junctions.
268
Myoinvasive adenocarcinoma: the irregular junction, when expanded by hyperplasia or carcinoma, often simulates myoinvasive carcinoma Tangential sectioning often reinforces this impression
Absence of stromal host response that is usual in myoinvasive carcinoma. Presence of endometrial stroma or normal glands means irregular junction (or adenomyosis).

Menstrual endometrium
Adenocarcinoma: â€œcytologic atypiaâ€• produced by degenerating, poorly preserved glandular elements
Endometrial stromal neoplasm: degenerating stroma may produce a pattern resembling endometrial stromal sarcoma with or without sex cord elements
Obtain history; menstrual fragments have degenerating, not neoplastic, nuclei.

Lymphoid nodules
Endometritis
The presence of scattered lymphoid nodules does not correlate with significant clinical disease Large numbers of lymphoid nodules and germinal centers are usually associated with the conventional sine qua non of â€œchronic endometritis,â€• the plasma cell.

Stromal â€œgranulocytesâ€•
Acute or chronic endometritis
â€œStromal granulocytesâ€• are a normal feature of the late secretory endometrium and serve as one of the original Noyes dating criteria. In the fullness of time it has been established that

these â€œgranulocytesâ€• are uterine NK cells (see text).
Clinically significant inflammation (of the type encountered in patients with established salpingitis) features the presence of easily found plasma cells and usually is accompanied by acute inflammation and necrosis of the surface epithelium.
Not infrequently, endometrial stromal cells or normal lymphoid constituents may have somewhat eccentric nuclei and amphophilic cytoplasm that mimics that of a plasma cell. This is usually a problem with one or two scattered cells in a fragment. Plasma cells have to be easily found before they amount to anything clinically.
129 ,270 ,271 ,272 ,273
Nuclear ground glass appearance of nuclei of epithelial cells in gestational setting and with progestogen therapy
Herpes endometritis
Herpes endometritis is rare; obtain history.
Immunohistochemistry may be helpful.
175

Findings	Diagnostic Confusion	Suggestions for Resolution	References

Table 41.4 Normal Findings in the Endometrium that have Relevance to Histopathologic Differential Diagnosis *(see text for Additional Differential Diagnostic Clues)*

Secretory cells are most prominent toward the uterine end of the tube and undergo cyclic changes in cell height and appearance, reflecting their elaboration, accumulation, and discharge of oviduct secretions as the menstrual cycle proceeds. Most often they have ovoid, somewhat dense nuclei, and they may contain an apical vacuole (Figure 41.48A, B). The oviduct fluid secreted by these cells serves many important functions and has been the subject of a review (233).

Intercalated cells have been thought to represent either effete

secretory cells or some type of reserve cells. They have a thin dense nucleus and little cytoplasm. Endocrine cells have been noted in the fallopian tube; their function is as mysterious here as it is in the uterus (234). The â€œbasal cellsâ€• reported in the early literature have been shown to be lymphocytes, which may represent a tubal component of a mucosa-associated lymphoid system (235 ,236 ,237 ,238 ,239). Scattered lymphocytes and occasional lymphoid follicles should be considered to be within normal limits and constitute part of the mucosa-associated lymphoid system (240).

Ciliogenesis is promoted by estradiol and deciliation by progesterone. Prolonged exposure to progestogens (whether endogenously as in pregnancy or exogenously) or withdrawal of estrogen (as in the postmenopausal years) leads to epithelial atrophy. Postmenopausal estrogen administration leads to regrowth of cilia.

Mitotic figures are rarely seen in the fallopian tube epithelium, so no cyclic regeneration occurs as in the endometrium. Both the transmission and scanning electron microscopic appearance of the normal tubal mucosa have been extensively documented over the past two decades.

Of interest to the diagnostic pathologist are the abnormalities of ciliogenesis found in patients with Kartagener's syndrome (241 ,242).

Light microscopy
Architectural features
Haphazardly arranged cells resembling normal proliferative phase endometrial stromal cells
Cells arranged in looping intersecting fascicles
Rounded or polygonal cells with moderate amount of cytoplasm
Biphasic pattern

Stromal component (featuring cellular endometrial stroma or fibroblastic stroma) + Epithelioid component
{â€¢ Trabecular epithelial pattern or
â€¢ nests or
â€¢ insular pattern or
â€¢ Sertoli-like tubular pattern or
â€¢ glands}
Complex plexiform vascular pattern
Vascular component not complex
Foci of neoplasm often exhibit standard smooth muscle features
When the entire neoplasm has this biphasic appearance the term â€œuterine tumor resembling ovarian sex cord tumorsâ€• has been used
When the change is focal within what is otherwise an endometrial stromal neoplasm (either stromal nodule or endometrial stromal sarcoma) the endometrial stromal diagnosis is supplemented with â€œwith epithelioid or glandular areasâ€•
Hyalin sometimes abundant with a tendency to be glassy

Cytological features
Nucleus
Blunt, round-to-fusiform, uniform, bland
Elongate, cigar-shaped
Round, crumpled
Small, round and regular nuclei

- Minimal nuclear pleomorphism
- Only rare mitotic figures

Cytoplasm
Scanty on H&E and trichrome)
Moderate amount (on H&E and trichrome), typically fibrillar
Cytoplasm may be clear around the nucleus, clear at the periphery

of the cell, or entirely clear
Scanty cytoplasm, or may have abundant eosinophilic or foamy (lipid-rich) cytoplasm
Immunohisto-chemistry
Normal endometrial stromal cells express CD10 and may express desmin; they are negative for cytokeratin and EMA.
Uterine smooth muscle cells express desmin and caldesmon. They also express CD10 (approximately 40%), CD34 (about a third), keratin (about 20%), and EMA (roughly half).
AE1 is positive in 40% of cases, desmin is positive in 80%, and CD34 in 10%.
Epithelioid areas are:

- Muscle specific actin (HHF-35) positive
- Vimentin positive
- Cytokeratin positive

Technique	Endometrial Stromal Cells	Usual Smooth Muscle Cells	Epithelioid Smooth Muscle Cells	Endometrial Stroma with Epithelioid and/or Glandular Areas

Table 41.5 Comparison of Differentiated Features for Endometrial Stromal Cells and Smooth Muscle Cells

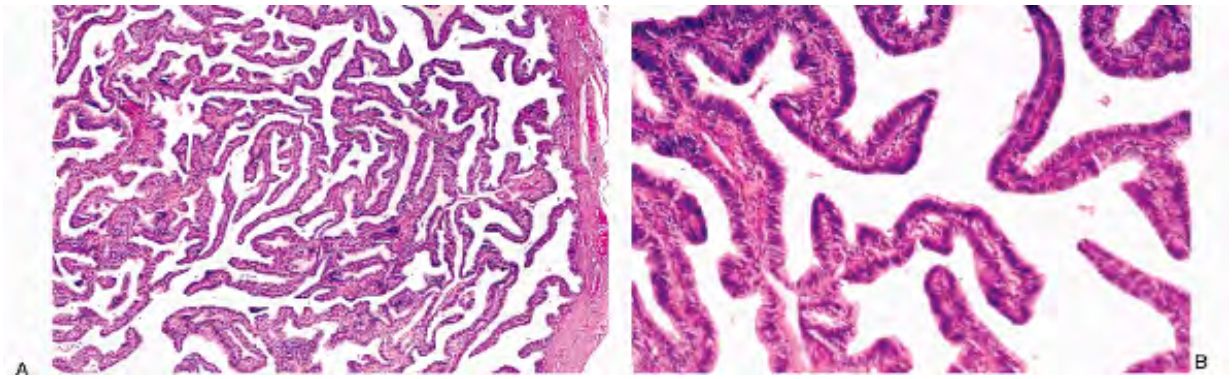

Figure 41.46 A . and B . Ampulla of the fallopian tube. Note the long slender plicae or folds resting on the muscularis.

Figure 41.47 This high-power photomicrograph of tubal epithelium shows numerous ciliated cells with a compressed secretory cell nucleus above the level of the ciliated cells. The cell with clear cytoplasm is probably a lymphocyte.

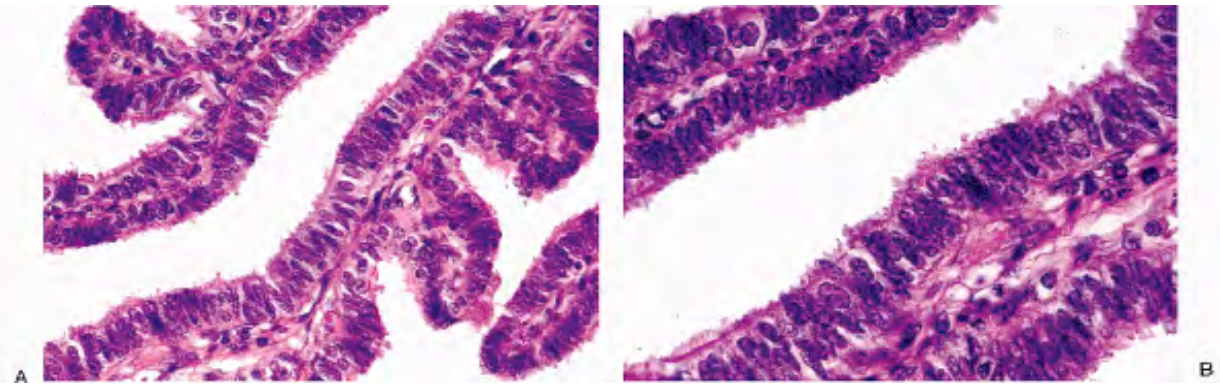

Figure 41.48 A . and B . In this area the tubal epithelial cells are crowded, a pattern that is common in the fallopian tube when ciliated cells are not numerous.

With the advent of genetic testing for BRCA-1 and BRCA-2 gene mutations, prophylactic salpingo-oophorectomies are being performed. Although there are no inherent morphological changes in the epithelium of a fallopian tube from a woman who harbors a BRCA-1 or BRCA-2 gene mutation, she is at an increased risk of having an in situ or invasive carcinoma. Therefore, in this setting the entire fallopian tube should be submitted for histological evaluation and scrutinized for occult malignancy (243 ,244).

Myosalpinx

The myosalpinx is composed of an inner circular layer and an outer longitudinal layer. The isthmus near the uterotubal junction also possesses an inner longitudinal layer. The presence of the muscular layer can be particularly helpful to the pathologist when trying to distinguish a tubo-ovarian complex from an ovarian serous neoplasm.

Physiology

The details of the physiology of the tube are beyond the scope of

this chapter; interested readers are referred to published reviews (229 ,245). Unresolved mysteries include how the sperm moves so rapidly from the vagina to the ampulla (in some cases within 5 minutes) and how the tube manages to orchestrate fertilization by ensuring that spermatozoa moving toward the ovary and an egg moving away from the ovary meet in the appropriate part of the fallopian tube.

Fallopian Tube in Pregnancy

The fallopian tube has already played its part when the fertilized ovum implants in the endometrium. It is now inactive throughout the gestational period. A muted version of endometrial decidual change often occurs in the endosalpingeal stroma during the latter part of pregnancy, while the epithelium of the fallopian tube undergoes atrophy (246) (Figure 41.49). The fallopian tube is the most common site of ectopic gestation. A review of physiologic factors in its development has been presented (247). Morphologic changes in the fallopian tube can be produced by birth control pills and of course tubal ligation (248 ,249 ,250).

Normal findings in the fallopian tubes that have relevance to histopathologic diagnosis can be found in Table 41.6 .

Paraovarian and Paratubal Structures

The broad ligament and environs are populated by a variety of tubular and cystic structures with the propensity to form clinically or surgically noticeable cysts (38 ,251). These are indicated in Figure 41.50 . Many are lined by mÃ¼llerian-type epithelium. Walthard rests are universal findings over the serosal surface of the fallopian tubes. They are lined by transitional-type epithelium. A more or less constant finding in sections that include the peritubal soft tissue are the tortuous remnants of the mesonephric ducts. These are lined by cuboidal epithelium and possess a fibromyovascular cuff.

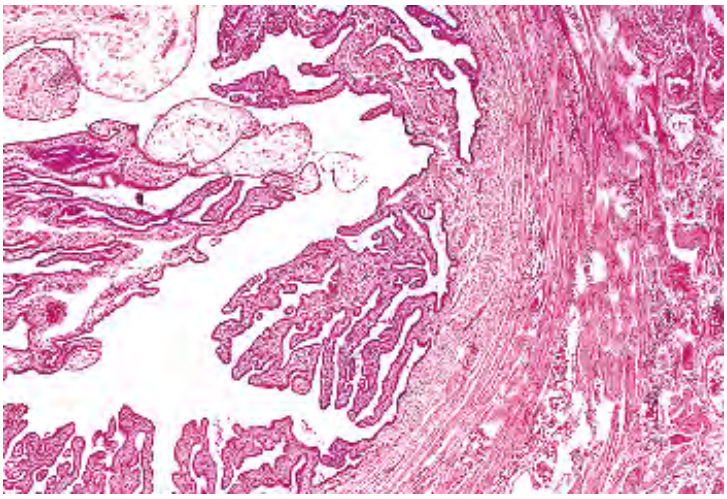

Figure 41.49 Fallopian tube containing decidual cells (upper left). The stromal cells of the plicae frequently undergo decidual change during pregnancy.

Supplemental Readings

A chronicle of the changing concepts of the uterus through the ages is provided by Ramsey (10), and a fascinating discussion of the role of preconceptions in filtering the â€œfactsâ€• of uterine anatomy is provided by Laqueur (252). There has been interesting speculation on the evolutionary purposes of menstruation (253 ,254).

Several textbooks of gynecological pathology provide coverage of normal uterine and fallopian tube anatomy and the differential diagnostic issues raised by departures from typical appearances.

Kurman RJ, ed. *Blaustein's Pathology of the Female Genital Tract.* 5th ed. New York: Springer-Verlag; 2002.

Several extensive treatises on reproductive endocrinology have been published or revised in recent years:

Strauss JF III, Barbieri RL. *Yen and Jaffe's Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management* . 5th ed. Philadelphia: Elsevier Saunders; 2004.

Speroff L, Fritz MA, eds. *Clinical Gynecologic Endocrinology and Infertility* . 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2004.

Decidual reaction (usually encountered in postpartum tubal ligation specimens but may also be seen in the tubes of patients on progestational agents)
Do not misinterpret as carcinoma
Nuclei are bland in decidua
246 ,250
Endosalpingiosis
Distinguish from endometriosis and ovarian serous tumor of low malignant potential (borderline tumors)
Look for endometrial stroma to confirm diagnosis of endometriosis; look for complex papillae with micropapillae to confirm diagnosis of serous LMP.

Crowded cells and dense nuclei
Carcinoma in situ
Carcinoma in situ features prominent nucleoli and abnormal mitotic figures. Nuclear atypia and glandular complexity can be significant in chronic salpingitis.

Mucinous and eosinophilic metaplasia (may be associated with Peutz-Jeghers syndrome)
Carcinoma
Metaplasia lacks the architectural complexity, the nuclear atypia, and the mitotic activity of carcinoma.

288 ,289
Squamous metaplasia
Walthard cell rests
Carcinoma
Metaplasia lacks the architectural complexity, the nuclear atypia, and the mitotic activity of carcinoma.

Finding	Diagnostic Confusion	Suggestions for Resolution	References when Relevant

Table 41.6 Normal Findings in the Uterine (Fallopian) Tube and Uterine Serosa that have Relevance to Histopathologic Differential Diagnosis *(see text for Additional Differential Diagnostic Clues)*

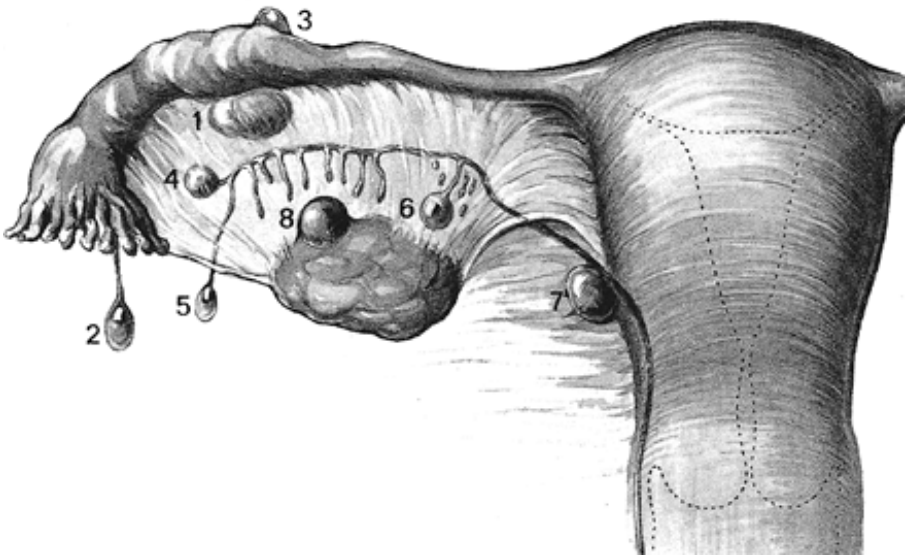

Figure 41.50 Topography of various cysts encountered in the female internal genitalia. 1, Paraovarian cyst of paramesonephric origin (type I); 2, hydatid cyst of Morgagni (paramesonephric origin); 3, subserosal mÃ¼llerian cyst (paramesonephric origin); 4, paraovarian cyst of mesonephric origin (type II); 5, Kobelt's cyst (appendix vesiculosa); 6, cyst of the paroophoron; 7, duct cyst; 8,

cyst of the rete ovarii. Reprinted with permission from: Janovski N, Paramanandhan T. *Ovarian Tumors, Tumors and Tumor-like Conditions of the Ovaries, Fallopian Tubes and Ligaments of the Uterus.* Philadelphia: WB Saunders; 1973:191â€“194.

Ovary

Philip B. Clement

Embryology

Approximately 5 weeks after fertilization, a thickening of the coelomic epithelium (mesothelium) along the medial and ventral borders of the mesonephros leads to the formation of the genital ridge. The gonadal anlage forms as a result of continued proliferation of this epithelium and the subjacent mesenchyme (1). Simultaneously, primordial germ cells migrate to the gonad from the yolk sac endoderm, reaching the genital ridge during the fifth and sixth weeks of embryonic life (2). These cells (oogonia) undergo mitotic activity and become most numerous at mid-gestation; two-thirds of them will undergo atresia by term (1,3). At 12 to 15 weeks' gestation, the oogonia begin meiosis and arrest in meiotic prophase, and are now referred to as primary oocytes (3,4,5).

At two months, the primitive gonad is recognizable as an ovary because, in contrast to the testis, it has remained basically unaltered. At 7 to 9 weeks' gestation, the outer zone of the ovary has enlarged to form the definitive cortex, which consists of confluent sheets of primitive germ cells admixed haphazardly with a smaller number of smaller pregranulosa cells (4,6). At 12 to 15 weeks, vascular connective tissue septa begin to radiate from the medullary mesenchyme into the inner portion of the cortex, and

extend into the superficial part of the cortex by 20 weeks (5,6). The cortex thereby

becomes divided into cellular groups composed of oocytes and pregranulosa cells (sex cords). Simultaneously, the pregranulosa cells begin to surround individual germ cells to form primordial follicles. Folliculogenesis begins in the inner part of the cortex at 14 to 20 weeks' gestation (2,3,5,7), and gradually extends to the outer cortex by the early neonatal period (8). The occasional follicles that mature into preantral and antral follicles in late gestation become surrounded by a condensation of mesenchymal cells that become the theca interna (4,7). The rete ovarii is present in the hilus as early as 12 weeks (5).

The origin of the gonadal sex cords (pregranulosa cells in the ovary and Sertoli cells in the testis) is controversial. Some investigators (2,4,8,9) believe that they are derived from the coelomic epithelium, while others (10) favor an origin from the â€œmesenchyme.â€• Still others (11,12) believe that the gonadal blastema is too undifferentiated to classify as either epithelial or mesenchymal. More recent observations indicate that the sex cords are likely of mesonephric origin (13,14,15,16). Satoh (14) found that although rudimentary cord-like structures arise from coelomic epithelial cells, they disappear before contributing to the formation of the definitive sex cords, which are derived from cells that originate from the mesonephros.

Gross Anatomy

The ovaries are paired pelvic organs that lie on either side of the uterus close to the lateral pelvic wall, behind the broad ligament and anterior to the rectum. Each ovary is attached along its anterior (hilar) margin to the posterior aspect of the broad ligament by a double fold of peritoneum, the mesovarium; at its medial pole to the ipsilateral uterine cornu by the ovarian (or utero-ovarian) ligament;

and from the superior aspect of its lateral pole to the lateral pelvic wall by the infundibulopelvic (or suspensory) ligament. The location of the ovary posterior to the broad ligament and a similar relationship of the ovarian ligament to the ipsilateral uterine (fallopian) tube aids in the determination of the laterality of a salpingo-oophorectomy specimen.

Prepubertal Ovaries

The ovary in the newborn is a tan, elongated, and flattened structure that lies above the true pelvis. It sometimes has a lobulated appearance with irregular edges (Figure 42.1A). It has approximate dimensions of 1.3 cm by 0.5 cm by 0.3 cm, and a weight of less than 0.3 gm (17,18,19). Throughout infancy and childhood, the ovary enlarges, increases in weight 30-fold, and changes in shape, so that by the time of puberty it has reached the size, weight, and shape of the adult ovary, and lies within the true pelvis (18,19). Inspection of the external and cut surfaces, particularly during the first few months of life and at puberty, may reveal prominent cystic follicles (20) similar to those seen in polycystic ovary disease (Figure 42.1B).

Adult Ovaries

Adult ovaries are ovoid with dimensions of approximately 3.0 to 5 cm by 1.5 to 3.0 cm by .6 to 1.5 cm, and a weight of 5 to 8 gm. Their size and weight, however, vary considerably depending on their content of follicular derivatives. They have a pink-white exterior, which in early reproductive life is usually smooth (Figure 42.1C), but thereafter becomes increasingly convoluted. Three ill-defined zones are discernible on the cut surface: an outer cortex, an inner medulla, and the hilus. Follicular structures (cystic follicles, yellow corpora lutea, white corpora albicantia) are typically visible in the cortex and medulla.

Postmenopausal Ovaries

After the menopause, the ovaries typically shrink to approximately one half their size in the reproductive era (21). Their size varies considerably, however, with the number of ovarian stromal cells and unresorbed corpora albicantia (22). Most postmenopausal ovaries have a shrunken, gyriform, external appearance (Figure 42.1D), while some are more smooth and uniform. They have a firm consistency and a predominantly solid, pale cut surface, although occasional cysts measuring several millimeters in diameter (inclusion cysts) may be discernible within the cortex. Small white scars (corpora albicantia) are typically present within the medulla. Thick-walled blood vessels may be appreciable within the medulla and the hilus.

Blood Supply

The ovarian artery, a branch of the aorta, courses along the infundibulopelvic ligament and the mesovarial border of the ovary where it anastomoses with the ovarian branch of the uterine artery. Approximately ten arterial branches from this arcade penetrate the ovarian hilus, becoming markedly coiled and branched as they course through the medulla (23). These helicine arteries possess longitudinal ridges of intimal smooth muscle along their length. At the corticomedullary junction, the medullary arteries and arterioles form a plexus from which smaller, straight cortical arterioles arise and penetrate the cortex in a radial fashion, perpendicular to the ovarian surface. The cortical arterioles branch and anastomose several times, forming sets of interconnected vascular arcades (23). These arcades give rise to capillaries that form dense networks within the theca layers of the ovarian follicles. The intraovarian veins accompany the arteries, becoming large and tortuous in the medulla and forming a hilar plexus that drains into the ovarian veins; the latter traverse the mesovarium and course

along the infundibulopelvic ligament (23). The ovarian veins also anastomose with tributaries of the uterine veins. The left and right ovarian veins drain into the left renal vein and the inferior vena cava respectively.

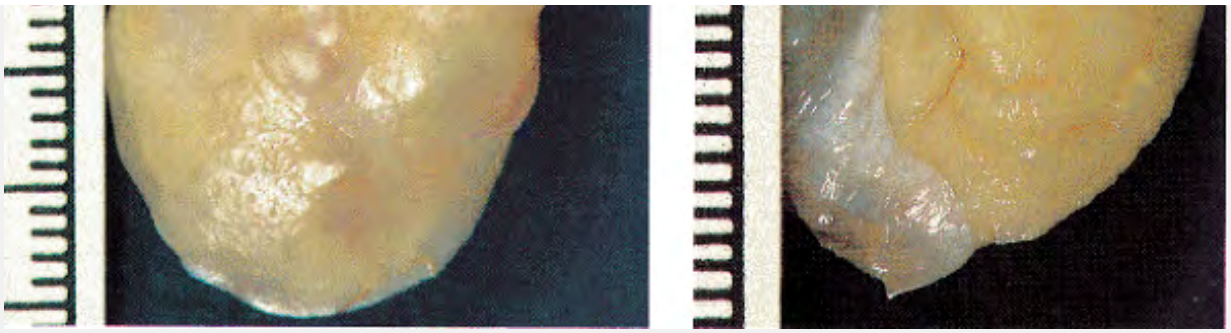

Figure 42.1 Gross appearance of ovary. A. Newborn, external aspect. B. Pubertal (age 15 years), sectioned surface. Note elongate shape and multiple cystic follicles. C. Adult (age 30), external aspect. D. Postmenopausal, external aspect. Note shrunken, gyriform appearance.

In postmenopausal women, the medullary blood vessels may appear particularly numerous and closely packed (Figure 42.2) and should not be mistaken for a hemangioma on microscopic examination. In addition, many of the same vessels may be calcified or have thickened walls and narrowed lumina due to medial deposition of a hyaline, amyloid-like material.

Lymphatics

The lymphatics of the ovary originate predominantly within the theca layers of the follicles. The granulosa layer of a maturing follicle is devoid of lymphatics in contrast to its counterpart within the corpus luteum, which possesses a rich supply of lymphatics (24). The lymphatics pass through the ovarian stroma, independent of blood vessels, to drain into larger trunks that form a plexus at the hilus. Within the hilus, the lymphatics and blood vessels converge, with the former coiled around veins in a helicoid fashion. Four to eight efferent channels pass into the mesovarium where they converge to form the subovarian plexus, which, in turn, is joined by branches

from the uterine (fallopian) tube and uterine fundus (24). Leaving the plexus, the drainage trunks diminish in number and size, passing along the free border of the infundibulopelvic ligament enmeshed with the ovarian veins. From there they accompany the ovarian vessels, juxtaposed to the psoas muscle, and drain into the upper para-aortic lymph nodes at the level of the lower pole of the kidney (24,25). The major lymphatic drainage of the ovary is therefore in a cephalad direction toward the para-aortic nodes. Accessory channels, however,

may bypass the subovarian plexus, passing through the broad ligament to the internal iliac, external iliac, and interaortic lymph nodes, or in some females, via the round ligament to the iliac and inguinal lymph nodes (24,25). When the pelvic and para-aortic lymph nodes are extensively replaced by tumor, retrograde lymphatic flow may represent a rare mechanism of tumor spread to the ovaries.

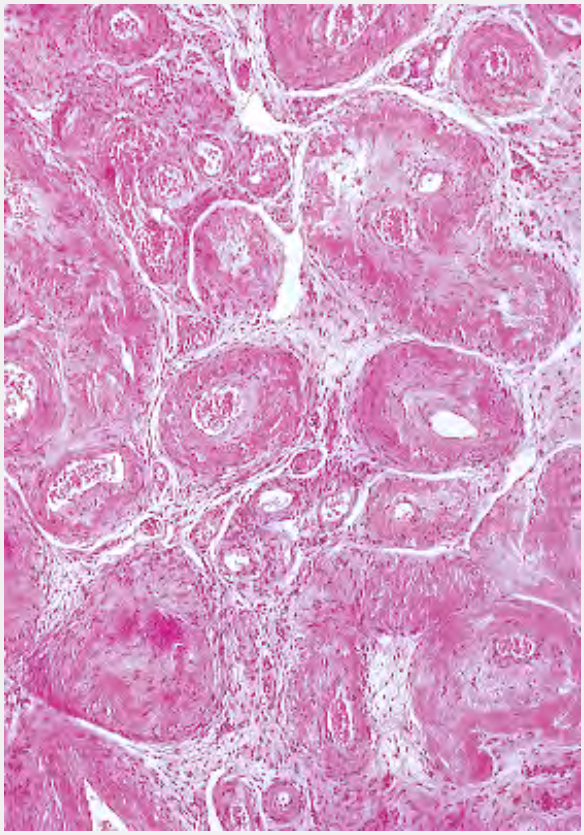

Figure 42.2 Numerous crowded thick-walled blood vessels within ovarian medulla of postmenopausal woman. Some of the vessels have an eosinophilic amyloid-like material within their walls.

Nerve Supply

The nerve supply of the ovary arises from a sympathetic plexus that is enmeshed with the ovarian vessels in the infundibulopelvic ligament (26). Nerve fibers, which are predominantly nonmyelinated, accompany the ovarian artery, entering the ovary at the hilus. Delicate terminal fibers, many surrounding small arteries and arterioles, penetrate the medulla and cortex to terminate as plexuses surrounding the follicles (26,27). Adrenergic nerve fibers and terminals are in close contact with smooth muscle cells in the cortical stroma and theca externa. The physiological significance of ovarian sympathetic innervation is not clear, although it has been suggested that it may play a role in follicular maturation, follicular rupture, or both (26,28,29). In addition, catecholamines can stimulate progesterone production by the ovarian follicles and androgen production by the ovarian stroma in vitro (30).

Surface Epithelium

Histology

The surface epithelium of the ovary consists of a single, focally pseudostratified layer of modified peritoneal cells. The cells vary from flat to cuboidal to columnar and several types may be seen in different areas of the same ovary (Figure 42.3). The surface cells are separated from the underlying stroma by a distinct basement membrane. This epithelium is extremely fragile and is almost always denuded in oophorectomy specimens because of undesirable rubbing

of the surface by the surgeon and the pathologist, as well as lack of prompt fixation resulting in drying. Preserved epithelium is often confined to areas protected by surface adhesions or lining sulci.

Histochemical studies have demonstrated glycogen, as well as acid and neutral mucopolysaccharides, within surface epithelial cells (31,32). Seventeen-beta hydroxysteroid dehydrogenase activity, absent in extraovarian mesothelial cells, also has been demonstrated (31). The surface epithelial cells are immunoreactive for cytokeratin, Ber-EP4, Wilms' tumor gene (WT1), calretinin, desmoplakin, vimentin, transforming growth factor alpha, Î±v/Î²3 integrin (and its ligand vitronectin), Î±- and Î²-catenins, and receptors for estrogen, progesterone, follicle stimulating hormone, and epidermal growth factor (33,34,35,36,37,38,39,40,41,42,43,44,45,46).

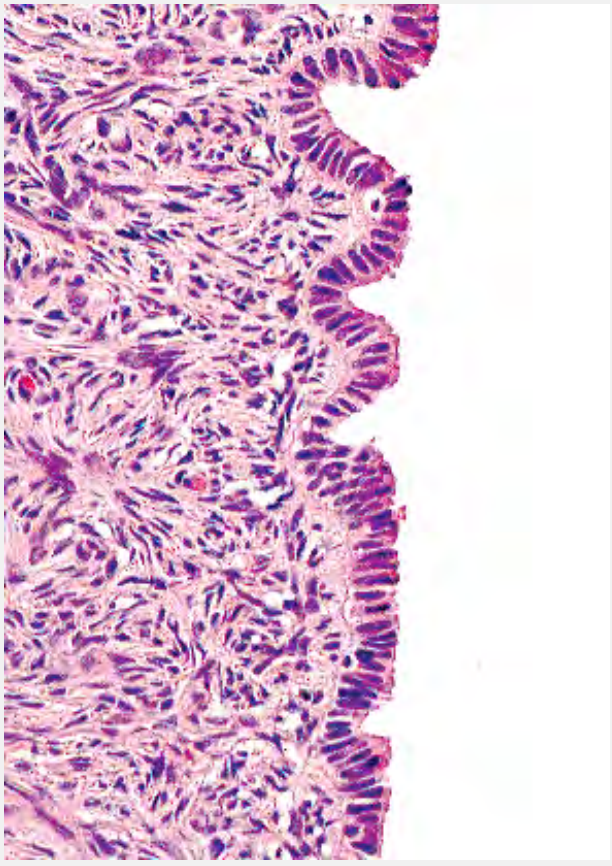

Figure 42.3 Ovarian surface epithelium composed of a single layer of columnar cells.

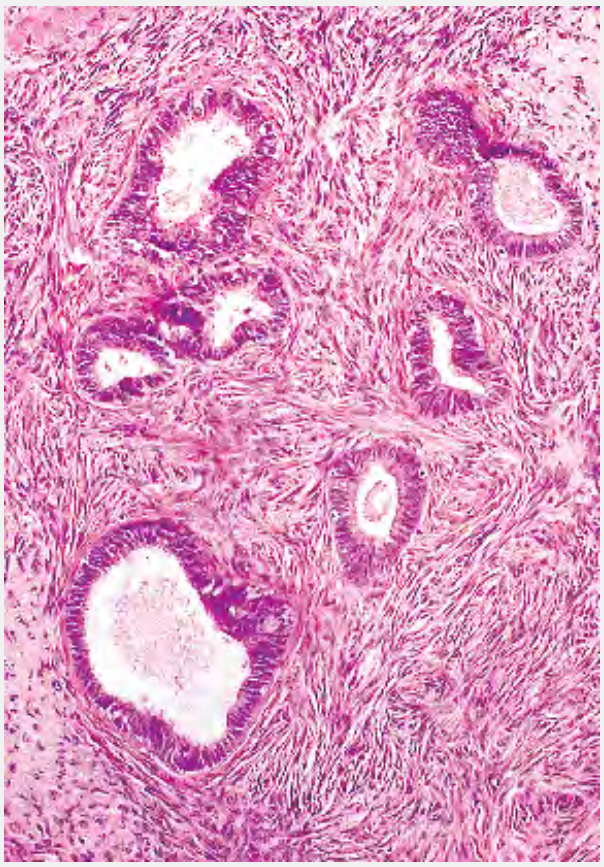

Figure 42.4 Epithelial inclusion glands within ovarian cortex.

Epithelial inclusion glands (EIGs) arise from cortical invaginations of the surface epithelium that have lost their connection with the surface. They often become cystic, resulting in epithelial inclusion cysts (EICs), which may be recognized on macroscopic examination; a diameter of 1 cm has been suggested as a dividing line between an

EIC and the smallest cystadenoma. EIGs have been identified on microscopic examination of ovaries from all age groups, including fetuses, infants, and adolescents (47,48). Inclusion glands and cysts (EIGCs) become more numerous with age, and are common incidental findings in late reproductive and postmenopausal age groups. They are typically multiple, scattered singly or in small clusters throughout the superficial cortex (Figure 42.4); less commonly, extension into the deeper cortical or medullary stroma may occur. EIGCs are typically lined by a single layer of ciliated tubal-type columnar cells; psammoma bodies within their lumina or the adjacent stroma are occasionally present. Similar glands, with or without associated psammoma bodies, encountered on the ovarian surface, within periovarian adhesions, and on the extraovarian peritoneum and omentum, are designated â€œendosalpingiosisâ€• (49). Less frequently, EIGCs may be lined by other mÃ¼llerian epithelia (endometrioid, mucinous), or nonspecific columnar or flattened cells (50,51). EIGCs are probably the site of origin of most cystic surface epithelial tumors (52). One study (53) found that EIGCs were more common in ovaries contralateral to a unilateral ovarian carcinoma and that they more often were lined by serous epithelium than in age-matched control patients without ovarian carcinoma. Dysplastic changes also have been described within EIGCs (52,54).

The histogenetic relationship between the ovarian surface epithelium, EIGCs, and tumors of epithelial type is reflected by the presence of markers associated with ovarian epithelial tumors within the normal surface epithelial cells and/or the cells lining EIGs. These have included WT1, E-cadherin, p53, CA 125, CA 19-9, CEA, hCG, MH99, placental lactogen, alpha-2 glycoprotein, beta-1 glycoprotein, placental alkaline phosphatase, human milk fat globule protein, and Î±v/Î²3 integrin/vitronectin (55,56,57,58,59,60,61,62,63). Hyperplasia and metaplasia of the surface epithelium, and of that within EIGs, are more common in women with polycystic ovarian disease and endometrial carcinoma (64), suggesting a possible

hormonal basis in some cases.

Urothelial differentiation is also within the metaplastic potential of the ovarian surface epithelium and pelvic peritoneum. Such differentiation typically takes the form of Walthard nests of transitional cells, a common microscopic finding within the serosa or the immediately subjacent stroma of the uterine (fallopian) tube, mesosalpinx, and mesovarium, or less commonly, the ovarian hilus (Figure 42.5) (65,66,67,68). The larger nests frequently become cystic and may be lined by columnar mucinous cells. Brenner tumors are also characterized by urothelial differentiation;

as many as one-half of those encountered by the pathologist are of microscopic size.

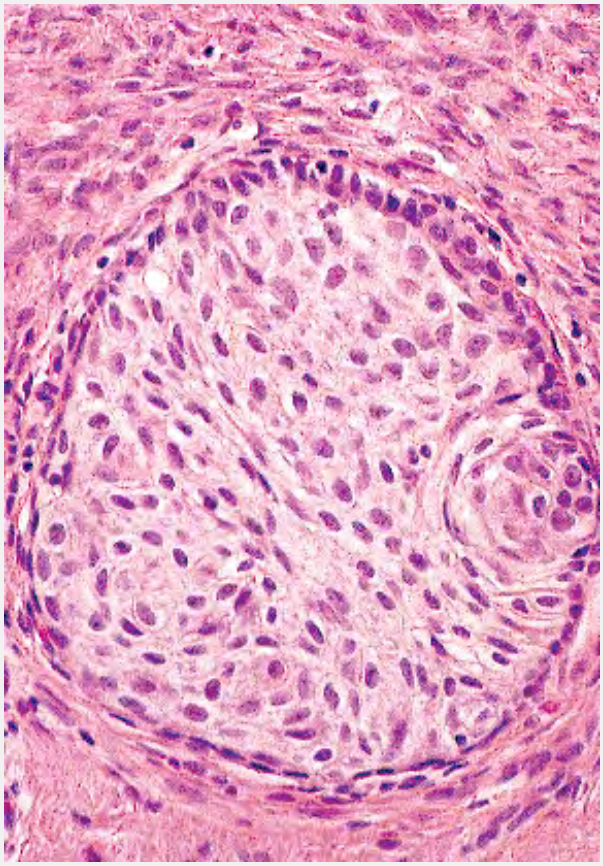

Figure 42.5 Walthard nest within ovarian hilus abutting medullary stroma.

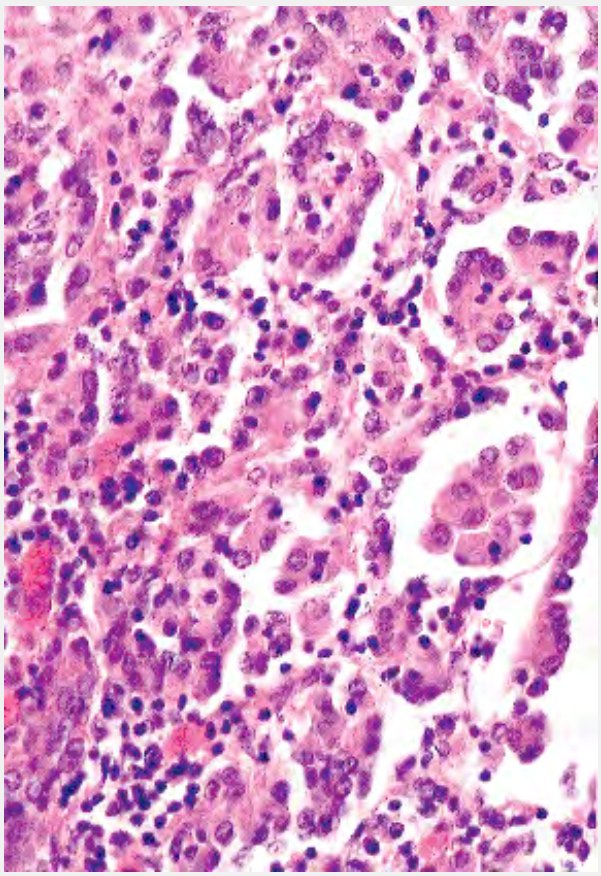

Figure 42.6 Hyperplastic mesothelial cells on ovarian surface. Note admixed inflammatory cells.

Hyperplastic mesothelial cells, usually a response to chronic pelvic inflammation, may involve the surface of the ovary and focally replace the ovarian surface epithelium. Florid examples exhibiting tubulopapillary (Figure 42.6) and pseudoinfiltrative patterns, as well as varying degrees of nuclear atypia, must be distinguished from a

malignant mesothelioma or a primary ovarian or metastatic carcinoma.

Ultrastructure

The ultrastructural appearance of the ovarian surface epithelium is similar to that of the extraovarian peritoneum (69,70,71). The cell surfaces by scanning and transmission electron microscopy have dome-shaped apices covered by numerous, often branching, microvilli, occasional single cilia, and pinocytotic vesicles (Figure 42.7). The cytoplasm contains abundant polysomes, free ribosomes, abundant mitochondria, and bundles of intermediate filaments and tonofilaments. Lipid droplets are sometimes present in the basal cytoplasm. The nuclei have indented nuclear membranes and peripheral nucleoli. Straight or convoluted lateral plasma membranes are reinforced by luminal junctional complexes, scattered desmosomes, and desmosomal-tonofilament complexes. The membranes may be widely separated in areas creating dilated intercellular spaces (70). A well-developed basal lamina separates the surface epithelium from the underlying stroma.

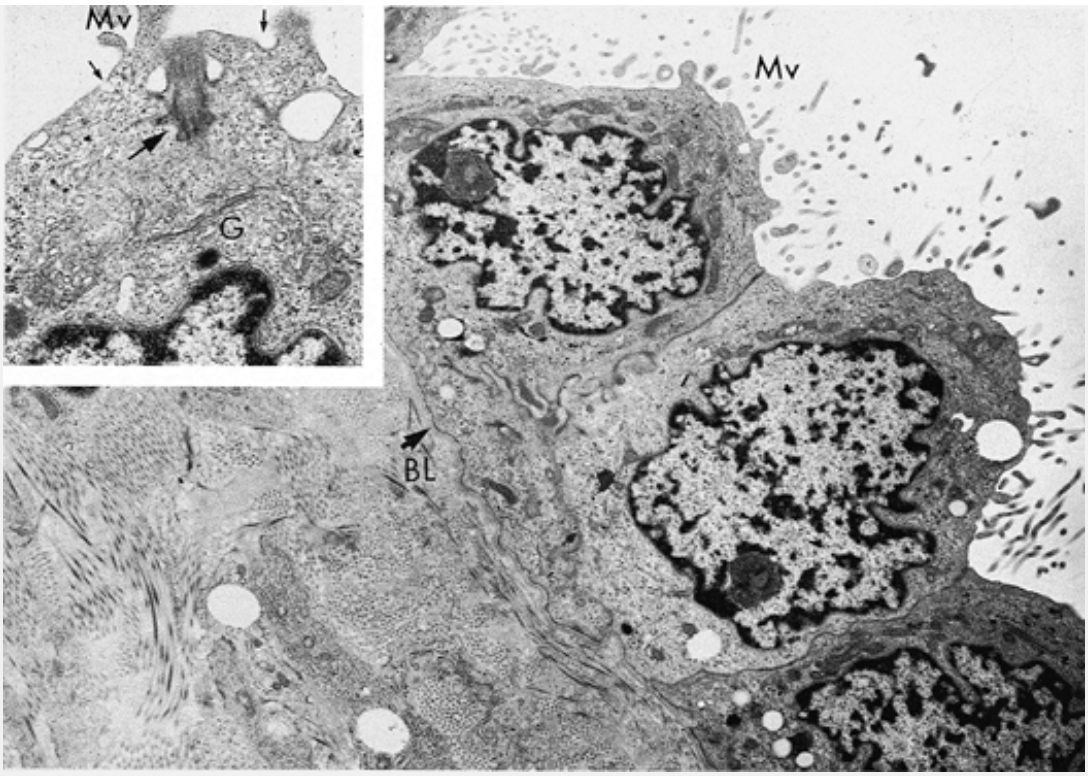

Figure 42.7 Electron micrograph of ovarian surface epithelium. The cells have numerous microvilli (Mv) and well-developed organelles in a perinuclear location. The nuclei have indented membranes and peripheral nucleoli. The lateral plasma membranes are reinforced by luminal junctional complexes and scattered desmosomes, but are occasionally widely separated producing dilated intercellular spaces. A well-defined basal lamina (BL) separates the cells from the underlying stroma (original magnification x6400). Inset: the surface microvilli are associated with micropinocytotic vesicles (short arrows) and occasional single cilia (long arrows). Note Golgi complex (G) (original magnification x22,000). Stroma

Histology

As the cortical and medullary stroma is continuous and similar in appearance, the boundary between these two zones is ill defined and arbitrary. The spindle-shaped stromal cells, which have scanty cytoplasm, are typically arranged in whorls or a storiform pattern (Figure 42.8). Fine cytoplasmic lipid droplets may be appreciable with special stains, especially in the late reproductive and postmenopausal age groups (72). Immunohistochemical stains reveal cytoplasmic vimentin, actin, and desmin (33,35,36,73,74). Stromal cells are separated by a dense reticulum network (Figure 42.8 inset) and a variable amount of collagen that is most abundant in the superficial cortex. Although the latter is frequently referred to as the tunica albuginea, it lacks the densely collagenous, almost acellular appearance and sharp delineation of the tunica albuginea of the testis.

A variety of other cells may be found within the ovarian stroma, most of which are probably derived from the cells of fibroblastic type. *Luteinized stromal cells*, which lie in the stroma at a distance from the follicles, are found singly or in small nests, most often in the medulla. They are polygonal cells with abundant eosinophilic to clear cytoplasm containing variable amounts of lipid, a central round nucleus, and a prominent nucleolus (Figure 42.9). These cells are typically immunoreactive for inhibin (75,76,77,78,79), calretinin (46,80), melan-A (81), CD10 (82), and occasionally, testosterone (83). The numbers of luteinized stromal cells increase during pregnancy and after the menopause; they are probably secondary to elevated levels of circulating gonadotropins during these periods (22,72). In one autopsy study, luteinized stromal cells were demonstrated after diligent searching in 13% of women under the

age of 55 and in one-third of women over that age; the frequency of their detection increased with increasing degrees of stromal proliferation (22). More exhaustive sampling might indicate that luteinized stromal cells are a normal finding in the ovary, particularly in later life. In this age group, the presence of luteinized cells is not usually associated with clinical evidence of a hormonal disturbance. In some older women, but more often in younger patients, however, more striking degrees of stromal luteinization (stromal hyperthecosis) are frequently associated with androgenic and estrogenic manifestations. Occasionally in such cases, nodules of luteinized stromal cells may be appreciable on low-power microscopic examination (nodular hyperthecosis).

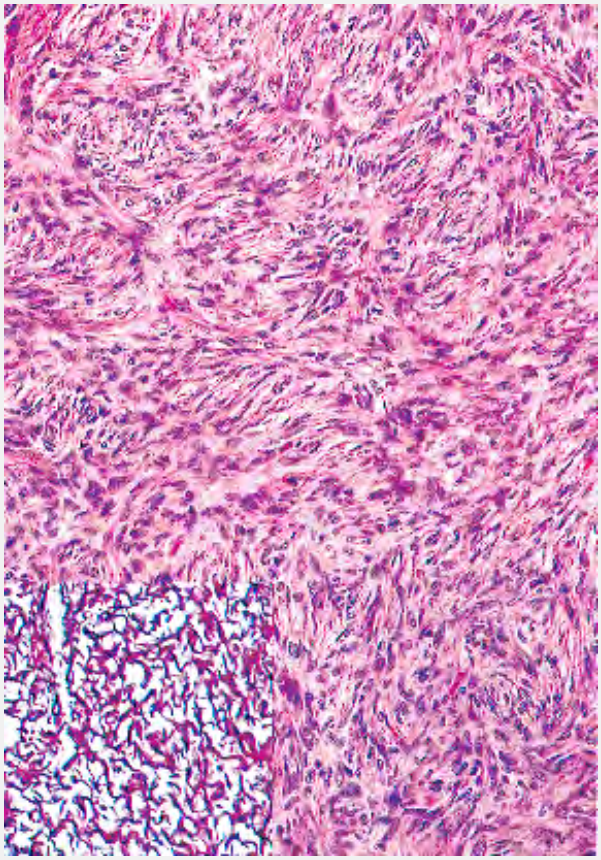

Figure 42.8 Ovarian stroma composed of whorls of plump spindle cells of fibroblastic type. Inset: note dense reticulum

network (reticulin stain).

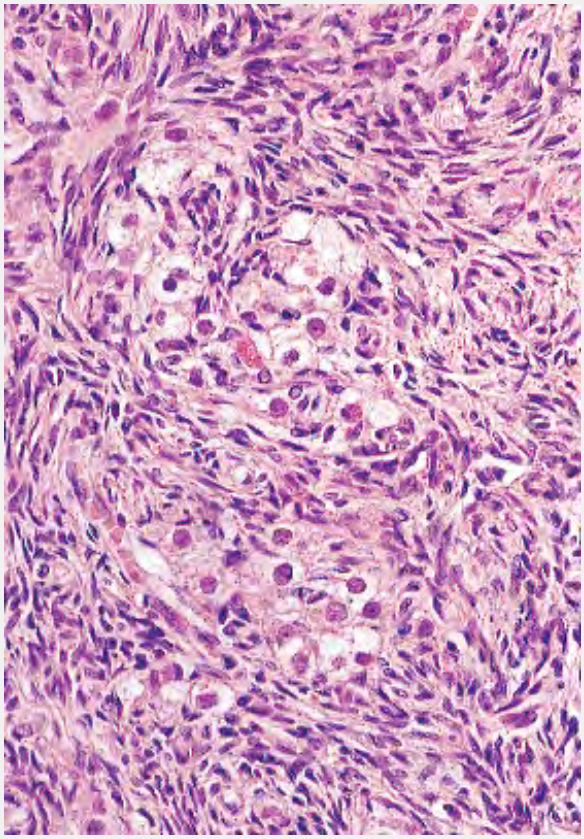

Figure 42.9 Luteinized stromal cells.

Enzymatically active stromal cells (EASC) are characterized by their oxidative and other enzymatic activity (72,84,85,86). The frequency of their detection and their numbers increase with age, occurring in over 80% of postmenopausal women, typically in the medulla (84,85). Some EASC correspond to luteinized stromal cells, but most cannot be distinguished from neighboring, nonreactive stromal cells in routine histologic preparations (84).

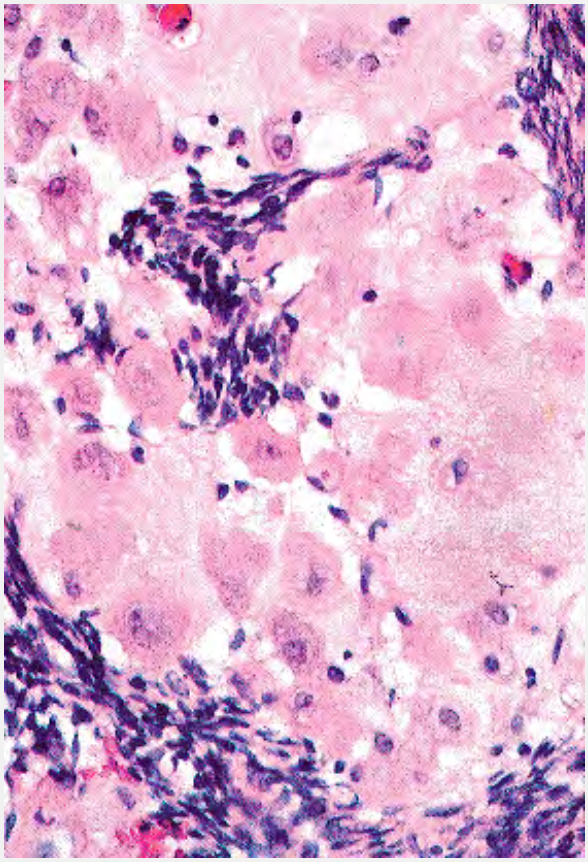

Figure 42.10 A nest of decidual cells within the ovarian stroma.

Decidual cells may occur singly, as small nodules, or as confluent sheets within the stroma of the superficial cortex or within periovarian adhesions (Figure 42.10). The appearance of the decidual cells is usually identical to eutopic decidua, but occasional examples may exhibit cytological atypia potentially mimicking metastatic carcinoma on histological examination (87,88,89,90,91,92). A network of capillaries and a sprinkling of lymphocytes are typically present within the decidual foci. A decidual reaction within the ovary is almost always a response of the ovarian stromal cells to elevated circulating or local levels of progesterone; progesterone receptors have been identified in the ovarian stromal cells (37). The process is

seen most commonly in pregnancy, occurring as early as the ninth week of gestation, and by term is present in virtually all ovaries. Less commonly it may occur in association with trophoblastic disease, in patients treated with progestins, in the vicinity of a corpus luteum, or in association with hormonally active, hyperplastic or neoplastic ovarian lesions (22,87,89). Prior pelvic irradiation may be a predisposing factor by increasing the sensitivity of the stromal cells to hormonal stimulation (89). Foci of ovarian decidua have been occasionally described in both pre- and postmenopausal women with no obvious cause (22,89).

Foci of *smooth muscle* may be seen within the ovarian stroma (Figure 42.11), most commonly within perimenopausal or postmenopausal women (93). The smooth muscle is bilateral in about 25% of cases and usually is confined to a few microscopic fields. It is often associated with other findings in the ovary, occurring with the hyperplastic ovarian stroma associated with stromal hyperthecosis or sclerocystic ovaries (94), and within the stroma surrounding nonneoplastic and neoplastic cysts, including endometriotic cysts. Rare endometriotic cysts may contain prominent amounts of smooth muscle (â€œendomyometriosisâ€•) (95). One study (93) found that almost 90% of women with ovarian smooth muscle metaplasia had uterine leiomyomas.

Nests of cells resembling *endometrial stromal cells* (â€œstromal endometriosisâ€•) occur within the ovarian stroma, usually in the absence of typical endometriosis (Figure 42.12) (96,97). Foci of mature *fat cells* may be encountered as an incidental histological finding within the subcapsular ovarian stroma (98,99); a possible association with obesity was noted in one study (99). Reinke-crystal-containing Leydig cells, presumably representing transformed stromal cells, may occur rarely, and are typically associated with stromal hyperthecosis or within the nonneoplastic stroma in or adjacent to an ovarian neoplasm (100,101,102). So-called â€œ*neuroendocrineâ€•* *or â€œAPUDâ€•* *type cells* have been demonstrated within the ovarian stroma in approximately 6% of normal women in one study

(103). The cells occur in small groups in the corticomedullary stromal junction and are argyrophilic and argentaffinic. Their clinical significance and hormonal function, if any, is unknown, but it has been suggested that they may represent the cell of origin of rare primary ovarian carcinoid tumors not associated with teratomatous or mucinous elements.

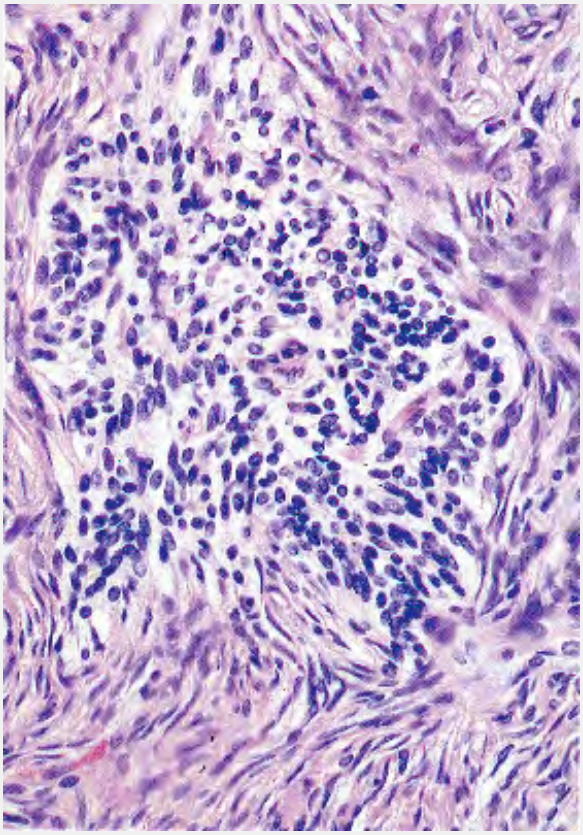

Figure 42.12 Focus of endometrial stromal cells (â€œstromal endometriosisâ€•) within ovarian cortex.

Aging Changes

Although there is typically a gradual increase in its volume from the fourth to the seventh decades (21,104), the ovarian stroma in postmenopausal women exhibits a wide spectrum of appearances (22,70,88). At one extreme, there is stromal atrophy manifested by a thin cortex and minimal amounts of medullary stroma (Figure 42.13). At the other extreme, there is marked stromal proliferation warranting the designation â€œstromal hyperplasiaâ€•. Most postmenopausal subjects, however, exhibit varying degrees of

nodular or diffuse proliferation of the cortical and medullary stromal cells that lie between these two extremes (Figure 42.14) (22,85), making the â€œnormalâ€• appearance difficult to define. Broad irregular areas of cortical fibrosis may be encountered in peri- and postmenopausal ovaries (22). When well-circumscribed, these foci resemble a small fibroma, but this designation is applied to lesions 1 cm or greater in diameter. A similar size limit could be used to distinguish between the foci of surface stromal papillarity commonly encountered in this age group (Figure 42.15) and serous surface papillomas. Cortical â€œgranulomasâ€• are common incidental microscopic findings in the late reproductive and postmenopausal age groups, having been demonstrated in up to 45% of women over the age of 40 (22,96,97,105,106,107). They consist of spherical circumscribed aggregates of epithelioid cells, lymphocytes, and

occasionally, multinucleated giant cells and anisotropic fat crystals (Figure 42.16). Cortical granulomas and the spherical, cloud-like, hyalin scars (Figure 42.17) present within the superficial cortical stroma of almost all postmenopausal ovaries are of uncertain histogenesis. It has been suggested that they may represent regressed foci of stromal endometriosis, ectopic decidua, or luteinized stromal cells.

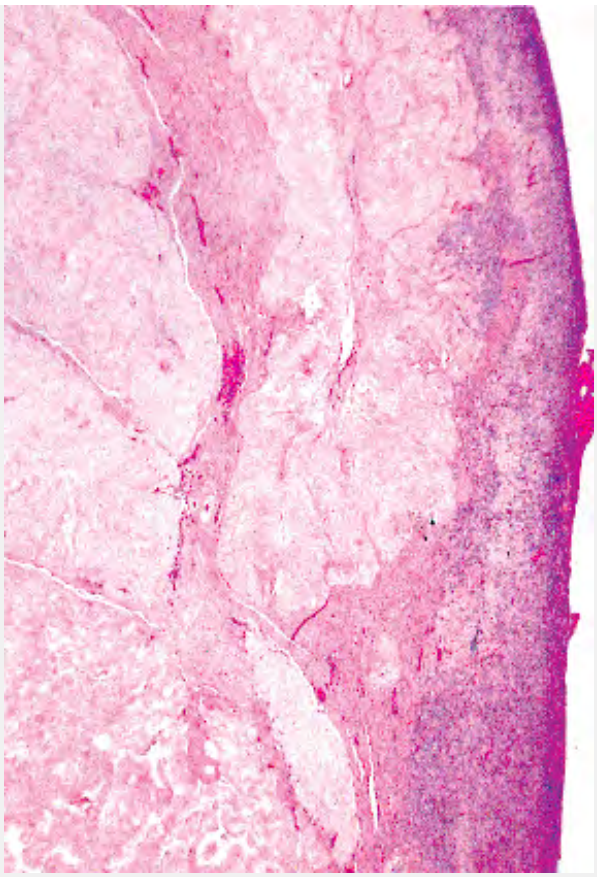

Figure 42.13 Atrophic postmenopausal ovary. The cortex is thin and multiple corpora albicantia are present within the medullla.

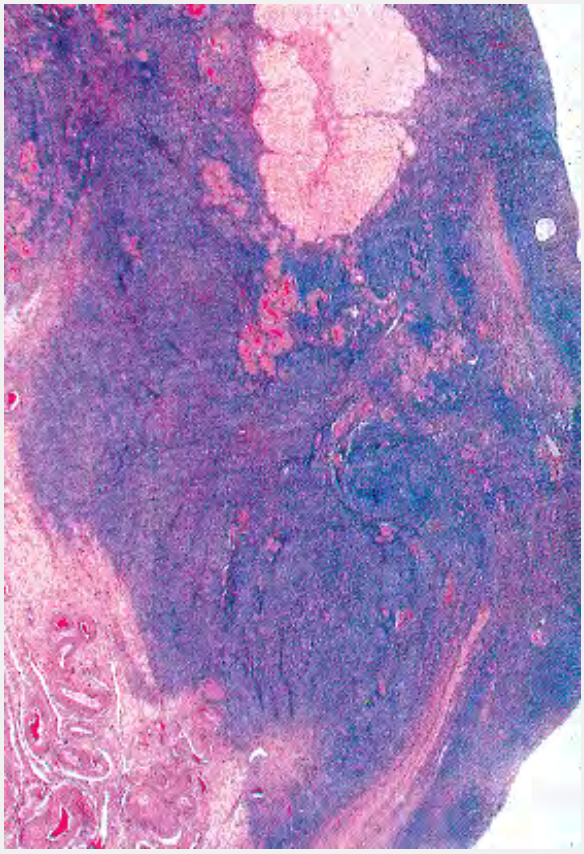

Figure 42.14 Postmenopausal ovary with a moderate degree of stromal proliferation.

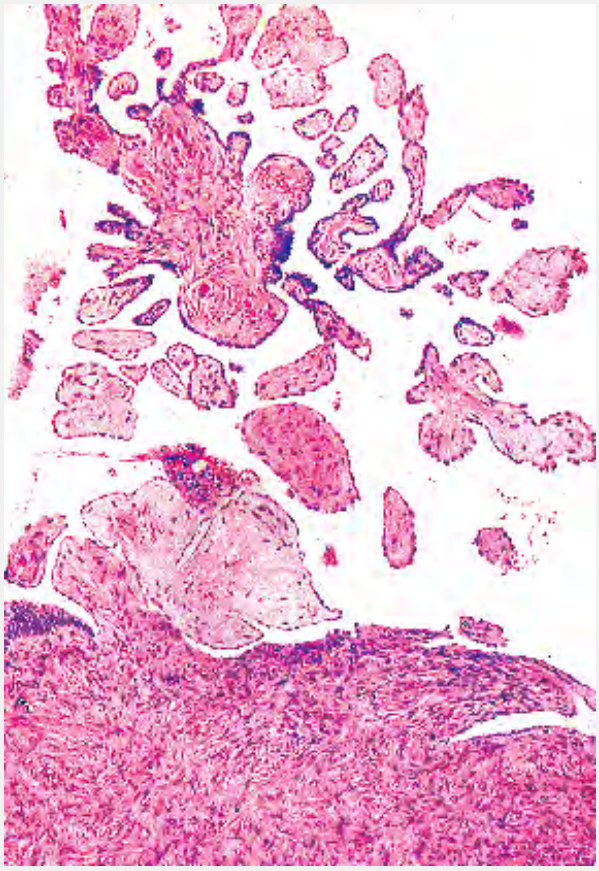

Figure 42.15 Papillary stromal projections from ovarian surface.

Ultrastructure

Typical ovarian stromal cells have slender spindle-shaped nuclei and complex cytoplasmic processes (70,85). Their scant cytoplasm is rich in organelles required for collagen synthesis, including free ribosomes and mitochondria. Tropocollagen, concentrated at the periphery of the cytoplasm, is deposited in the extracellular space and eventually converted to collagen (Figure 42.18). Rows of micropinocytotic vesicles occur along the plasma membrane and desmosome-like attachments may be found between the cells (85). Luteinized stromal cells have abundant cytoplasm-containing lipid

droplets and steroidogenic organelles, including smooth endoplasmic reticulum, mitochondria with tubular cristae, and Golgi (70,85,86,108). Some cells have ultrastructural features that are intermediate between those of fibroblasts and luteinized cells (70,85). Argyrophilic stromal cells have 300 to 750 nm, electron-dense, membrane-bound, cytoplasmic granules (103).

Hormonal Aspects

Numerous studies have demonstrated the steroidogenic potential and the gonadotropin-responsiveness of the ovarian stroma in both pre- and postmenopausal women (109,110,111,112,113,114,115,116,117,118,119,120,121). In vitro incubation of ovarian stromal tissue indicates that its principal steroid product is androstenedione, in addition to smaller quantities of testosterone and dehydroepiandrosterone (122). In vitro production of androgens is enhanced by human chorionic

gonadotropin (hCG), pituitary gonadotropins, and insulin, consistent with the presence of receptors for these hormones within the stromal cells (83,86,123). To what extent the ovarian stroma contributes to the androgen pool in normal premenopausal women is unknown, but it is likely that it is the source of small amounts of testosterone. With cessation of follicular activity at the time of the menopause, the ovarian stroma becomes, together with the adrenal glands, the major source of androgens. Testosterone and androstenedione are the major androgens secreted by the ovarian stroma in postmenopausal women (109,110,111,113,121), and in vitro and in vivo studies have shown that ovaries with stromal hyperplasia secrete more androstenedione, estrone, and estradiol than normal ovaries (114,116). Approximately 80% of the circulating androstenedione in postmenopausal women, however, is of adrenal origin (110). Despite a cessation of follicular synthesis of estradiol (E2) in postmenopausal subjects, small amounts of this hormone are present in the circulation (probably derived from the adrenal glands) by peripheral conversion of estrone (110,124), and from the ovarian stroma itself (109,111,125). Estrone, however, becomes the major circulating estrogen after the menopause, derived predominantly from the peripheral aromatization of androstenedione that occurs in fat, muscle, liver, kidney, brain, and adrenals (110,125,126). Increased aromatization in postmenopausal women, likely due to high endogenous LH levels in these subjects, leads to a two-fold increase in the daily production rate of estrone compared to that in premenopausal women; aromatization is also higher in obese subjects. In some postmenopausal women, sufficient estrogen is elaborated by this mechanism to prevent the clinical manifestations of estrogen withdrawal and to play a role in the genesis of endometrial carcinoma (104,110). An association between the degree of stromal proliferation and postmenopausal endometrial adenocarcinoma has been noted (104), and the ovarian stroma in postmenopausal women with endometrial adenocarcinoma produces more androgens in vitro than that of control subjects without

endometrial cancer (127). The variations that exist in the ovarian steroid hormone output from one postmenopausal woman to another may correspond to similar variations in the morphologic appearance of the stroma in this age group, although no correlative functional and structural studies have been performed.

Primordial Follicles

Histology

The approximately 400,000 primordial follicles present at the time of birth fill the ovarian cortex (Figure 42.19). After this period, their numbers decrease progressively through the processes of atresia and folliculogenesis until their eventual disappearance that marks the end of the menopause. However, rare follicles may persist for several years after the cessation of menses, accounting for sporadic ovulation and occasional episodes of postmenopausal bleeding (128). In the reproductive era, primordial follicles are found scattered irregularly in clusters throughout a narrow band in the superficial cortex. They consist of a primary oocyte, measuring 40 to 70 Âµm in diameter, surrounded by a single layer of flattened, mitotically inactive, granulosa cells resting on a thin basal lamina (Figure 42.20). Rare primordial (and maturing) follicles may contain multiple oocytes, particularly in individuals who are less than 20 years of age (19,129,130,131). The oocyte is arrested at the dictyate stage of meiotic prophase at the time of birth, enters an interphase period until follicular maturation prior to ovulation, or undergoes degeneration during atresia (132). The large spherical nucleus of the oocyte has finely granular, uniformly dispersed chromatin and one or more dense, thread-like nucleoli (132); rare oocytes may have multiple nuclei (130,131). The cytoplasm of the oocyte contains a paranuclear, eosinophilic, crescent-shaped zone consisting of a complex of interrelated organelles, so-called Balbiani's vitelline body

(BVB) (133,134). Within the vitelline body is a dark spot (the centrosome) surrounded by a halo, which in turn is flanked by darker, PAS-positive, granular zones rich in mitochondria (133,14). The cytoplasm of the oocyte lacks the abundant glycogen and the high alkaline phosphatase activity characteristic of the primordial germ cells and the oogonia of the embryonic gonad.

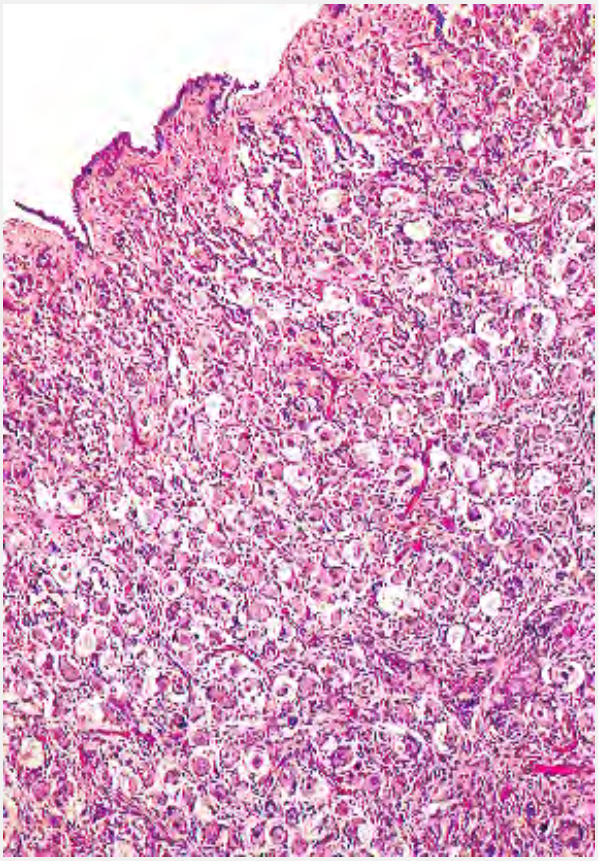

Figure 42.19 Newborn ovary. Multiple primordial follicles fill the ovarian cortex.

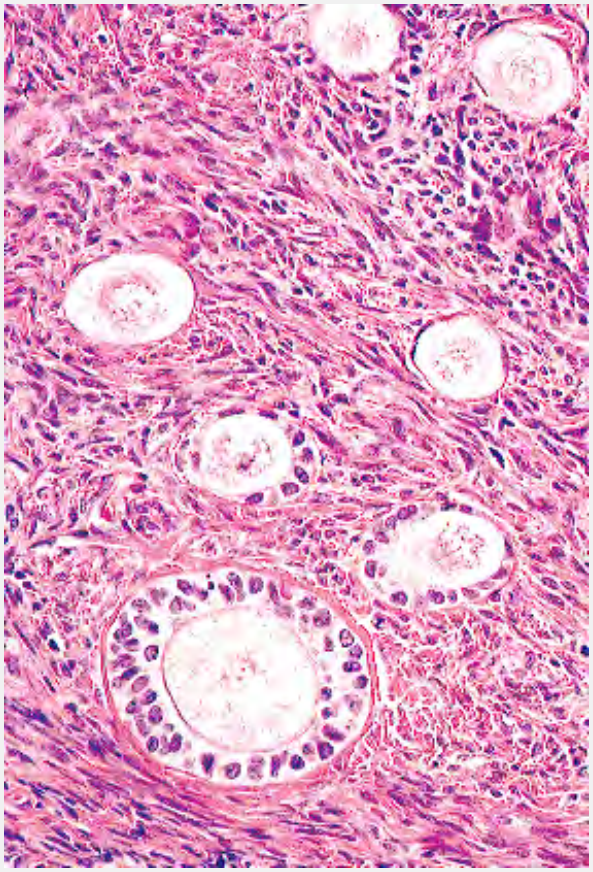

Figure 42.20 Primordial follicles (four at top of figure) and primary follicles (three at bottom of figure).

Ultrastructure

The granulosa cells of the primordial follicle have sparse organelles, occasional desmosomal attachments with each other, and microvillous projections that attach to the oocyte by tight apposition (70). Within the oocyte, the juxtanuclear centrosome of the BVB (Figure 42.21A) consists of dense granules, closely packed vesicles, and dense fibers that form a basket-like structure at the periphery of the centrosome (Figure 42.21B) (133,134). The centrosome is surrounded by a zone of smooth endoplasmic reticulum (ER) that

represents the halo seen by light microscopy. More peripheral and constituting the rest of the BVB are a concentration of most of the oocyte's organelles, including multiple Golgi complexes, prominent compound aggregates,

numerous mitochondria intimately associated with sparsely granular ER, and annulate lamellae (Figure 42.21B) (133,134). The latter structures, which may be attached or immediately adjacent to the nucleus or free within the BVB, are constantly present in primary oocytes and other rapidly growing embryonal or neoplastic cells. They are arranged in stacks or concentric arrangements of up to 100 parallel, smooth, paired membranes that delineate greatly flattened cisternal spaces, 30 to 50 Âµm wide. At regularly spaced intervals, the paired membranes of each lamellar unit become fused with one another (132). When the lamellae are sectioned along a tangential plane, the sites of apposition of the membranes are seen as regularly spaced annuli 100 nm in diameter. At their periphery they are connected to the granular ER (133). The paired membranes of the annulate lamellae mimic the two leaflets of the nuclear membrane, and it is likely that they are formed from its outer leaflet (70,132,133). Their function is not known with certainty, but it has been suggested that they may have a role in nucleocytoplasmic exchange of substances related to metabolic activity or the transfer of genetic information (70,133).

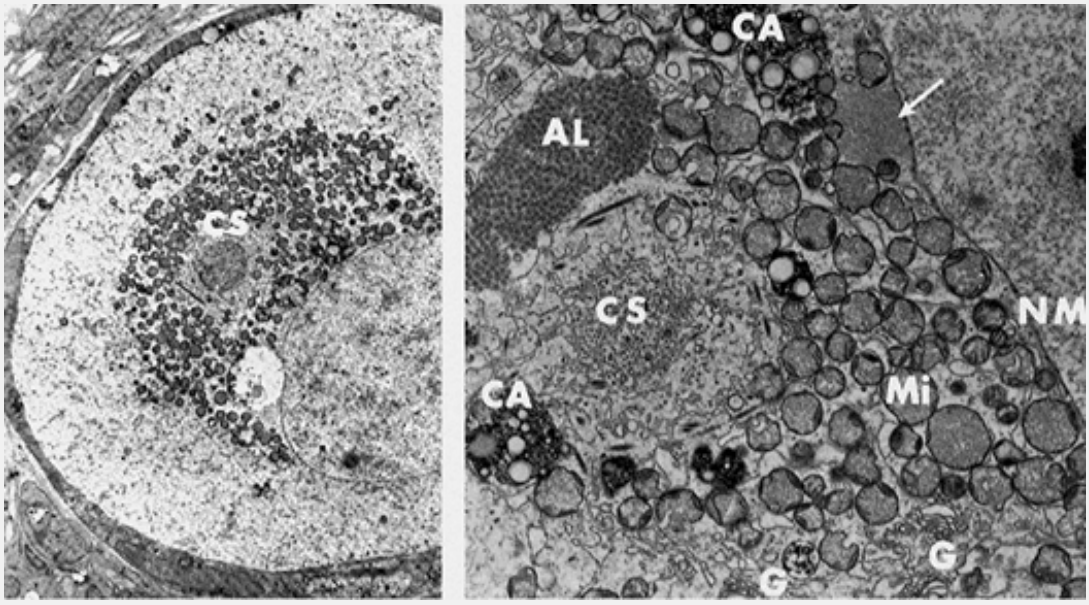

Figure 42.21 Electron micrograph of a primordial follicle. A. Balbiani's vitelline body consists of a juxtanuclear centrosome (CS) surrounded by a condensation of mitochondria, Golgi complexes, endoplasmic reticulum, and lysosomes (original magnification. x2400). B. Detailed view of Balbiani's vitelline body. A cluster of closely packed spiral fibrils (arrow) is attached to the nuclear envelope (NM). The centrosome (CS) is composed of dense granules, some arranged periodically on fine fibers, and small vesicles, with a peripheral zone of endoplasmic reticulum and dense fibers. Surrounding the centrosome are masses of mitochondria (Mi) and compound aggregates (CA). A stack of annulate lamellae (AL) is seen tangentially. Note the prominent endoplasmic reticulum in close association with multiple Golgi complexes at the periphery of the vitelline body. Reprinted with permission from:

Hertig AT. The primary human oocyte: some observations on the fine structure of Balbiani's vitelline body and the origin of the annulate lamellae. *Am J Anat* 1968;122:107â€“137.

In some oocytes, Golgi, ER, and mitochondria may also be found outside the vitelline body, closely applied to the entire circumference of the nucleus (133). Similarly, microtubules present throughout the oocyte cytoplasm are most prevalent around the circumference of the nuclear membrane. Bundles of spiral filaments occasionally abut the nuclear membrane (Figure 42.21B) or are seen in the more peripheral cytoplasm (134). A variety of different vacuoles may also be seen in the peripheral cytoplasm, some containing multiple small vesicles (133).

Maturing Follicles

Histology and Ultrastructure

Folliculogenesis

Folliculogenesis refers to the continuous process occurring throughout reproductive life whereby cohorts of primordial follicles undergo maturation during each menstrual cycle. Follicular maturation begins during the luteal phase and continues throughout the follicular phase of the next cycle. Each month only one such follicle, the preovulatory (or dominant) follicle, achieves complete maturation, culminating in the release of the oocyte (ovulation). The other follicles that have begun the maturational process undergo atresia at earlier stages of their development. Folliculogenesis and atresia also occur prenatally, throughout childhood and during pregnancy, although maturing follicles rarely reach the preovulatory follicle stage during these periods (19,135,136,137,138,139,140,141,142,143).

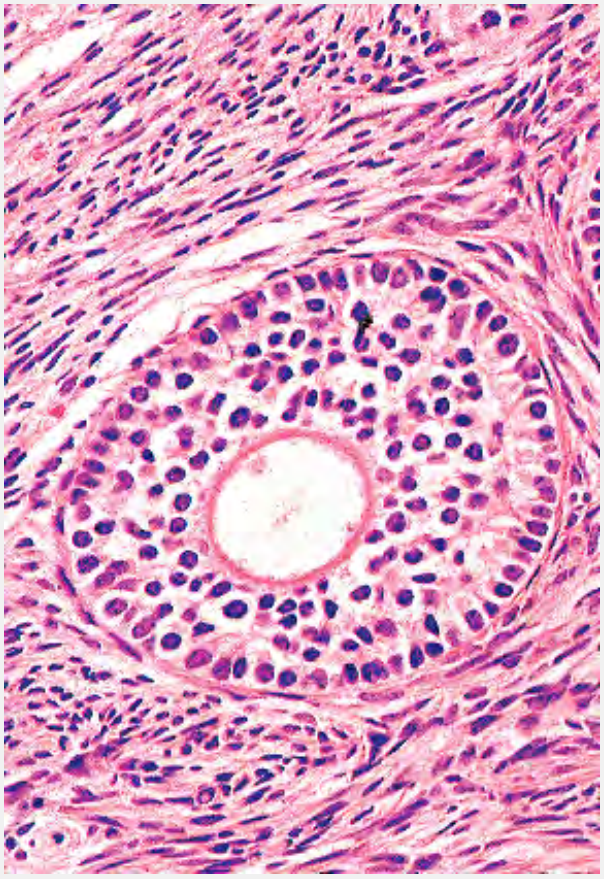

Figure 42.22 Preantral follicle. Several layers of granulosa cells surround the oocyte. A theca interna layer is not yet apparent.

The first morphological evidence of follicular maturation is the assumption of a cuboidal to columnar shape of the granulosa cells accompanied by enlargement of the oocyte (*primary follicle*) (Figure 42.20). Mitotic activity in the granulosa cells results in their stratification and three to five concentric layers around the oocyte (*secondary or preantral follicle*) (Figure 42.22). At this stage an eosinophilic, PAS-positive, homogeneous, acellular layer, known as the zona pellucida, appears, encasing the oocyte. Its formation is usually attributed to the granulosa cells, but the oocyte may also play a role. At the end of its development, the zona pellucida is a 20

to 25 Âµm thick membrane rich in acid mucopolysaccharides and glycoprotein (Figures 42.22,42.23,42.24,42.25) (70). Preantral follicles measure from 50 to

400 Âµm in diameter, and as they increase in size, they migrate into the deeper cortex and medulla. Simultaneously, the surrounding ovarian stromal cells become specialized into several layers of theca interna cells and an outer, ill-defined layer of theca externa cells. Secretion of mucopolysaccharide-rich fluid by the granulosa cells results in their separation by fluid-filled clefts that eventually coalesce to form a single large cavity or antrum lined by several layers of granulosa cells (*tertiary, antral, or vesicular follicle*). The first evidence of antrum formation occurs in follicles that are 200 to 400 Âµm in diameter, after which the follicles progressively enlarge due to continued fluid secretion into the antrum. Concurrently, the oocyte enlarges to its definitive size and assumes an eccentric position at one pole of the follicle. At this site the granulosa cells proliferate to form the cumulus oophorus which, containing the oocyte in its center, protrudes into the antrum (*mature or Graafian follicle*) (Figure 42.23).

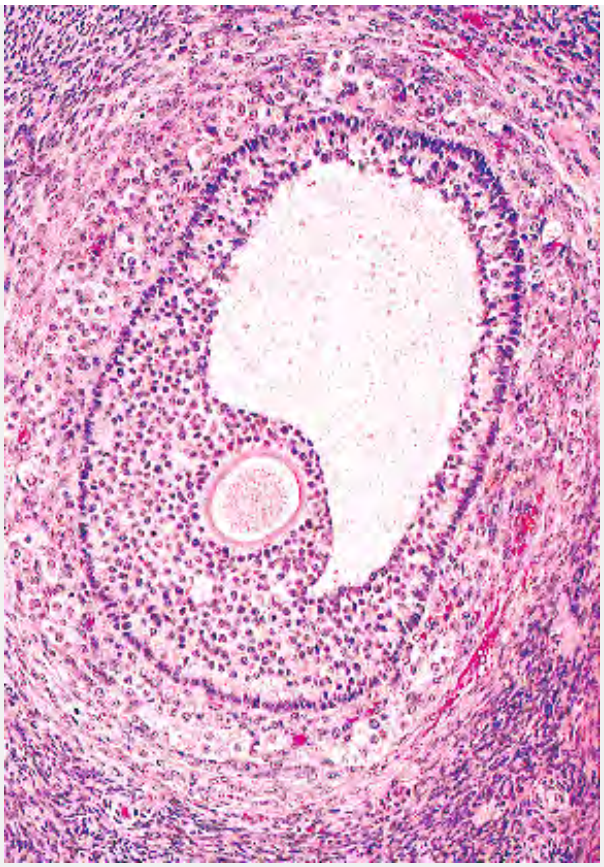

Figure 42.23 Mature follicle. Oocyte within cumulus oophorus projects into antrum. The theca layers are well developed.

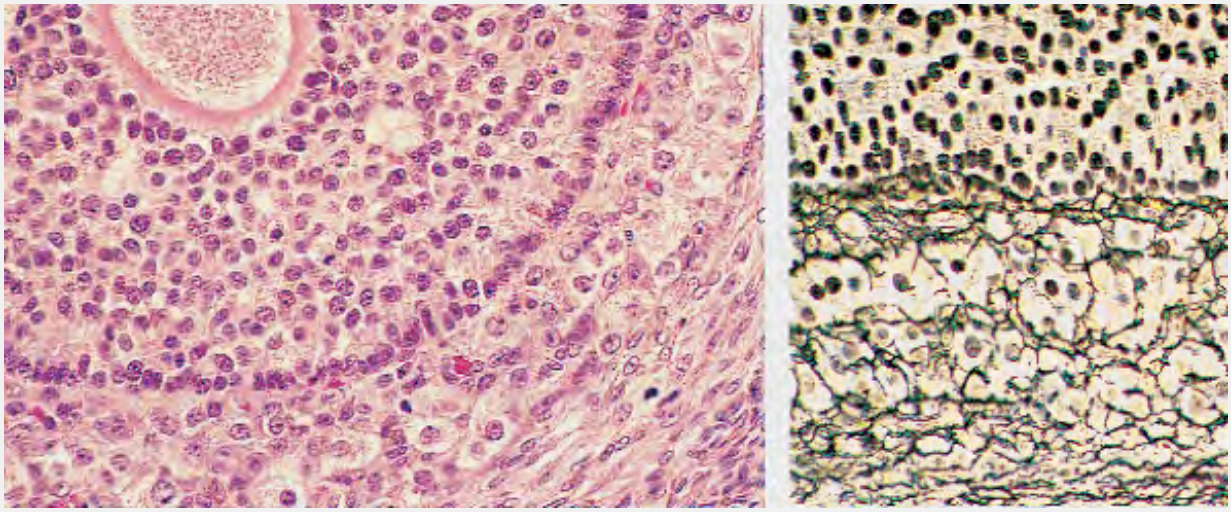

Figure 42.24 A. Mature follicle, high power view. The granulosa layer, which contains several Call-Exner bodies, abuts the zona pellucida of the oocyte. The granulosa layer is surrounded by a layer of luteinized theca interna cells. Note mitotic figures in granulosa and theca cells. B. There is a reticulum network in the theca interna layer, but an absence of reticulin in the granulosa layer.

Ovulation

During each cycle, only a small number of mature follicles (<4 per ovary) reach a diameter of 4 to 5 mm by the mid-to late luteal phase; one of them will become the preovulatory follicle of the subsequent cycle (144,145). Late in follicular growth, the oocyte, its surrounding zona pellucida, and a single layer of radially-disposed, columnar granulosa cells (the corona radiata) detach from the cumulus oophorus and float in the antral fluid. The preovulatory follicle, shortly before ovulation, reaches a diameter of 15 to 25 mm (28,145) and partially protrudes from the ovarian surface at the eventual rupture point, or stigma. Here the overlying surface

epithelial cells exhibit progressive flattening, degeneration, and desquamation. The stroma in this area becomes attenuated and almost avascular, with degeneration of the stromal cells, fragmentation of collagen fibers, and an accumulation of intercellular fluid (28). These surface epithelial and stromal changes that immediately precede ovulation may be secondary to local ischemia and the release of proteolytic enzymes and prostaglandins into the stroma. The preovulatory follicle then ruptures, possibly secondary to the contraction of the perifollicular smooth muscle cells, with liberation of the follicular fluid and oocyte (with its surrounding layers) into the peritoneal cavity. Following ovulation, the stigma is occluded by a mass of coagulated follicular fluid, fibrin, blood, granulosa and connective tissue cells; it is eventually converted to scar tissue.

Shortly before ovulation, the oocyte within the ovulatory follicle enters telophase of the first meiotic division. Chromosomal reduction occurs by migration of one-half the oocyte chromosomes into a portion of the oocyte cytoplasm that separates from the cell as the first polar body. The first meiotic division begun in fetal life is now complete, and the oocyte is now designated the secondary oocyte. Immediately after expulsion of the first polar body, the secondary oocyte enters the second meiotic division, arresting at metaphase until fertilization occurs.

Granulosa Layer

Granulosa cells are almost entirely formed from their embryonic precursors by the time of birth (19). Those within maturing and mature follicles are polyhedral cells 5 to 7 Âµm in diameter; the cells resting on the basement membrane are often columnar. The granulosa cells have pale, scanty cytoplasm, indistinct cell borders, and small, round to oval, hyperchromatic nuclei that typically lack nuclear grooves (Figure 42.24A) (146). Mitotic figures within granulosa cells are usually numerous in maturing follicles, decreasing

in numbers prior to ovulation. Until the onset of luteinization several hours prior to ovulation, cytoplasmic lipid is absent (or sparse) as are steroidogenic histochemical patterns (147,148). The cytoplasm of granulosa cells of primary, secondary, and mature follicles is immunoreactive for cytokeratin, vimentin, inhibin, CD99, melan-A, mÃ¼llerian inhibiting substance, WT1, and desmoplakin (33,35,36,75,77,78,81).

The granulosa cells typically surround small cavities, referred to as Call-Exner bodies (Figure 42.24A), which have a distinctive appearance, representing one of the most specific features of granulosa cells, both normal and neoplastic. Call-Exner bodies are delimited from the granulosa cells by a basal lamina, and typically contain a deeply eosinophilic, PAS-positive, filamentous material consisting of excess basal lamina (70). Unlike the theca layers, the granulosa layer of the maturing and Graafian follicles is avascular and devoid of a reticulum framework (Figure 42.24B).

Mitochondria with lamelliform cristae, granular ER, free ribosomes, and Golgi gradually increase in abundance within the granulosa cells of maturing follicles. These ultrastructural features suggest active protein synthesis. Histochemical and ultrastructural features (abundant smooth ER and mitochondria with tubular cristae) indicative of steroid biosynthesis are absent until shortly before ovulation (72,84,147,148,149,150). The granulosa cells of follicles of varying stages contain adhaerens junctions, gap junctions, and desmosomes between adjacent granulosa cells (35,70,132). The slender cytoplasmic extensions of the granulosa cells of the corona radiata that traverse the zona pellucida have gap junctions and puncta adhaerentia with the plasma membrane of the oocyte (Figure 42.25).

Theca Layers

In contrast to granulosa cells, theca cells differentiate continuously from the stromal cells at the periphery of developing follicles from

fetal life until the end of the menopause. The thecal component of the antral follicle is

characterized by a well-developed theca interna and a less well-defined theca externa. The theca interna layer is three or four cells in thickness and lies external to the granulosa layer (Figure 42.24A) from which it is separated by a basement membrane. Unlike the granulosa cells of the developing and mature follicles, the theca interna cells typically have a luteinized or partially luteinized appearance (Figure 42.24A) and exhibit steroidogenic histochemical patterns (72,147,148,149). Luteinization of the theca interna of maturing follicles is particularly prominent during pregnancy. The round to polygonal cells are 12 to 20 micra in diameter and have abundant, eosinophilic to clear, vacuolated cytoplasm containing variable amounts of lipid; a central, round, vesicular nucleus typically contains a single, prominent nucleolus (Figure 42.24A). The cells differ from granulosa cells but resemble stromal cells in being immunoreactive for vimentin but not cytokeratin (36); theca cells are also immunoreactive for inhibin, calretinin, and melan-A (46,77,81). Mitotic figures are typically present with the theca cells of maturing follicles. The layer contains a rich vascular plexus consisting of dilated capillaries, as well as a dense reticulin network that surrounds each cell (Figure 42.24B). A tangential section through the theca interna may result in seemingly isolated nodules of luteinized theca cells that may occasionally be misinterpreted as foci of stromal luteinization.

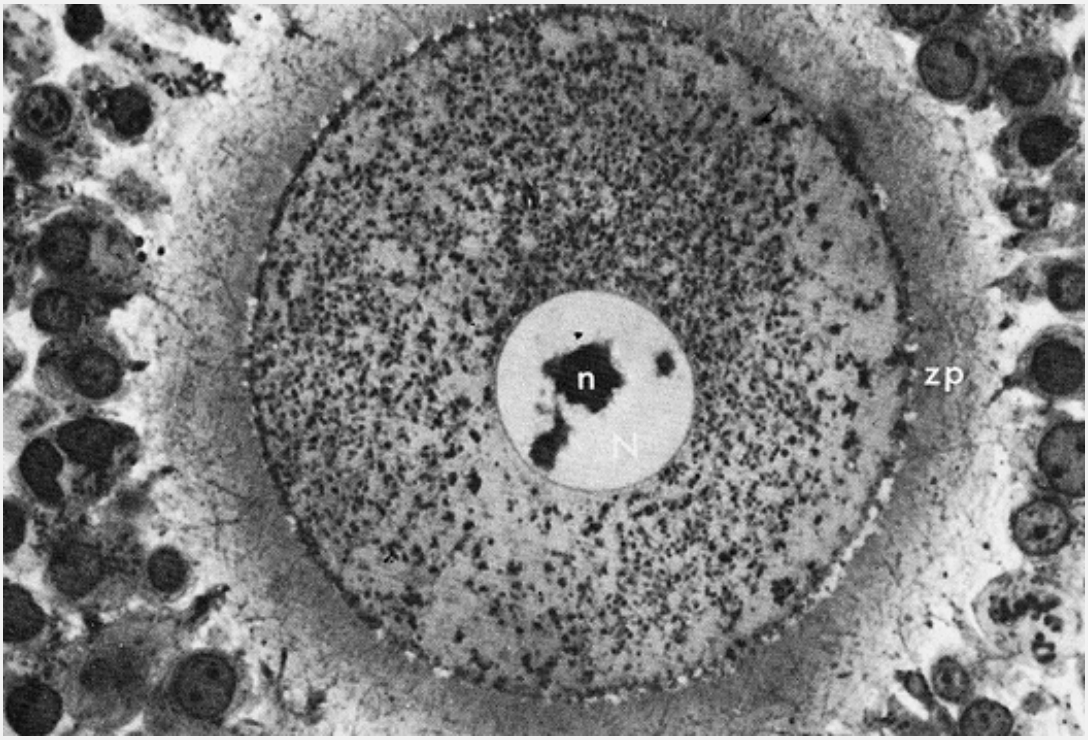

Figure 42.25 Maturing oocyte. Note the uniform distribution of the organelles and the row of dense granules in the cytoplasm immediately subjacent to the plasma membrane of the oocyte. A continuous zona pellucida (zp) surrounds the oocyte and separates it from the granulosa cells. Numerous cytoplasmic processes of the granulosa cells are visible within the zona pellucida. N, nucleolus. Thick section, OsO4 fixed, Epon-embedded, toluidine blue stain. Reprinted with permission from: Baca M, Zamboni L. The fine structure of the human follicular oocytes. *J Ultrastruct Res* 1967;19:354â€“381.

The theca externa is an ill-defined layer of variable thickness that surrounds the theca interna and merges almost imperceptibly with the adjacent ovarian stroma. It is composed of circumferentially arranged collagen bundles, blood and lymphatic vessels, and plump spindle cells that lack steroidogenic histochemical features (151).

The spindle cells of the theca externa are typically highly mitotic and may be misinterpreted as fibrosarcoma, particularly when only the edge of the follicle is seen microscopically (Figure 42.26).

Ultrastructural examination of theca interna cells reveals the organelles associated with steroidogenesis, similar to those within granulosa-lutein cells. The theca externa cells,

some of which exhibit smooth muscle differentiation, lack such organelles (152).

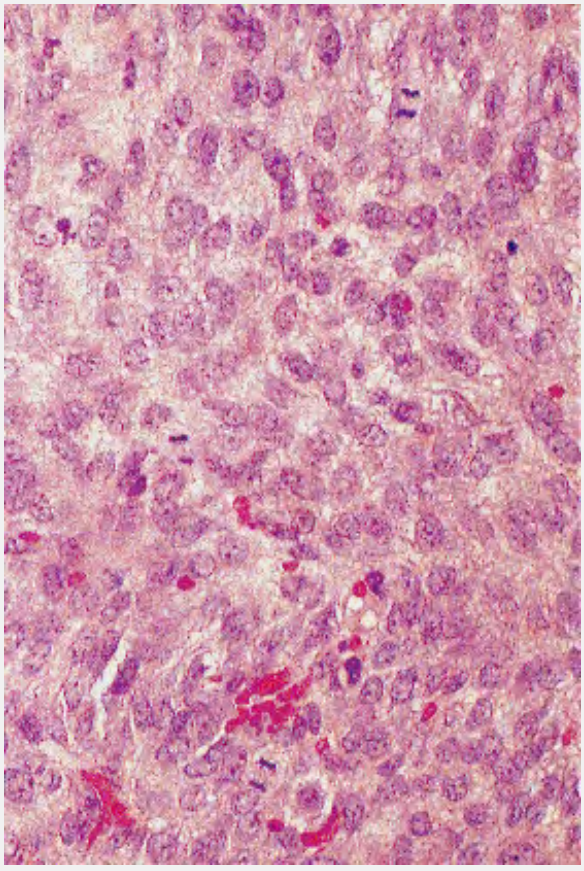

Figure 42.26 Theca externa of mature follicle composed of plump spindle cells. Note mitotic figures.

Hormonal Aspects

The initiation of folliculogenesis and early preantral follicular development is independent of gonadotropin influence, whereas the later stages of follicular maturation are under gonadotropin control. As a small antral follicle develops into a preovulatory follicle, the sequence of endocrine events within its antral fluid differs from most, if not all, other antral follicles in the same ovary (153,154). The early stages of this development are associated with an increase in FSH receptors and intrafollicular FSH within the preovulatory follicle (153,154,155,156). There is a concomitant increase in estradiol (E2) receptors within the granulosa cells and the E2 level within the follicular fluid. The latter reaches peak concentration (10,000 times the circulating level) during the mid- to late proliferative phase when plasma FSH falls to a basal level. At this stage the preovulatory follicle is self-sustaining, continuing to mature under the influence of intrafollicular FSH and E2 (118). During the late proliferative phase, plasma LH rises and LH-receptors within the granulosa cells of the preovulatory follicle (but not other follicles) become apparent (156). In contrast, LH-receptors are present within the theca cells of all follicles throughout the follicular phase. Eden et al. found concentrations of insulin-like growth factor (IGF1) to be significantly higher in the follicular fluid of preovulatory follicles than their matched cohorts, and suggested that IGF1 may have a role in the selection of the dominant follicle (157).

Whereas circulating E2 is likely derived from both the granulosa cells and the LH-stimulated theca cells, intrafollicular E2 is derived almost exclusively from the granulosa cells by both de novo synthesis and by FSH-dependent aromatization of theca-derived androstenedione (118,158). Aromatase activity is highest in the preovulatory follicle, thereby maintaining a high E2:androstenedione ratio (153,154,159). In contrast, follicles that will undergo atresia are FSH- and aromatase-deficient and have high androstenedione:E2 ratios within their intrafollicular fluid. High circulating estrogen levels initiate a

preovulatory surge of plasma LH (160,161) that induces luteinization of the granulosa cells, an increase in intrafollicular progesterone (P) concentration, and a small preovulatory rise in circulating P (153,154,162). The rising plasma P level and the peaking estrogen level further augment the LH surge, as well as initiating a smaller increase in FSH, triggering ovulation. The latter has been estimated to occur 36 to 38 hours after the onset of the LH surge, 24 to 36 hours after the estradiol peak, and 10 to 12 hours after the LH peak (162).

The ovarian follicles also produce nonsteroidal hormones. Inhibin, a glycoprotein synthesized by the granulosa cells, is secreted into the follicular fluid and ovarian venous effluent in amounts that correlate with steroid levels (162,163,164). Inhibin, which is predominantly under the control of LH (165), reduces, by negative feedback, FSH secretion from the hypothalamicâ€“pituitary unit. High concentrations of prorenin are present within the fluid of mature follicles (166), and their granulosa cells, as well as theca and stromal cells, are immunoreactive for renin and angiotensin II (167). The function, if any, of the reninâ€“angiotensin system within the ovary is currently unknown.

Corpus Luteum of Menstruation

Following ovulation on the fourteenth day of the typical 28-day menstrual cycle, and in the absence of fertilization, the collapsed ovulatory follicle becomes the corpus luteum of menstruation (CLM). When mature, the CLM is a 1.5 to 2.5 cm, round, yellow structure with festooned contours and a cystic center filled with a gray, focally hemorrhagic coagulum.

Histology

During the 14 days following ovulation, the CLM undergoes an orderly sequence of histological changes that allow an approximate

estimation of its age. Corner has described these stages in detail, using endometrial histology and menstrual data to establish the age of the CLM (168,169). A subsequent study that correlated the histologic date of the CLM (using Corner's criteria) with the interval between the LH peak and the biopsy of the CLM, determined that the use of the histology of the CLM for retrospective timing of ovulation is subject to an error of variable magnitude due to unequal duration of each stage as well as considerable individual variation (170).

In contrast to the granulosa cells of the maturing and preovulatory follicles, the luteinized granulosa cells of the mature CLM (granulosa-lutein cells) are large, 30 to 35 micra, polygonal cells with abundant, pale, eosinophilic cytoplasm that may contain numerous small lipid droplets (Figures 42.27, 42.28) (151). The spherical nucleus contains one or two large nucleoli. The histochemical pattern of these cells varies with the age of the CLM, but is generally typical of steroid hormone-producing cells (72,148,149,171). The cytoplasm of luteinized granulosa cells contains vimentin, but in contrast to granulosa cells of maturing and mature follicles, little or no cytokeratin (35). The luteinized granulosa cells are also immunoreactive for inhibin and calretinin (46,77).

The theca interna forms an irregular and often interrupted layer several cells in thickness around the circumference of the CLM (Figure 42.27) and ensheathes the vascular septa that extend into its center (151). When these septa are cut in cross section, triangular-shaped nests of theca cells appear at intervals throughout the granulosa layer. In all but the earliest stages of the CLM, the theca lutein cells are approximately half the size of granulosa-lutein cells. They contain a round to oval nucleus with a

single prominent nucleolus. Their less abundant, more darkly staining cytoplasm contains lipid droplets, which are usually larger than those in granulosa-lutein cells, and exhibits steroidogenic histochemical patterns (148), and immunoreactivity for inhibin, calretinin, and melan-A (46,77,81).

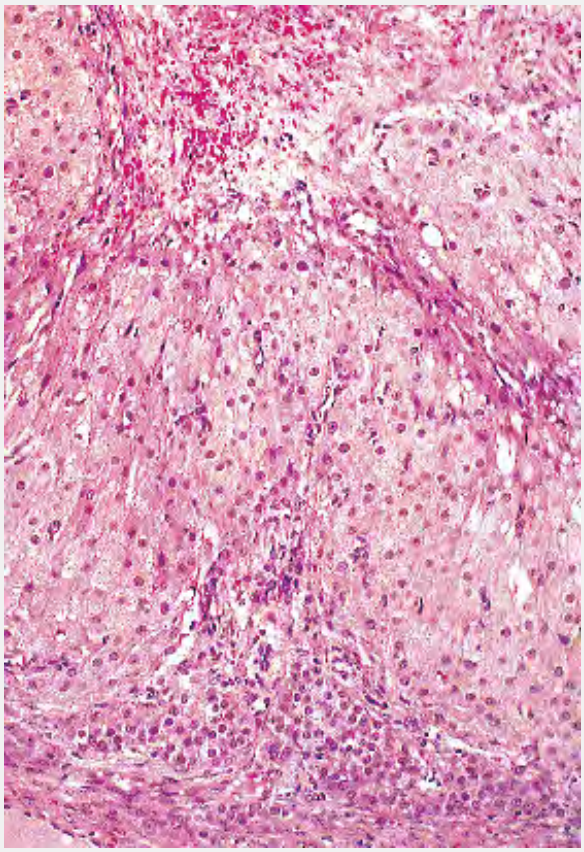

Figure 42.27 Mature corpus luteum of menstruation. The lining is composed of a thick layer of large granulosa-lutein cells and an outer, thinner layer of smaller theca-lutein cells. The cavity (top of figure) contains erythrocytes and fibrin.

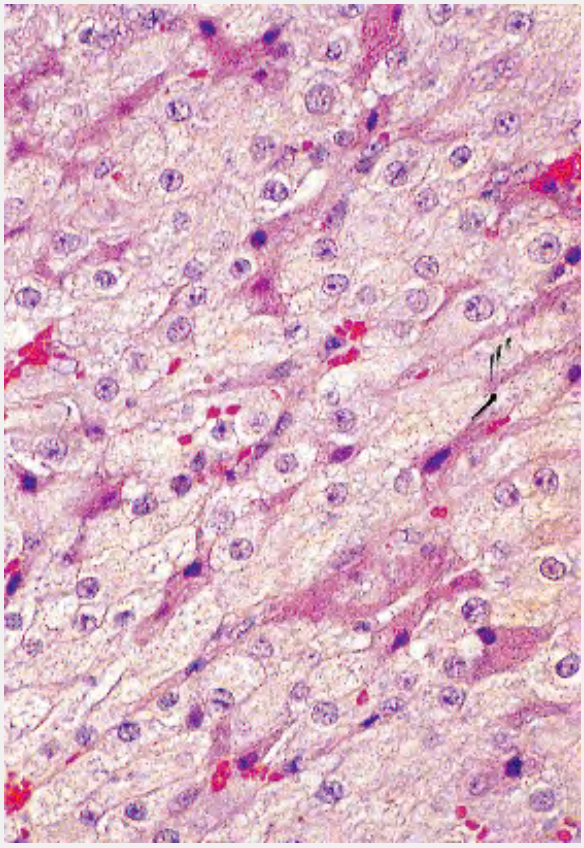

Figure 42.28 Mature corpus luteum of menstruation. K cells with darkly staining cytoplasm and pyknotic nuclei are interspersed between granulosa-lutein cells.

A third type of cell, the so-called â€œKâ€• cell, occurs in small numbers within the theca interna of the mature follicle and appears in greater numbers within the granulosa layer of the early CLM (146). K cells persist until menstruation at which time they degenerate. They are characterized by a stellate shape, a deeply eosinophilic cytoplasm, and an irregular, hyperchromatic or pyknotic nucleus (Figure 42.28). The cytoplasm is uniformly sudanophilic due to the presence of phospholipid (146). K cells lack the histochemical patterns of steroidogenic cells and have been shown to be T-lymphocytes (172).

During the maturation of the CLM, capillaries originating from the theca interna layer penetrate the granulosa layer and reach the central cavity. Fibroblasts that accompany the vessels form an increasingly dense reticulum network within the granulosa layer as well as an inner fibrous layer that lines the central cavity (Figure 42.27) (32).

Involutional changes begin on the eighth or ninth day following ovulation (168). The granulosa-lutein cells decrease in size, develop pyknotic nuclei, and accumulate abundant cytoplasmic lipid (Figure 42.29). There is a

decrease in histochemical staining of enzymes associated with steroid biosynthesis and an increase in hydrolytic enzymes (149). Eventually the cells undergo dissolution and are phagocytosed (173). There is progressive fibrosis and shrinkage over a period of several months and eventual conversion to a corpus albicans.

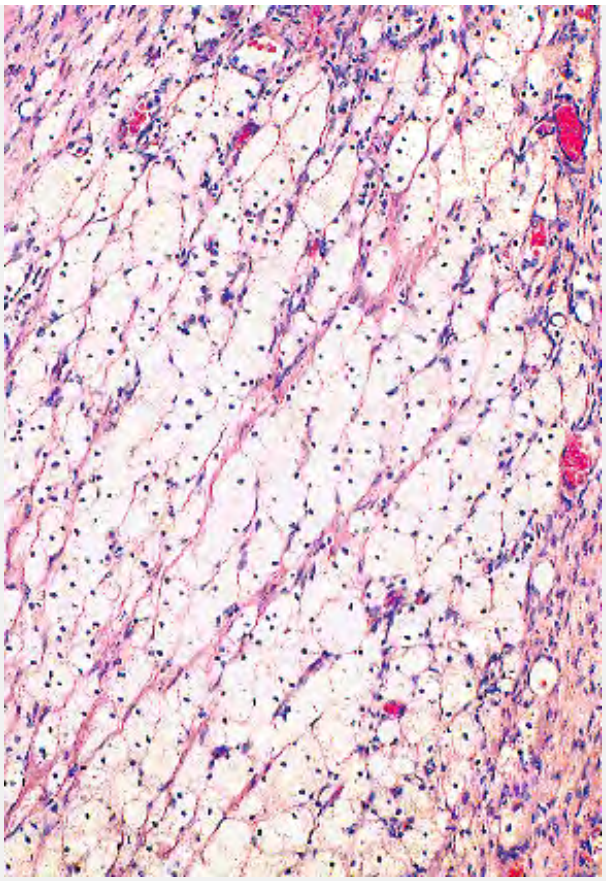

Figure 42.29 Degenerating corpus luteum of menstruation. Granulosa-lutein cells have pyknotic nuclei and abundant cytoplasmic lipid.

Ultrastructure

At the ultrastructural level, luteinization is characterized by a gradually increasing content of steroidogenic organelles, specifically smooth ER and abundant mitochondria with tubular cristae (Figure 42.30) (151,173,174,175,176). The smooth ER exhibits a characteristic regional modification in the form of a folded-membrane complex consisting of highly-folded, radiating, tubular cisternae that communicate and interdigitate with adjacent cisternae (175). Well-developed, dispersed and perinuclear Golgi, free and bound

ribosomes, lipid droplets, and lipofuscin pigment are also seen (Figure 42.30) (151,173,174,175). The cells are separated by a narrow space of variable width, but occasionally the outer leaflets of their plasma membranes become closely apposed and reinforced by desmosomal and pentilaminar tight junctional complexes (151,173,176). Nearly all the cells have a free surface that borders on a broad pericapillary space from which they are separated by an interrupted basal lamina (151). Many irregular microvillous cytoplasmic extensions project into these pericapillary, as well as the intercellular, spaces (Figure 42.30) (70,151,173,175). Occasional interdigitation of these microvilli between adjacent cells form intercellular channels (175). Underlying the microvilli is a narrow zone of cytoplasm filled with a network of filaments that also extend into the microvilli (151).

Theca-lutein cells are similar ultrastructurally to granulosa lutein cells except for the presence of localized perinuclear Golgi and the absence of folded-membrane complexes, microvilli, and a network of fine filaments (151,175). The varying degrees of cell density appreciable on histological examination are also seen at the ultrastructural level and may represent a fixation artifact. The theca externa layer of the CLM does not differ significantly from that of the Graafian follicle.

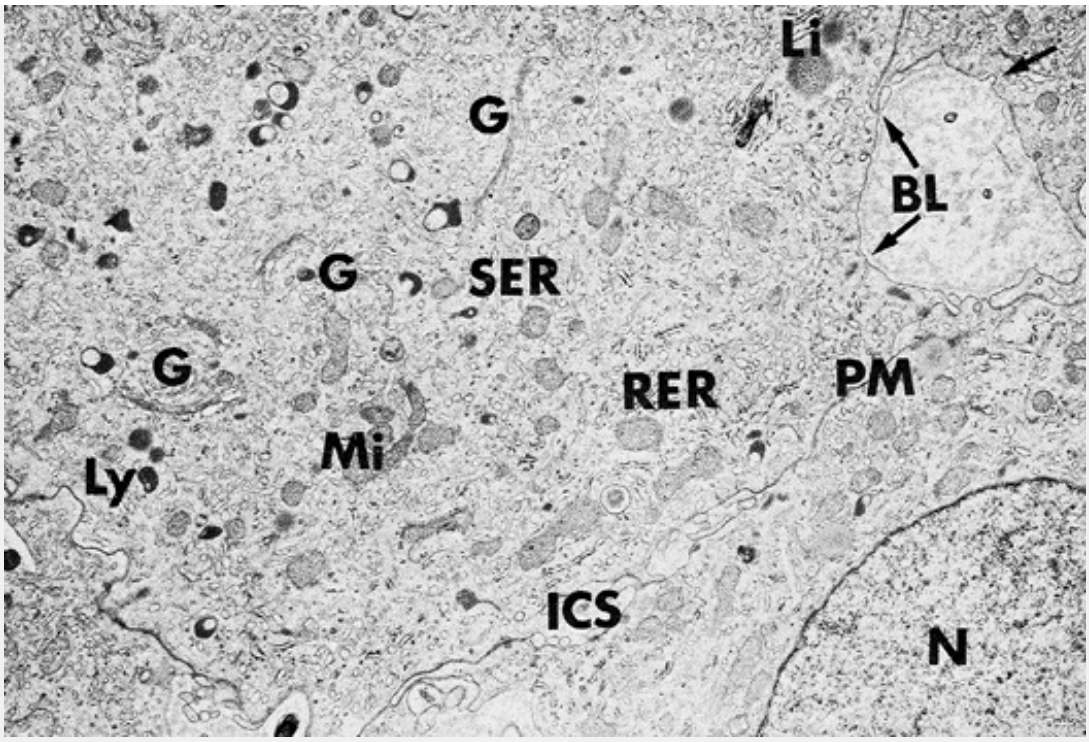

Figure 42.30 Electron micrograph of granulosa-lutein cell of a mature corpus luteum of menstruation. Note abundant smooth ER (SER), mitochondria (Mi), Golgi complex (G), rough ER (RER), lipid droplets (Li), and intercellular space (ICS). BL, basal lamina; N, nucleus of granulosa-lutein cell; Ly, lysosomes; PM, plasma membrane; arrows, micropinocytotic vesicle (original magnification x3600). The lutein cells of the degenerating CLM exhibit disorganization and fragmentation of the smooth ER, alterations of the mitochondria, and an increase in cytolysosomes (70). Lipid droplets are increased and irregular in size and show increased osmiophilia (173).

Hormonal Aspects

The formation and function of the CLM is under the control of LH, reflected by the high content of LH receptors within the granulosa-lutein cells (156,162). Receptors for FSH (140) and growth hormone (158) have also been identified in the corpus luteum, although their roles in luteal function are unknown. Although P is the major steroid formed in vivo and in vitro by the CLM, it also synthesizes (both in vitro and in vivo) estrone and E2, as well as androgens, mostly androstenedione (177).

After ovulation, LH, FSH, and E2 levels fall, but the LH concentration is sufficient to maintain the CLM, producing a mid-luteal peak in P and E2. If fertilization does not occur, the increased levels of P and estrogen through negative feedback result in a fall of LH and FSH to basal levels, a reduction in LH and FSH receptors within the CLM, and a marked decline in P and E2 synthesis after the 22nd day of the cycle (155,156,162,178,179). These changes are reflected by the morphological involution of the CLM and the onset of menses. Luteolysis appears to be estrogen related, possibly secondary to an estrogen-induced reduction in LH receptors or by enhancement of the luteolytic action

of prostaglandins synthesized by the CLM (162,180). A nonsteroidal LH-receptor-binding-inhibitor, which increases in concentration during the luteal phase, may also play a role (162).

Corpus Luteum of Pregnancy

Gross Appearance

On gross inspection, the corpus luteum of pregnancy (CLP) may be indistinguishable from the CLM, but is usually larger and bright yellow in contrast to the orange-yellow of the late CLM (181). The larger size, which may account for up to half the ovarian volume, is

due primarily to the presence of a central cystic cavity that is filled with fluid or a coagulum composed of fibrin and blood (91,141,182). The cavity size, however, can be highly variable. If the central cyst results in a corpus luteum that is over 3 cm in diameter, the CLP (or less commonly a CLM) is designated a corpus luteum cyst; if less than this size, a cystic corpus luteum. When the cavity of a CLP is large, typically in the first trimester, the wall may lose its convolutions, becoming stretched and attenuated to the extent that it may consist focally of only the inner fibrous layer. Obliteration of the cavity usually begins by the fifth month and is typically completed by term (142). The CLP thus gradually decreases in size, and by the last trimester, it is not a conspicuous structure. During the puerperium, the CLP undergoes involution and conversion to a corpus albicans.

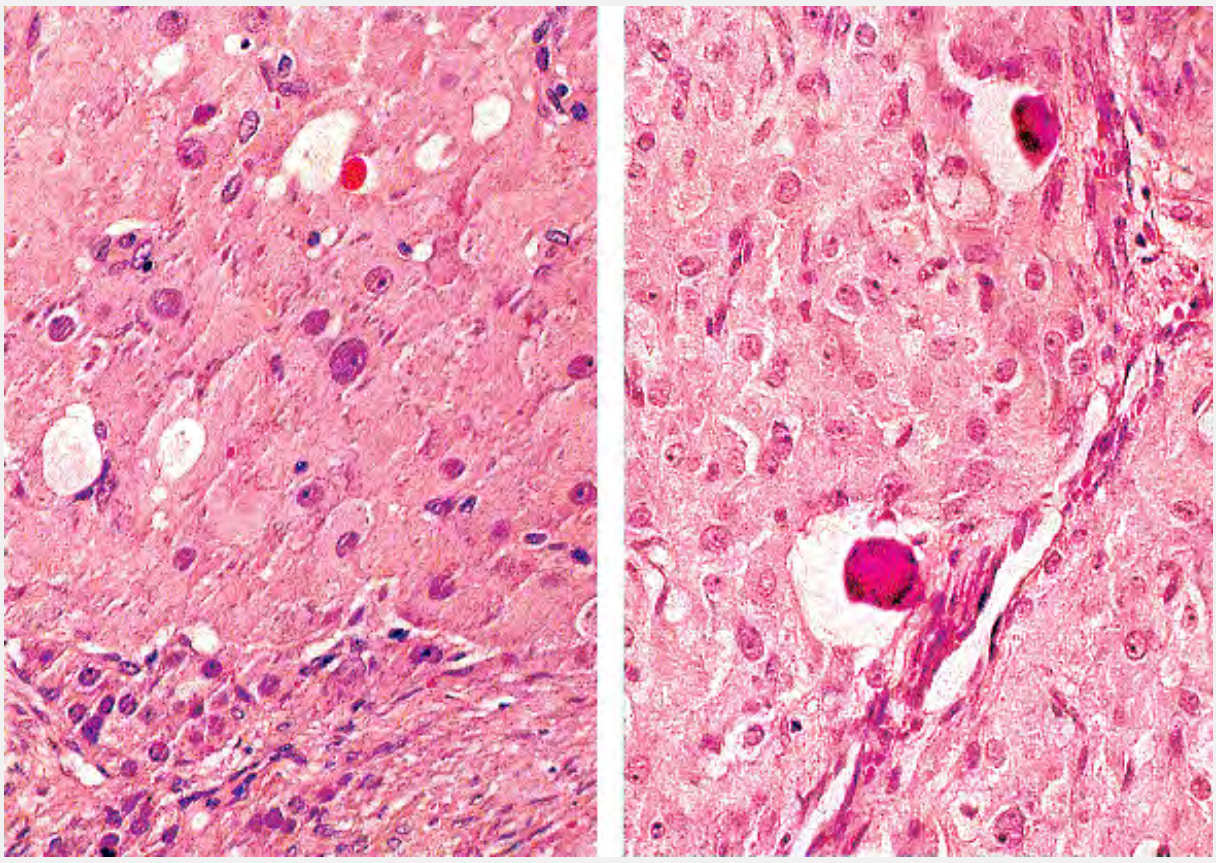

Figure 42.31 Corpus luteum of pregnancy. A. Note granulosa-

lutein cells with large irregular vacuoles and densely eosinophilic hyalin body. Nests of theca cells are seen at bottom left. B. Focal calcification within a late corpus luteum of pregnancy.

Histology

The CLP, in contrast to the CLM, does not mature in an orderly sequence that allows an estimation of its age; however, early and late stages are recognizable on histological examination.

Granulosa Layer

The first morphological evidence within the corpus luteum that conception has occurred is the absence of the regressive changes that normally appear in the CLM on the 8th or 9th days. Instead, the granulosa lutein cells enlarge, reaching their maximum size of 50 to 60 Âµm by 8 to 9 weeks' gestation. They assume a round or polyhedral shape with abundant eosinophilic cytoplasm, round to oval, vesicular nuclei, and one or two prominent nucleoli (142) (Figure 42.31A). The granulosa cells of the early CLP are characterized by cytoplasmic vacuoles that initially are tiny but eventually enlarge to occupy almost the entire cell, often with displacement and flattening of the nucleus (Figure 42.31A). The vacuoles tend to diminish in number and size as gestation progresses, and usually disappear after the 4th month. Fine, diffusely scattered, cytoplasmic lipid droplets are also commonly seen within the cells, particularly in early CLP. With increasing age of the corpus luteum, the droplets become fewer and larger (142).

Eosinophilic colloid or hyalin droplets within the granulosa cells of a CLP, which can be identified as early as 15 days after ovulation, are almost diagnostic of pregnancy; they may occur very rarely, however, within a CLM (142). These inclusions initially appear as small, round or irregular,

often multiple, droplets that enlarge, possibly by fusion of smaller droplets into one or several large bodies that may fill the entire cell (Figure 42.31A). They become more numerous as gestation progresses (182), although by term their numbers decrease as they undergo calcification, which continues into the puerperium (Figure 42.31B). It is likely that these calcified bodies eventually are resorbed, as they are not a feature of corpora albicantia.

K cells identical to those within CLM are typically found in the granulosa layer of the early CLP. They are most numerous in the second, third, and fourth months of gestation after which time they are rarely encountered (141,142,182).

Theca Layer

The theca interna is thickest in the early CLP at which time it resembles its counterpart in the CLM, surrounding the granulose-lutein layer and forming triangular-shaped, vascular septa that extend into the latter. In the CLP, the theca cells are polyhedral or round and approximately one fourth the size of the granulosa-lutein cells (Figure 42.31A). Their cytoplasm is more darkly staining and granular than in the latter, and is typically not vacuolated. Their nuclei are central, round, and more hyperchromatic than those of the granulosa cells; one or two prominent nucleoli are usually present. The characteristic colloid inclusions seen within the granulosa cells are absent or very rare within the theca cells. Occasional K cells may be seen in early pregnancy, but in smaller numbers than in the granulosa layer (146,182). After the 4th month, the theca interna and its trabeculae become much thinner as the theca cells become smaller and fewer in number, with darker, more irregular, oblong to spindle-shaped nuclei, so that they resemble fibroblasts (182). By term, the theca interna layer has almost completely disappeared.

Connective Tissue

As in the mature CLM, the central cystic cavity is typically lined by a layer of fibrous tissue, composed of variable numbers of fibroblasts, collagen and reticulin fibers, and blood vessels (126). Its thickness is highly variable, not only within the same CLP, but also from one CLP to another and from one phase of pregnancy to another (182). As noted, in some CLP with large cystic cavities, the granulosa layer is focally absent, and its wall is formed entirely by this fibrous layer. As gestation advances, the central cyst or coagulum is eventually obliterated by connective tissue that may exhibit focal hyalinization and calcification (141).

Reticulin staining reveals a pattern similar to that of the mature CLM; that is, a dense pattern within the theca interna and inner fibrous layer, and a sparser framework within the granulosa layer (142). In the early CLP, many, often large, vessels are present in the theca externa and interna, from which emanate smaller vessels that penetrate the granulosa and inner fibrous layers. In the late CLP, the vessels develop sclerotic walls with luminal narrowing or obliteration (142,182). The amount of connective tissue around the vessels increases in proportion to the decreasing vascularization and regression of the theca interna layer.

Ultrastructure

The ultrastructural appearance of the CLP is similar to that of the CLM, and remains intact throughout pregnancy despite a reduction in its metabolic activity (183,184,185). The increased cell volume of the granulosa cells in the CLP is reflected by increased smooth ER that exhibits many folded-membrane complexes. There is also an increase in rough ER that is localized in stacks and characteristic concentric whorls not usually seen in the CLM (175,184). Electron-dense, 150 to 200 nm, membrane-bound granules are closely associated with the cisternae of the rough ER. Mitochondria, including large spherical mitochondria not seen in the CLM, are typically highly variable in their size, shape, and internal structure

(175,184). The colloid or hyalin inclusions consist of homogeneous electron-opaque material that may surround occasional needle-shaped crystals (Figure 42.32). They typically have no relationship to any organelle, although occasional smaller hyalin bodies are surrounded by rough ER. The vacuoles seen by light microscopy are lined by attenuated microvilli and contain an electron-translucent material (183). Unlike the CLM, extensive bundles of microfilaments are typically encountered throughout the cytoplasm in most lutein cells, and become more prominent as pregnancy progresses (183,184). Collagen fibrils are encountered more frequently in the intercellular and perivascular spaces of the term CLP compared to the CLM.

Hormonal Aspects

Following fertilization, placental hCG stimulates P production by the granulosa-lutein cells. P concentration within the postovulatory corpus luteum increases six-fold, while the E2 level drops to 10% of that within the preovulatory follicle (153,154). HCG alone cannot maintain P secretion from the CLP for more than a few days, and the regulation of P secretion beyond that time is unknown. P production by the CLP begins to decline by the end of the second month of gestation with a concomitant increase of placental P production. However, in vivo and in vitro studies indicate that the CLP continues to produce P throughout the remainder of gestation, albeit in reduced amounts, consistent with the maintenance of its structural integrity until term (140,183,184,186,187). It is not known if P derived from the CLP has a biological role during this period or is redundant because of the massive P production by the placenta (177,188).

There is a rapid decline in function during the puerperium, reflecting falling hCG levels during this period.

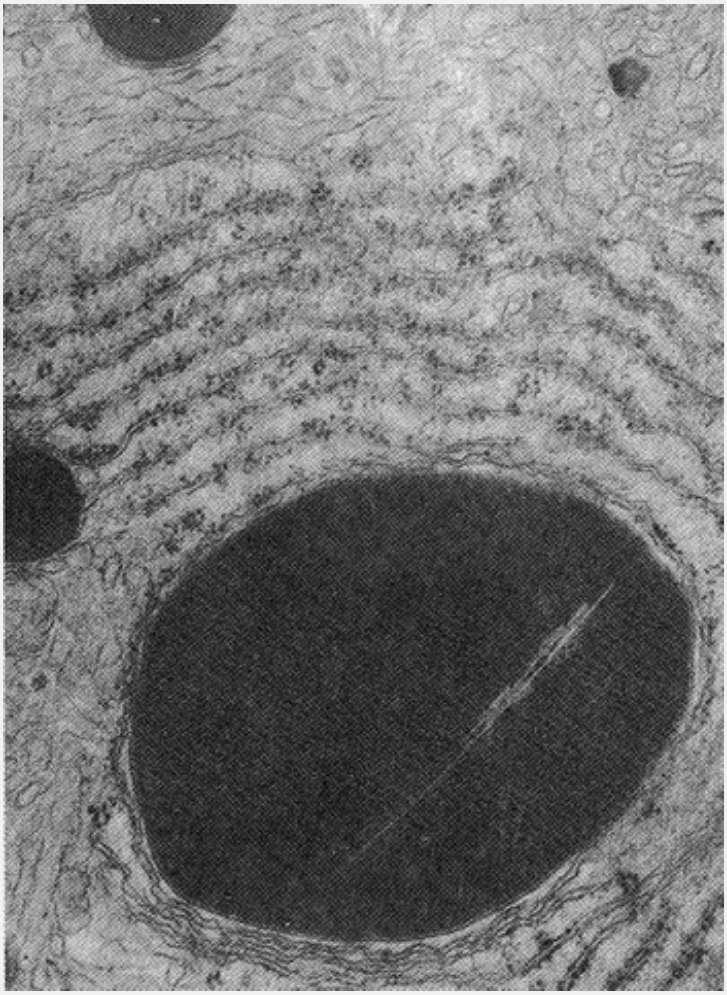

Figure 42.32 Hyalin bodies within a lutein cell from a corpus luteum of pregnancy consisting of homogeneous, electron-opaque material. Note needle-shaped cleft within the largest hyalin body. Some smaller hyalin bodies are surrounded by granular ER (original magnification x22,000). Reprinted with permission from:

Adams EC, Hertig AT. Studies on the human corpus luteum. I. Observations on the ultrastructure of development and regression of the luteal cells during the menstrual cycle. *J Cell Biol* 1969;41:696â€“715.

Relaxin, a polypeptide hormone, is also produced during gestation and the puerperium by the CLP, probably under the control of hCG (188,189,190,191). The concentration of relaxin in ovarian vein plasma during pregnancy correlates with P levels. The placenta and uterus have also been suggested as additional, but less important, sources for this hormone. Its reported actions include cervical dilatation and softening, inhibition of uterine contractions, and relaxation of the pubic symphysis and other pelvic joints (188,189,190,191). Immunoreactivity for renin and angiotensin II, similar to that noted within the preovulatory follicle (see above), has been demonstrated within the CLP (167), consistent with the observation that prorenin, likely of ovarian origin, increases 10-fold in pregnant women soon after conception (166).

Corpus Albicans

The regressing CLM is invaded by connective tissue that gradually converts it to a scar, the corpus albicans. The degenerating corpus luteum and the young corpus albicans may contain macrophages laden with ceroid and hemosiderin pigment (192,193). The mature corpus albicans is a well-circumscribed structure with convoluted borders composed almost entirely of densely packed collagen fibers with occasional admixed fibroblasts (Figures 42.13, 42.33). Focal calcification and ossification may be occasionally encountered. Most corpora albicantia are eventually resorbed and replaced by ovarian stroma. Persistent corpora albicantia are typically found in the medulla of postmenopausal women (Figure 42.13) suggesting that this resorption process decelerates or terminates prior to the menopause.

Atretic Follicles

Histology

Of the original 400,000 primordial follicles present at birth,

approximately 400 mature to ovulation. The remaining 99.9% undergo atresia, a process that begins before birth and continues throughout reproductive life, but is most intense immediately after birth and during puberty and pregnancy (135,136,137,138,139,141,143). Factors that initiate atresia and determine which follicles will ultimately undergo atresia are unknown. The atretic process varies with the stage of follicular maturation that has been reached. Atresia of early follicles (primordial and preantral) begins with degeneration

of the oocyte manifested by nuclear changes (chromatin condensation, pyknosis, fragmentation) and cytoplasmic vacuolation. Degeneration of the granulosa cells soon follows and the follicle disappears without a trace. In contrast, atresia of follicles that have reached the antral stage of development is more complex and variable, but ultimately leads to obliterative atresia and the formation of a scar, the corpus fibrosum. The earliest evidence of this process is mitotic inactivity of the granulosa cells and a decrease in their numbers, manifested by thinning and focal exfoliation of the granulosa layer. Some follicles may persist for an indefinite period of time at this stage as atretic cystic follicles (Figure 42.34); those that exceed 3 cm are designated follicular cysts. Atretic cystic follicles and follicular cysts may persist for a number of years after the menopause (194,195). Atretic follicles are ultimately invaded by vascular connective tissue that eventually fills the central cavity (Figure 42.35). The oocyte may persist for an indefinite period of time but eventually degenerates. Concurrent with these changes, the basement membrane between the granulosa and theca interna layers becomes transformed into a thick, wavy, eosinophilic, hyalinized band, the so-called â€œglassy membraneâ€• (Figures 42.35, 42.36). The theca interna layer typically persists, often with prominent luteinization (Figures 42.35, 42.36), until the late stages of

atresia at which time cords and nests of theca cells become surrounded by proliferating connective tissue (Figure 42.36). Luteinization of both theca and granulosa layers is particularly striking in atretic follicles during infancy and childhood (196) and pregnancy (Figure 42.37) (142).

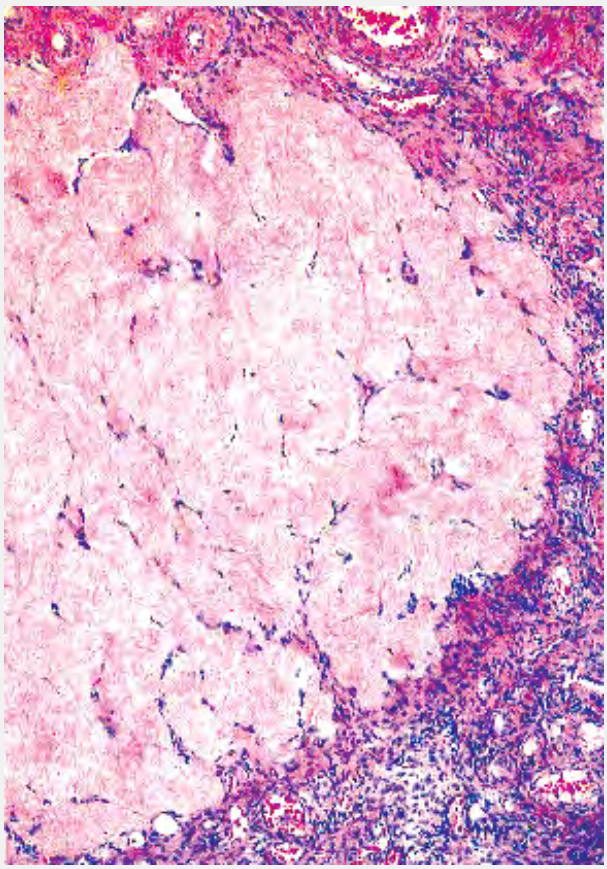

Figure 42.33 Corpus albicans.

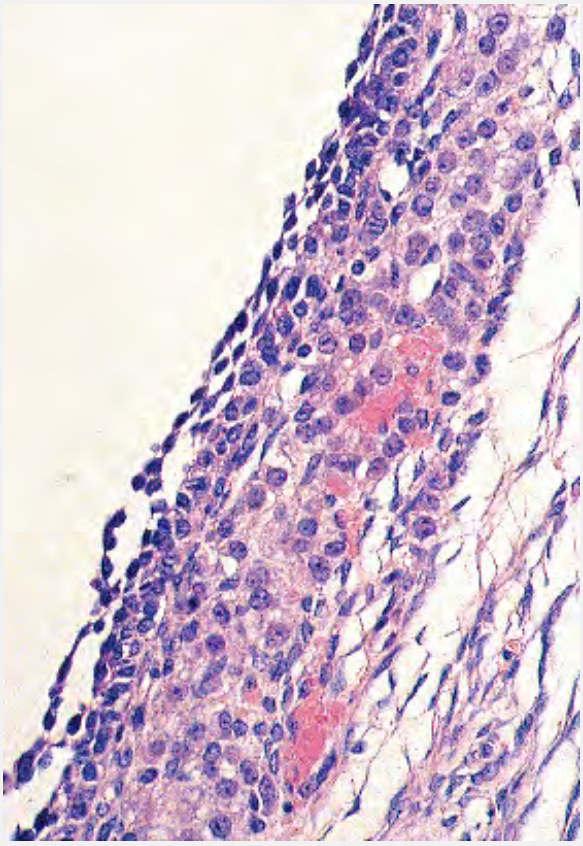

Figure 42.34 Lining of atretic cystic follicle composed of a thin inner layer of small, exfoliating granulosa cells and an outer, luteinized theca interna layer.

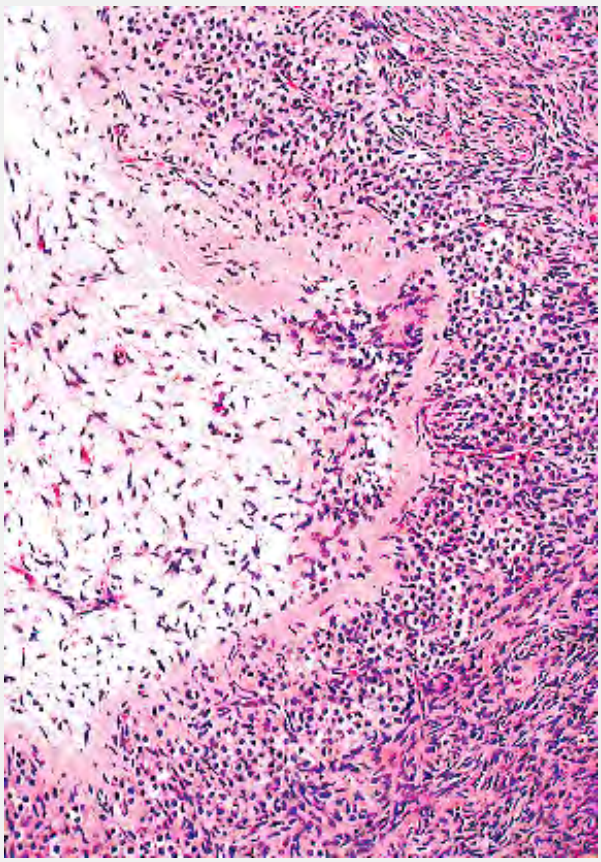

Figure 42.35 Atretic cystic follicle undergoing obliterative atresia. Loose connective tissue is replacing the central cavity. The wavy basement membrane (â€œglassy membraneâ€•) is thickened and hyalinized. A prominent layer of luteinized theca interna is evident.

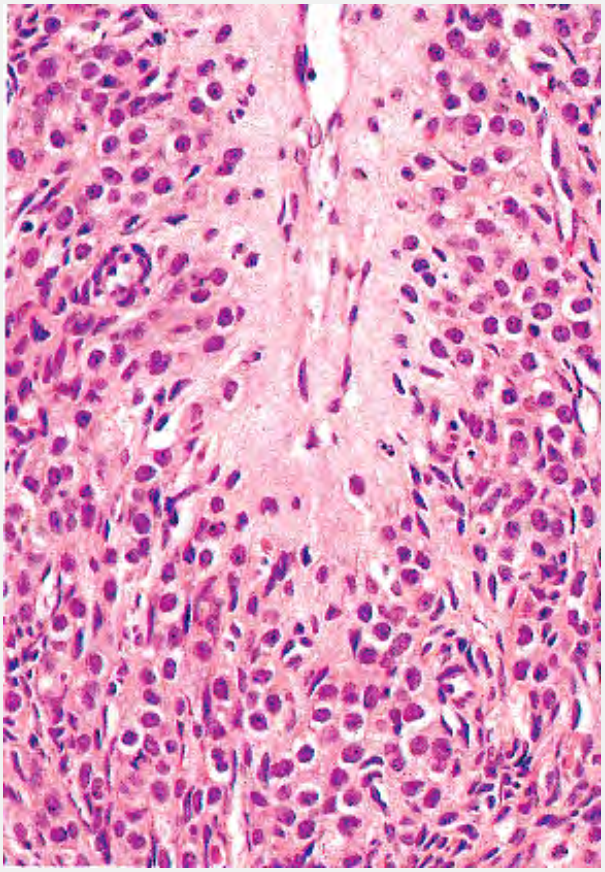

Figure 42.36 Edge of follicle in late stage of obliterative atresia. Hyalinized fibrous tissue occupies the central cavity and extends into the persistent luteinized theca interna layer.

Microscopic proliferations of persistent granulosa cells within the centers of atretic follicles of pregnant, and less commonly nonpregnant women, may mimic small granulosa cell tumors (Figure 42.37), or rarely, Sertoli cell tumors (197). Similarly, structures resembling microscopic gonadoblastomas and sex cord tumors with annular tubules have been identified within atretic follicles in up to 35% of normal fetuses and infants (131,198,199). There is no evidence to suggest that any of these tumorlike proliferations represent early stages of neoplasia.

Continued shrinkage and hyalinization of an atretic follicle produces a serpiginous strand of hyalin tissue, the corpus fibrosum or atreticum (Figure 42.38). Like corpora albicantia, most corpora fibrosa are probably resorbed by the ovarian stroma.

Hormonal Aspects

In contrast to preovulatory follicles, the microenvironment of follicles undergoing atresia is predominantly androgenic, with high concentrations of intrafollicular androstenedione and low concentrations of FSH and E2 (17,119,153,154,200). As noted, these follicles are deficient in granulosa cells, and the residual granulosa cells do not respond to FSH in vitro (145); both FSH- and LH-receptors are lower than in nonatretic follicles (156). Oocytes from atretic follicles are unable to complete the first meiotic division (145). It is likely that an androgenic intrafollicular milieu is the major factor that halts follicular growth and initiates atresia of that follicle.

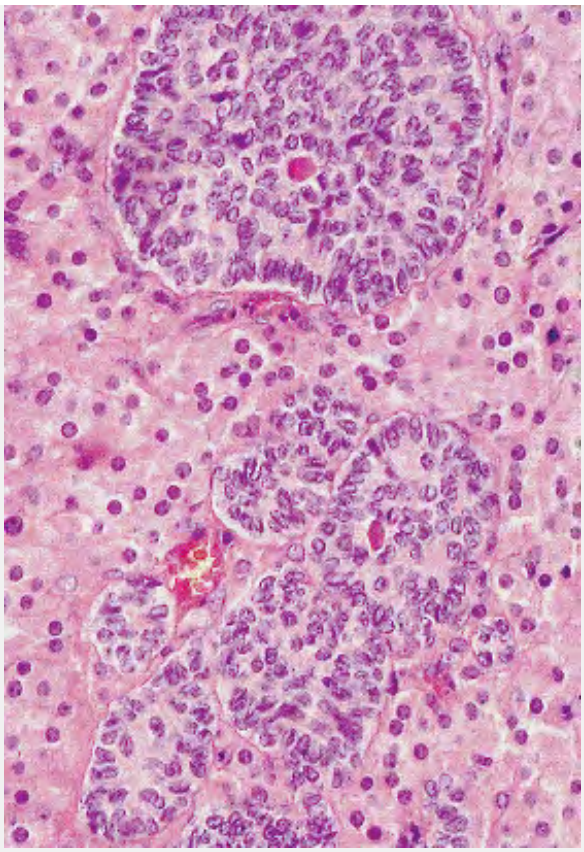

Figure 42.37 Atretic follicle in pregnancy. Within the center of the follicle is a proliferation of persistent granulosa cells surrounded by luteinized theca interna cells.

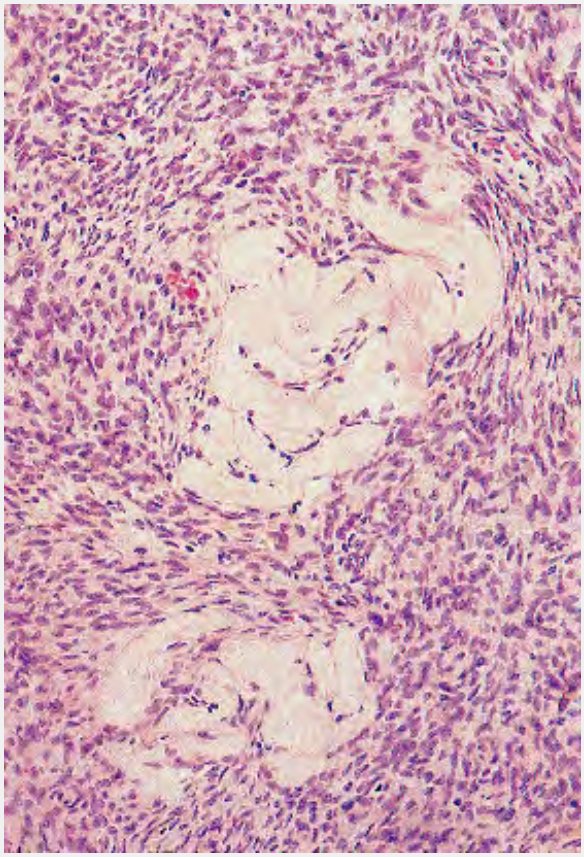

Figure 42.38 Two corpora fibrosa.

Hilus Cells

Histology

Ovarian hilus cells, morphologically identical to testicular Leydig cells (with the exception of a female chromatin pattern), are present during fetal life but not during childhood. They reappear at the time of puberty and are demonstrable in most postmenopausal women (201,202,203). Their number and location can be highly variable, and their numbers increase during pregnancy, with increasing age after the menopause, and with increasing degrees of ovarian stromal

proliferation and stromal luteinization (22). Mild hilus cell hyperplasia is a relatively common incidental histological finding in postmenopausal women (85).

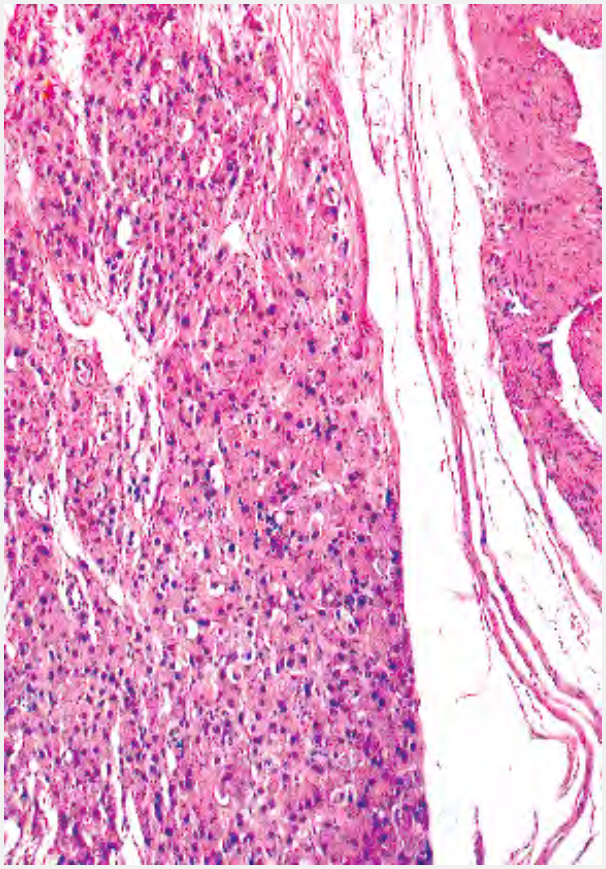

Figure 42.39 Nest of hilus cells adjacent to large vessel within the ovarian hilus.

Hilus cell aggregates of variable size and shape are typically found in the ovarian hilus and adjacent mesovarium (Figures 42.39, 42.40). They are more numerous in the lateral and medial poles of the hilus and near the junction of the ovarian ligament with the ovary, typically lying close to the junction of the hilus with the medullary stroma (Figure 42.40) (201). The aggregates are closely associated

with large hilar veins and lymphatic sinusoids, and may form nodular protrusions into their lumina. Hilus cells characteristically ensheathe, or less commonly lie within, nonmedullated nerves (Figure 42.41), and occasionally surround the rete ovarii (201). Nests may also be present within the medullary stroma near the hilus, probably representing extensions of the hilus into the medulla. Also, as previously noted, cells of hilus-type may also occur rarely within the ovarian stroma at a distance from the hilus (stromal Leydig cells). Hilus cells also may be encountered rarely in the perisalpinx and fimbrial endosalpinx (204).

Hilus cells nests are unencapsulated, typically lying within loose connective tissue, or rarely ovarian-type stroma, within the hilus (101). The cells are 15 to 25 micra in diameter, round to oval, less commonly elongate, with abundant eosinophilic cytoplasm and a spherical vesicular nucleus with one or two prominent nucleoli (Figure 42.42). The nuclei, particularly in postmenopausal

women, may have hyperchromatic, bizarre nuclei. Hilus cells are typically strongly immunoreactive for inhibin, calretinin, and melan-A (77,81).

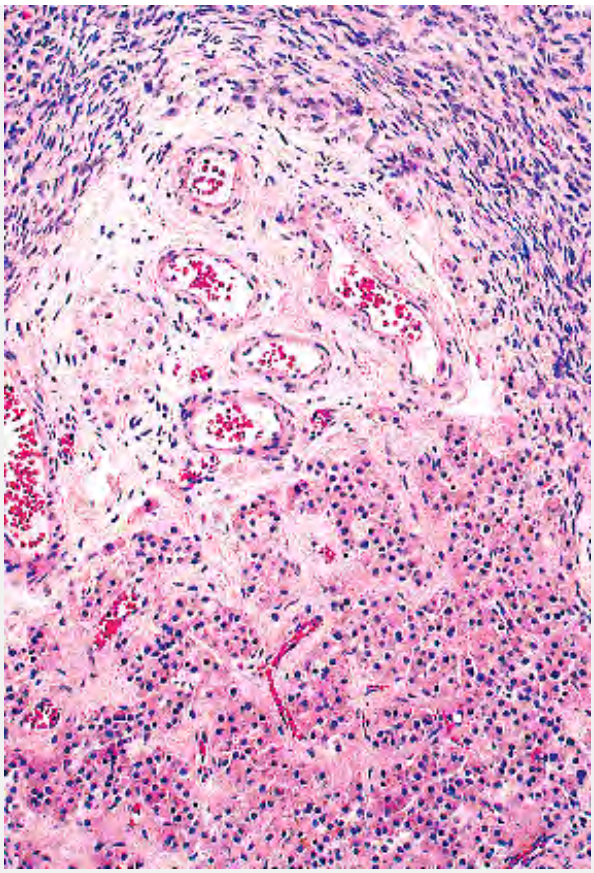

Figure 42.40 Nest of hilus cells with admixed small blood vessels abutting medullary stroma (top of figure).

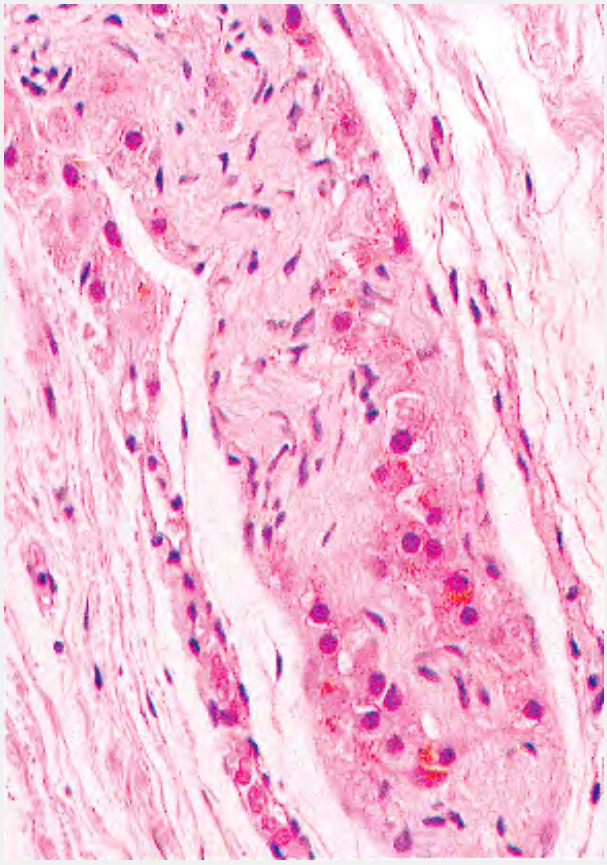

Figure 42.41 Perineural and intraneural hilus cells. Note fine brown lipochrome pigment within hilus cells.

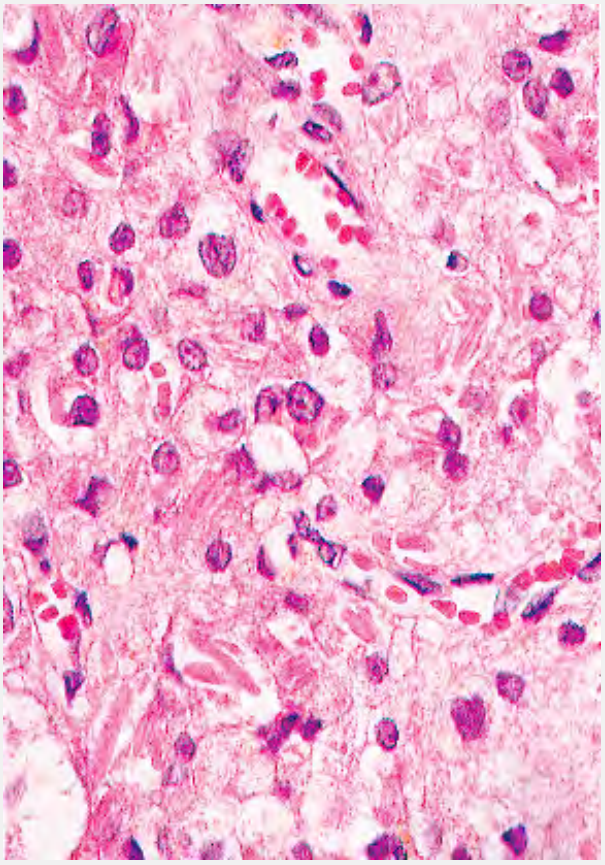

Figure 42.42 Hilus cells with Reinke crystals.

Hilus cells contain specific crystals of Reinke, which are homogenous, eosinophilic, nonrefractile, rod-shaped structures, 10 to 35 Âµm in length, with blunt, but occasionally tapered, ends (Figure 42.42). The crystals typically lie in a parallel or stacked arrangement within a cell, and often are surrounded by a clear halo; occasionally they appear to extend through or overlie cell membranes. The crystals are unevenly distributed and are typically present in only a minority of cells; frequently they cannot be identified (205). Their visualization may be facilitated by the use of Masson's trichrome and iron hematoxylin methods that stain them magenta and black respectively. Additionally, the crystals fluoresce yellow when H&E stained sections are viewed by ultraviolet light (206). Also present

within hilus cells, often in greater numbers than crystals, are spherical or ellipsoidal hyalin structures that have an otherwise identical appearance to crystals and probably represent their precursors. Elongated erythrocytes compressed within capillaries should not be confused with crystals and crystal-precursors. The cytoplasm of Leydig cells may also contain perinuclear eosinophilic granules, peripheral lipid vacuoles, and golden-brown lipochrome pigment (Figure 42.41). Delicate collagen fibrils surround each cell. Typically admixed with the hilus cells are fibroblasts and cells intermediate in appearance between the two cell types (207). The hilus cells and intermediate cells have intimate attachments to nerves, including true synaptic connections, suggesting that hilus cells may originate from hilar fibroblasts, possibly under the inductive influence of hilar nerves (201,207).

Hilus cells should be distinguished from adrenal cortical rests. The latter are extremely rare in the ovary (208), but are found in the mesovarium, and occasionally within the ovarian hilus, in approximately one-quarter of women (209). Their histologic appearance mimics that of the normal adrenal cortex, with most of the cells containing numerous lipid vacuoles.

Ultrastructure

Hilus cells have a steroidogenic ultrastructure consisting of prominent smooth endoplasmic reticulum and mitochondria with tubular cristae, as well as well developed Golgi, large lysosomes, and osmiophilic lipid inclusions (207). Reinke crystals have a true crystalline appearance composed of dense parallel hexagonal microtubules with a mean thickness of 12 nm separated by clear spaces 15 nm wide producing a â€œwoven fabricâ€• appearance (Figure 42.43) (207). The crystals are typically oriented in many directions in the same cell. They appear to be formed by progressive association of precrystalline units each of which is composed of bundles of four or five parallel filaments (Figure 42.43).

Typically found admixed with hilus cells are fibroblasts and cells intermediate in ultrastructural appearance between the two cell types. Hilus cells, and more commonly the intermediate cells, have intimate attachments to nerves in the form of simple membranous contacts, invaginations of axon terminals into hilus cells, or surface membrane thickenings resembling a true synapse (207).

Hormonal Aspects

The light and electron microscopic morphology and enzyme content of hilus cells are those of steroid hormone-producing cells, although to what extent hilus cells contribute to the steroid hormone pool in normal females is unknown (32,201). In vitro incubation studies indicate that the major steroid produced by ovarian hilus cells is androstenedione and that it is produced in amounts higher than that produced from ovarian stroma (210). Lesser amounts of E2 and P are also produced in vitro. Hilus cells are responsive in vivo to both exogenous and endogenous hCG stimulation, manifested by an increase in their numbers, cell size, and mitotic activity (202).

Rete Ovarii

The rete ovarii, the ovarian analog of the rete testis, is present in the hilus of all ovaries. It consists of a network of irregular clefts,

tubules, cysts, and intraluminal papillae, lined by an epithelium that varies from flat to cuboidal to columnar (Figure 42.44) (211,212). Solid cords of similar cells may also be seen. Characteristically, the rete is surrounded by a cuff of spindle-cell stroma similar to, but discontinuous from, the ovarian stroma (Figure 42.44).

The cytoplasm of the cells of the rete is immunoreactive for cytokeratin, EMA, vimentin, and desmoplakin (35,36,213). Ultrastructural examination has revealed two types of cells, one ciliated and the other nonciliated with apical microvilli (35). The cytoplasm contains many mitochondria, a moderate amount of rough ER, many free polyribosomes, and some glycogen. Numerous desmosomes with associated tonofilament bundles connect adjacent cells. The basal lamina is well defined.

The rete juxtaposes and may communicate with mesonephric tubules within the mesovarium (212). Rare hilar cysts originate from the rete, and small tumorlike proliferations of the rete have been referred to as â€œrete adenomasâ€• (212,214). The transitional cell metaplasia that has been encountered in the rete epithelium may account for the occasional small hilar Brenner tumors that have been contiguous with and possibly derived from the rete (211).

Placenta

Steven H. Lewis

Kurt Benirschke

Introduction

The placenta is problematic for the pathologist. Many normal histologic variations may be mistaken for pathology and conversely, important pathologic alterations may be difficult to discern. Unique in pathology, the placenta, as a specimen, provides data about two patients and has three different anatomic sources. It is fetal, yet mostly extraembryonic in its differentiation and has maternal attachments. The placenta may be pivotal in adjudicating the etiology of â€œbad babiesâ€• in litigation (1 ,2) but more importantly, an objective, thorough, well-documented analysis can provide data important for both maternal and neonatal care. Acknowledging the placenta's many histologic and pathologic varients, its complicated derivation and its role in legal cases, the pathologist should become accustomed to obtaining information from both pediatric and obstetrical providers. The relevance of varients and alterations viewed by the pathologist can thereby be better understood.

These complex considerations cannot be addressed without a thorough understanding of the placenta's normal structure, and it is to this end that this chapter is devoted. Pathologic entities are

discussed to better demonstrate normal anatomy and histology. For more encyclopedic and complete discussions regarding placental pathology, the reader is directed elsewhere (1 ,2). It is easiest and most appropriate to describe (and for that matter, â€œreportâ€•) the principal structural components of the placenta in a compartmentalized manner. These consist of the umbilical cord, the membranes (amnion and chorion), the villous parenchyma, and the maternal decidual tissue.

Routine Storage, Examination, and Processing

After obstetric delivery, placentas may be stored at 4Â°C in a refrigerator before examination. The period of time for this storage generally should not exceed 1 week. Placentas should not be frozen before evaluation as freezing renders the gross examination difficult and histologic features are obscured. For refrigeration, suitable containers include

cardboard buckets or styrofoam storage cups. It has been advocated by some to immediately fix the placenta in 10% buffered formalin for later examination (3). It should be noted that when this method of processing is used, placental weights increase by a factor of approximately 10% (4).

It should be underscored that although assessment of the placenta is considered in the pathologist's domain, it is the obstetrical provider who first visualizes the specimen. An educated clinician may aid the pathologist by submitting it. Otherwise it becomes â€œdiscarded.â€• Most institutions do not perform histologic evaluation of all placentas from all deliveries and a discarded placenta can be of no use when problems are associated with pregnancy, labor and delivery, and the neonatal period. Labor and delivery suites should have a list of appropriate clinical and pathologic entities that require pathologic examination of the

placenta (5). Because of the frequent turmoil in labor and delivery areas and because problems may often arise in neonates within the first few days of life, the week of storage of all placentas is highly important. It is common for academic institutions to perform histologic examination on approximately 10% to 20% of all delivered placentas.

The gross morphologic assessment of the placenta should be approached in a thorough, routine fashion. Our procedure for the gross assessment and sectioning of placentas is illustrated in Table 43.1 .

The placenta is removed from its container and its shape is described. It is usually discoid, but additional lobes may be present. Next, it is convenient to note the location of insertion of the umbilical cord, describe its length and diameter, note irregularities in its contour and texture, describe its color, and note the number of vessels it contains. The cord is then amputated at its base, and representative sections are immersed in fixative.

Attention is next directed to the membranes (amnion and chorion), which are inspected for completeness. Usually, the placenta is delivered vaginally with the membranes surrounding the placental maternal surface (â€œSchultzeâ€•). The membranes are then manually reflected to their normal anatomic position and the smallest distance from the point of rupture to the placental disk (the narrowest width of membranes) is measured. When this measurement equals zero (after vaginal delivery), a low-lying or marginal placenta previa is implicated. The membranes are then assessed for their color, transparency, sheen, and surface irregularities, as well as for the presence of membranous vessels or accessory lobes. The membranes are then removed from the placental disk margin, keeping track of the point of rupture. This point is grasped with a toothed forceps and rolled in a concentric fashion to produce a â€œmembrane roll.â€• With the membranes rolled in such a fashion, the point of rupture can be identified

histologically. The presence of inflammatory cells confined to this region suggests early mild chorioamnionitis. Representative sections are immersed in fixative.

The fetal surface of the placenta is next examined. Chorionic vascular thrombi, if present, and nodules or irregularities of the amnion are noted. The maternal surface of the placenta is inspected, and any blood clot that has settled in the storage container with the dependent portions of the organ is removed. Areas of blood clot that are adherent or discolored brown (indicating chronicity) and that are depressing the maternal surface are considered indicative of retroplacental hemorrhage (clinically designated as abruptio). Should this be noted, the dimensions or percentage of the maternal surface involvement are recorded. The organ is next weighed free of its cord and associated membranes. The average weight of the term placenta is approximately 400 to 600 g. Placental weight varies with neonatal weight and normal weights have been reviewed for all gestational ages (1). The average dimensions of the term placenta are approximately 18 Ã— 16 Ã— 2.3 cm.

The villous parenchyma is then inspected by sectioning the placenta at 1- to 2-cm intervals looking for irregularities in the parenchyma that indicate infarction, thrombi, or other pathologic entities. There are normally 16 to 20 cotyledonous units that do not have distinct functional correlates. An absent cotyledon may indicate a portion of retained placenta in utero. Representative sections of abnormal areas are blocked out, and areas of normal-appearing parenchyma (usually three) are placed into fixative along with the already sectioned membrane roll and umbilical cord.

The fixation of the materials for study is routine. We prefer to fix tissues in Bouin's solution for a period of 24 hours before trimming and submission for final processing. This process of fixation allows for excellent tissue penetration and ease of sectioning. In addition, it provides superior cytologic detail. The drawbacks to the Bouin's

fixation are twofold. One is that if certain special studies are of interest (i.e., immunohistochemistry and in situ hybridization), Bouin's fixation may interfere with antigenâ€“antibody reactions or nucleic acid hybridization. This problem may be eliminated by fixing tissues desired for such studies in Bouin's solution for only a limited period of time. For small uterine cervix biopsies, it has been shown that Bouin's fixation for less than 8 hours produces good results with in situ hybridization (6). The second problem with Bouin's fixation is that if in the final preparation lithium carbonate is omitted, increased extraneous pigment formation occurs.

Pathologists are accustomed to using 10% buffered formalin solution for the processing of most tissues, and this is not contraindicated in the processing of placentas. We find that when using formalin, the period of time required to create sufficient tissue hardness for proper sectioning delays processing and histologic resolution is somewhat inferior to that obtained with Bouin's fixation. It is our

procedure to stain tissue sections with hematoxylin and eosin (H&E) or hematoxylin-phloxine and saffron (HPS). Other standard special stains may be used for the detection of specific infectious agents, secretory activity, or structural composition (silver stains, periodic acid-Schiff (PAS), Masson's trichrome, etc.). Furthermore, a host of immunohistochemical stains have been used to elucidate functions of specific placental cell types.

Umbilical Cord

Embryology

Specific embryologic considerations are germane to the understanding of the normal umbilical cord structure, including its frequent possession of embryologic remnants. The open region on the ventral surface of the developing

embryo diminishes in size and then forms the early umbilicus. Through this structure extend both the yolk stalk and the body stalk, as well as the allantois. This cylindrical structure elongates, and its surface becomes covered by the expanding amnion. This is a single-layered epithelium on a layer of connective tissue. Therefore, the developing umbilical cord contains the yolk stalk, a pair of vitelline blood vessels, the allantois, and the allantoic blood vessels (two arteries and one vein) and is covered by amnionic epithelium. These anatomic relationships explain the presence of the omphalomesenteric duct (the connection between developing endoderm and the yolk sac) and the allantoic duct (which has its communication in early gestation with the urachus) within sections of proximal (fetal) umbilical cord.

Gross Morphology

The gross anatomic features of the umbilical cord that are of importance are the location of its insertion in the placental disk, its length, and the number of vessels. The presence of true knots (Figure 43.1) may be considered normal when there is no adverse outcome, yet this occurrence may lead to fetal demise when the knot is tight. The presence of vascular tortuosities (false knots) is common and rarely of clinical significance (Figure 43.2). The finding of meconium staining and the presence of surface plaques are definitely abnormal and are described below.

The normal umbilical cord is pearly white and somewhat translucent. The length of the umbilical cord has great significance, principally when it is excessively long or excessively short. Cord length has been shown to vary with gestational age, and measurements indicate that the cord elongates as gestation proceeds. At approximately 20 weeks' gestational age, the average cord length is 32 cm (7). The normal length of the umbilical cord at term has been determined to be, on average, between 55 and 65 cm (1 ,7 ,8 ,9 ,10) (Figure 43.3). The literature contains many articles that relate the significance of abnormal cord lengths with both in utero fetal activity and neonatal outcome. The reader is referred to an extensive review of the subject (1).

Benirschke K, Kaufmann P. *Pathology of the Human Placenta.* 3rd ed. New York: Springer-Verlag; 1995.

Figure 43.2 False knot. Note the unrelated abnormal membranous vessels connecting placental lobes.

Histology

Histologic examination of the umbilical cord shows several distinct layers. On the surface is a well-defined single layer of amnionic epithelium. The epithelium is squamoid and, in the region of fetal cord insertion, often becomes multilayered and closely resembles its epidermal contiguity. Electron microscopy studies performed on cord amnionic cells

have suggested that the epithelium is responsible for fluid equilibrium activities (11). True squamous metaplasia of the umbilical cord is considered a normal variant, and ultrastructural studies of this epithelium have shown morphologic similarities between this epithelium and the fetal epidermis (12).

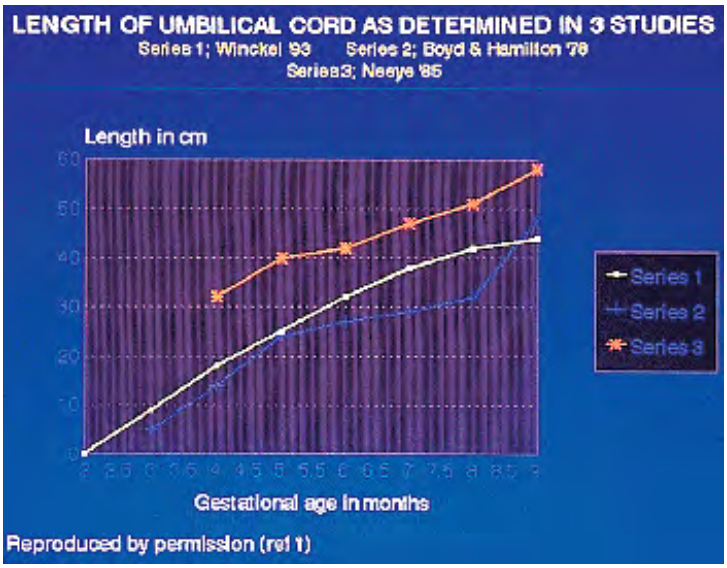

Figure 43.3 Normal cord length dimensions associated with changes in gestational age. Reprinted with permission from: Benirschke K, Kaufmann P. *Pathology of the Human Placenta.* 3rd ed. New York: Springer-Verlag; 1995.

Deep to the amnionic epithelium that comprises the surface of the cord is the substance of Wharton's jelly. This material largely is composed of mucopolysaccharides (hyaluronic acid and chondroitin sulfate). Ultrastructural examination of this material shows the presence of delicate interlacing microfibrils and sparse collagen. Mast cells are prominent. Their frequency is increased in the near periphery of the cord vasculature (13). In this same region, and in the cord in general, macrophages are rarely identified.

Embedded within the substance of Wharton's jelly are the umbilical vessels. There have been considerable interest and discussion focused on the identification of vasa vasorum and vascular neuronal innervation. Although the vasculature of the umbilical cord is of a considerable caliber, there are no vasa vasorum or lymphatic channels present in this structure. Studies investigating vascular innervation have concluded that no nerves are present within the umbilical cord. This has been borne out by electron microscopic studies (14). Occasionally, however, autonomic

nerves are identified using acetylcholinesterase thiocholine techniques in the proximal (fetal) end of the cord (15). Such findings are compatible with the persistence of peripheral vagal neuronal elements associated with the ductus venosus, which are entrapped in the proximal portion of the umbilical cord. Certainly any neuronal vestiges found within the umbilical cord are best considered as remnants, and to date there has been no demonstration of their functional significance (16).

Since the yolk sac connects to the primitive midgut through the body stalk in early development, vestiges of this epithelium-lined duct are common in the umbilical cord. The persistence of the omphalomesenteric duct is characterized by a tubular structure present within Wharton's jelly and lined by a single layer of low cuboidal to columnar, mucin-secreting epithelium (Figure 43.4Aâ€“D). Remnants of the duct may form cystic structures that contain a variety of endodermally-derived epithelia, including pancreatic, intestinal (small and large), and gastric components. Such findings are rarely of any clinical significance, although secretory products of gastric origin resulted in umbilical vascular ulceration, hemorrhage, and fetal death in a case report described by Blanc and Allan (17).

The allantois differentiates as a protuberance from the yolk sac into the body stalk and is essential for the development of the umbilical vessels. This structure is incorporated into the anterior aspect of the hindgut, where it communicates with the urachus. Remnants of the allantoic duct are often found in sections of proximal umbilical cords. Its intimate relationship with the formation of umbilical vessels explains its presence between the two umbilical arteries, when it is identified. These remnants rarely have clinical significance. The lining of this tract is often devoid of a lumen and consists of aggregates of epithelial cells with a variety of epithelia represented (transitional, bladder, and yolk sacâ€“derived endodermally classified cells) (Figure 43.5).

The vasculature of the umbilical cord is composed of two arteries and a single vein. The arteries possess no internal elastic lamina and have a double-layered muscular wall. Each of these muscular layers is composed of a network of interlacing smooth muscle bundles. The vein does have an inner elastic lamina. As noted, no vasa vasorum are present. Remnants of the vitelline vasculature in the proximal portion of the cord sometimes may be observed in sections taken from this region. The umbilical vein, which generally has a larger diameter, possesses a thinner muscular coat consisting of a single layer of circular smooth muscle (Figure 43.6A, B).

Of further interest, distinguishing umbilical vasculature from other systemic vessels, is that no true vascular adventitia is found. Near the placental insertion, it is common to identify anastomotic channels between the two umbilical arteries (18 ,19) (Figure 43.7).

Transverse serial sections confirm that two umbilical arteries spiral in parallel around the umbilical vein. Often, multiple twists in the cord occur. The proposed origin of this spiraling has been extensively discussed; however, its true functional significance and origin remain to be definitively elucidated (1).

Pathologic Alterations

Distinguishing normal anatomy from pathologic entities is the essence of proper understanding of the normal anatomy and histology of the umbilical cord. Most pathology of the cord may be seen in the gross sense. Histology is confirmatory. A tight knot with notching indicating stricture associated with proximal vascular dilatation may result in fetal death. Interestingly, although true knots occur frequently and are associated with long cords, adverse outcomes are rare events; therefore, in most instances a true knot can be considered a normal variant. The absence of an umbilical artery is a well-established observation and easy to identify

grossly or in histologic sections (Figure 43.8). This phenomenon has been found in approximately 1% of neonates. The association of this finding with congenital anomalies is well known, and these malformations often take the form of urinary tract malformations.

Persistence of a second (right) umbilical vein is an unusual phenomenon. The pathologist is cautioned in this regard. It is not unusual to find histologic sections identifying more than three vessels in an umbilical cord. This finding is related to commonly identified tortuosities. These tortuosities have been termed â€œfalse knotsâ€• (Figure 43.2) and have

little clinical significance. An exception is that these vessels rarely may be prone to thrombosis.

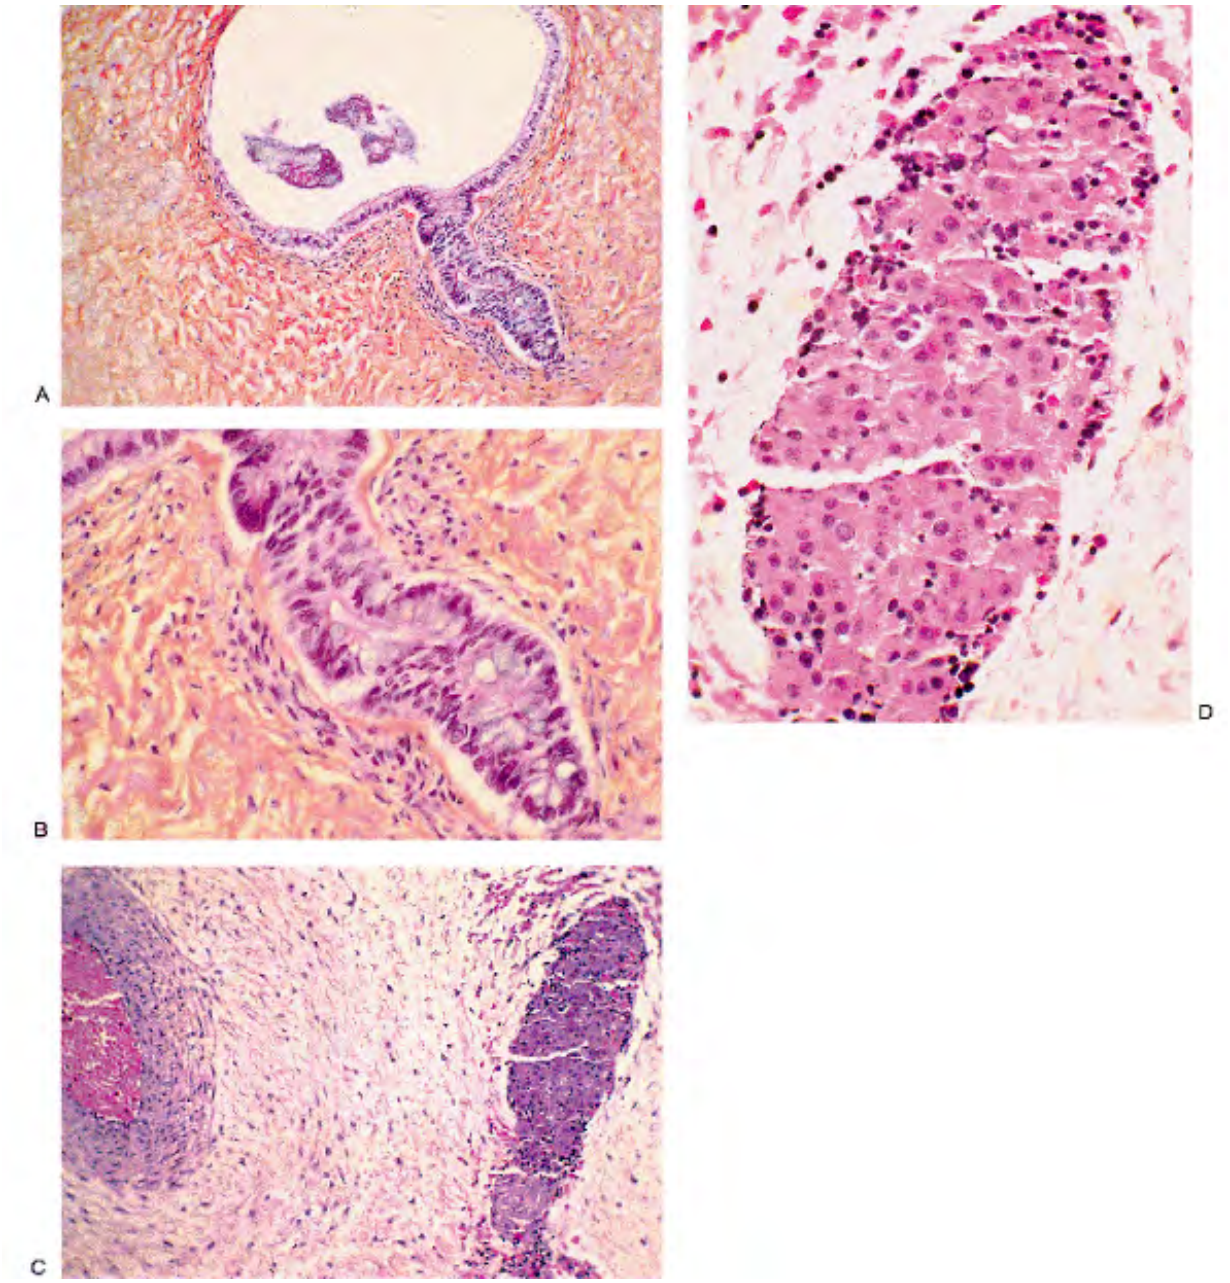

Figure 43.4 Omphalomesenteric duct remnant (A) with enteric epithelia (B). Omphalomesenteric duct adjacent to umbilical vein (C) with unusual finding of hepatic tissue (D).

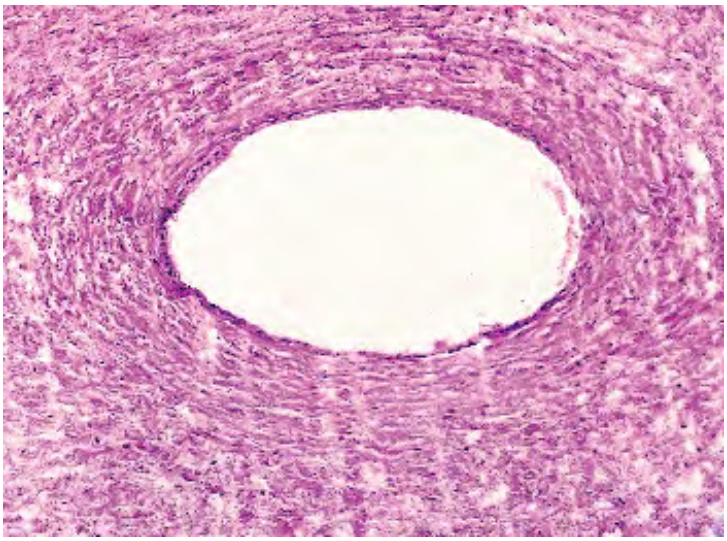

Figure 43.5 Allantoic duct remnant hematoxylin and eosin (H&E stain).

The presence of thrombotic material in the vasculature of the umbilical cord is truly pathologic. The process may be related to the genesis of a single umbilical artery when it occurs in early gestation. Abnormal umbilical insertions may cause thrombosis.

Velamentous cord insertions are abnormal and are characterized by the presence of the umbilical vasculature implanting in the placental membranes as opposed to the usual implantation over the placental disk (Figure 43.9). These vessels course independently within the chorion and are unguarded by the protective substance of the umbilical cord (Wharton's jelly). Thrombosis thus results from pressure on those vessels by fetal parts, and these vessels are subject to injury at the time of spontaneous or, more commonly, artificial membrane rupture.

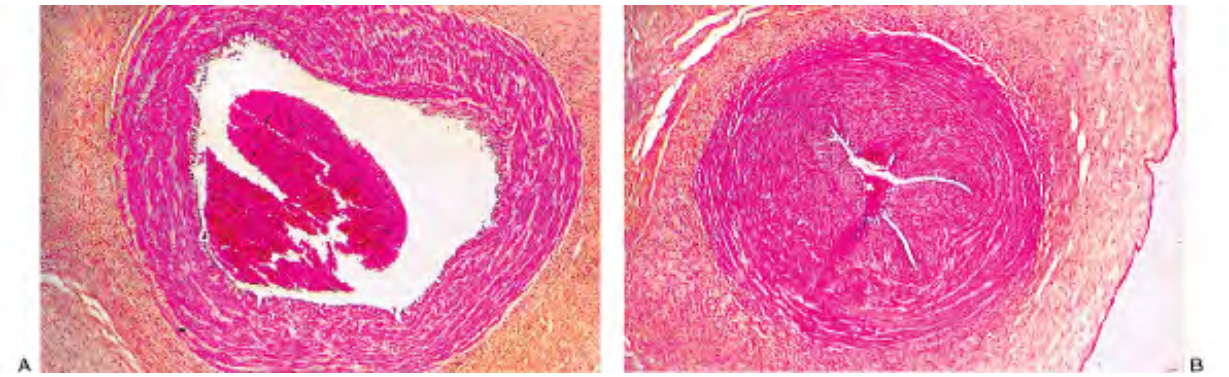

Figure 43.6 Umbilical vein (A) and artery (B) [hematoxylin-phloxine and saffron (HPS) stain].

Other abnormalities and pathologic findings of the umbilical cord (certainly to be distinguished from normal morphology and histology) that are of clinical importance are umbilical cord vascular rupture, complete absence of Wharton's jelly (Figure 43.10), and neoplasms of the umbilical cord [hemangioma (Figure 43.11) and teratoma, both unusual findings].

Most significant when considering normal histologic changes in the umbilical cord is the presence of hemorrhagic material in the perivascular region, which would suggest umbilical cord vascular rupture. Although true cord hematomas do occur on occasion (Figure 43.12), the presence of hemorrhage in this region is common and generally attributed to the mode of delivery of the placenta, with traction or clamping of the umbilical cord producing this artifactual finding (Figure 43.13).

Umbilical torsion and stricture are associated with excessive fetal movement and focal absence of Wharton jelly,

respectively. Both are associated with adverse outcomes (1). In the former, the normal twist or coiling of the cord becomes excessive. There is an association with long cords. The latter is less well understood but may at times be a function of torsion

(Figure 43.14). Additionally, excessive coiling has been associated with increased fetal activity, cocaine use, abnormal fetal heart rate tracings and preterm deliveries (20). Nascent dimensions of cord width are therefore germane. There is little literature that actually defines the dimensions of normal cords, although published data correlate abnormalities associated with fat and thin cords (7 ,8) (Figure 43.15).

Figure 43.7 Normal proximal anastomosis of umbilical arteries rendering the appearance of a single umbilical artery.

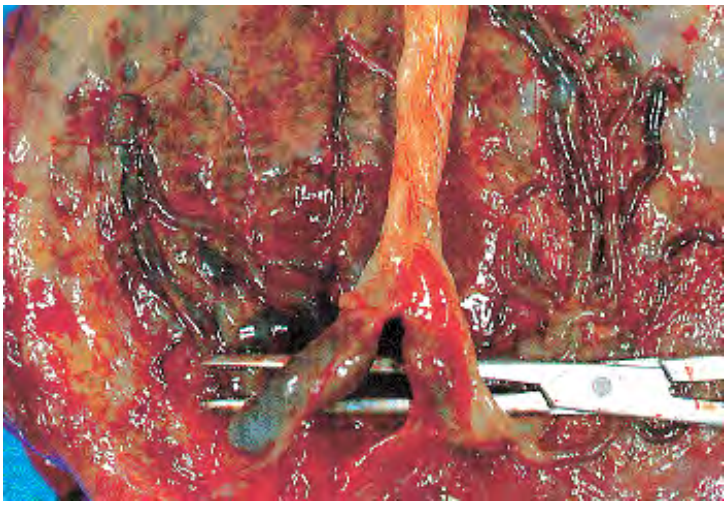

Figure 43.10 Furcate insertion of umbilical cord. Umbilical cord vessels insert into placental substance individually (UA, *left* ; UA and UV, *right*) not surrounded by Wharton's jelly.

Another definitively pathologic entity that must be distinguished from normal histology is the presence of leukocytes within the cord substance. Such findings are indicative of funisitis and are

the result of inflammatory response to infectious antigens and recruitment through inflammatory pathways (Figure 43.16). When the process is prominent (severe) and with calcifications, the term *necrotizing funisitis* is applicable. Such severe pathology is indicative of chronic inflammation and may be seen in syphilis as well as other infections (1) (Figure 43.17). The identification of fungal elements about the umbilical cord are often difficult to discern from an overgrowth storage phenomenon. In this regard, the difficulty lies in the usual absence of associated inflammatory infiltrate. The cord, when involved, has white surface plaques. Fungal elements (i.e., *Candida albicans*) may be identified merely with hematoxylin and eosin stains, although special stains for fungi can be helpful when such pathology is suspect (1).

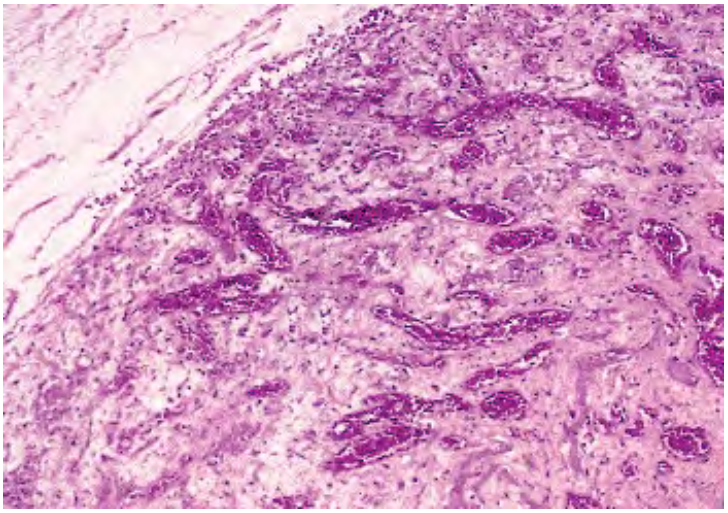

Figure 43.11 Dilated vascular lumina of umbilical cord hemangioma (HPS stain).

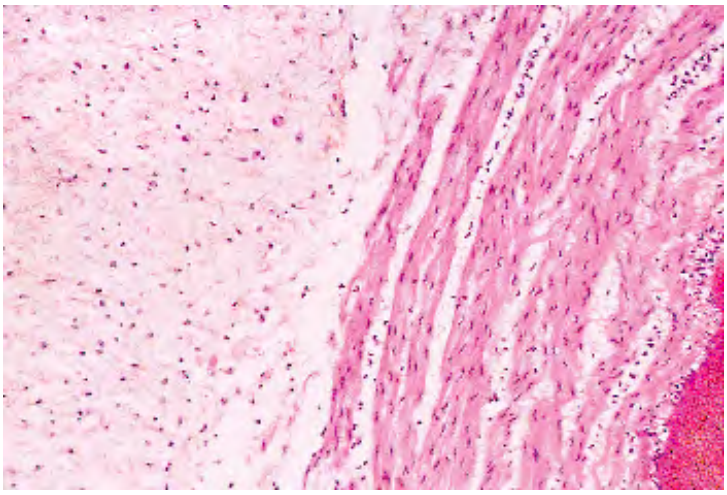

Figure 43.16 Acute funisitis. Polymorphonuclear leukocytes are present within the umbilical vein muscularis and adjacent Wharton's jelly.

Last, a finding in the cord that is notably pathologic is meconium-induced medial destruction (Figure 43.18A, B), which results from direct meconium toxicity and necrobiosis of vascular media (21). Associated vascular spasm and medial degeneration may adversely affect hemodynamics in the cord and chorionic vasculature.

Ramification of Chorionic Vasculature

At this point it is convenient to discuss the ramification of the umbilical vessels in the chorionic plate. The umbilical cord inserts in a central or eccentric fashion. Although abnormal insertion at the margin (Battledore) and in the membranes (velamentous) comprises a small portion of cord insertions, both should be considered pathologic

and not normal variants insofar as they have been attributed to adverse outcomes when extensively analyzed (22).

Figure 43.17 Necrotizing funisitis with intense perivascular malformations associated with calcification (peripheral white circular bands) may be seen in the gross.

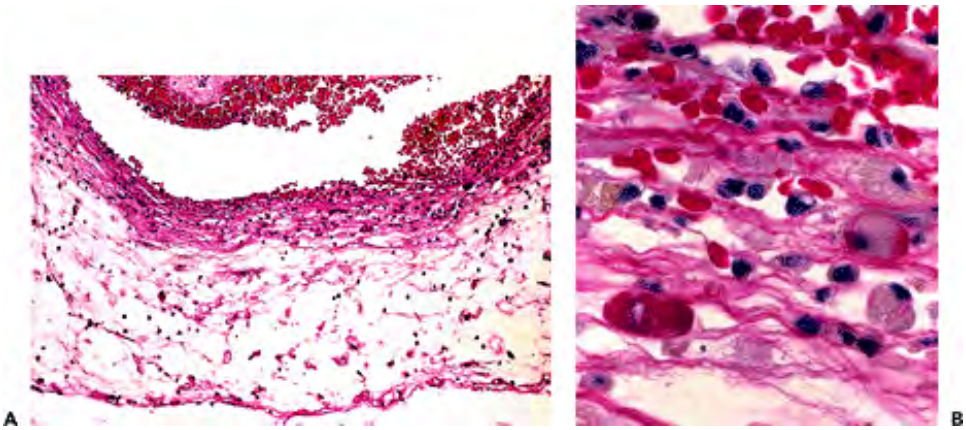

Figure 43.18 Globular degenerated necrobiotic medial cells so effected by meconium. The process is focal and contrasts with adjacent normal myocytes. Luna Ishak stain (A). Intensified magnification for delineation (B). Reprinted with permission from: Rana J, Ebert GA, Kappy KA. Adverse perinatal outcome with an abnormal umbilical coiling index. *Obstet Gynecol* 1995;85:573â€“578.

The pattern of vascular ramification within the chorion is described as either magistral (characterized by large-diameter vessels, radially diminishing in caliber to the periphery of the placenta) or disperse (characterized by multiple small vessels emanating directly from the cord insertion site). It is of interest that in the chorionic vasculature, no distinction can be made between branches of the umbilical vein and umbilical arteries using histologic criteria (in counterdistinction to the aforementioned description of differentiation between vein and artery in the umbilical cord). The only means of identifying which vessels are branches of arteries and which are veins is by noting their gross anatomic distribution. Arteries always cross over veins when observed from the fetal surface (Figure 43.19). The notation of such vascular relationships is of extreme significance when considering vascular anastomoses, as may be seen in some twin pregnancies (23).

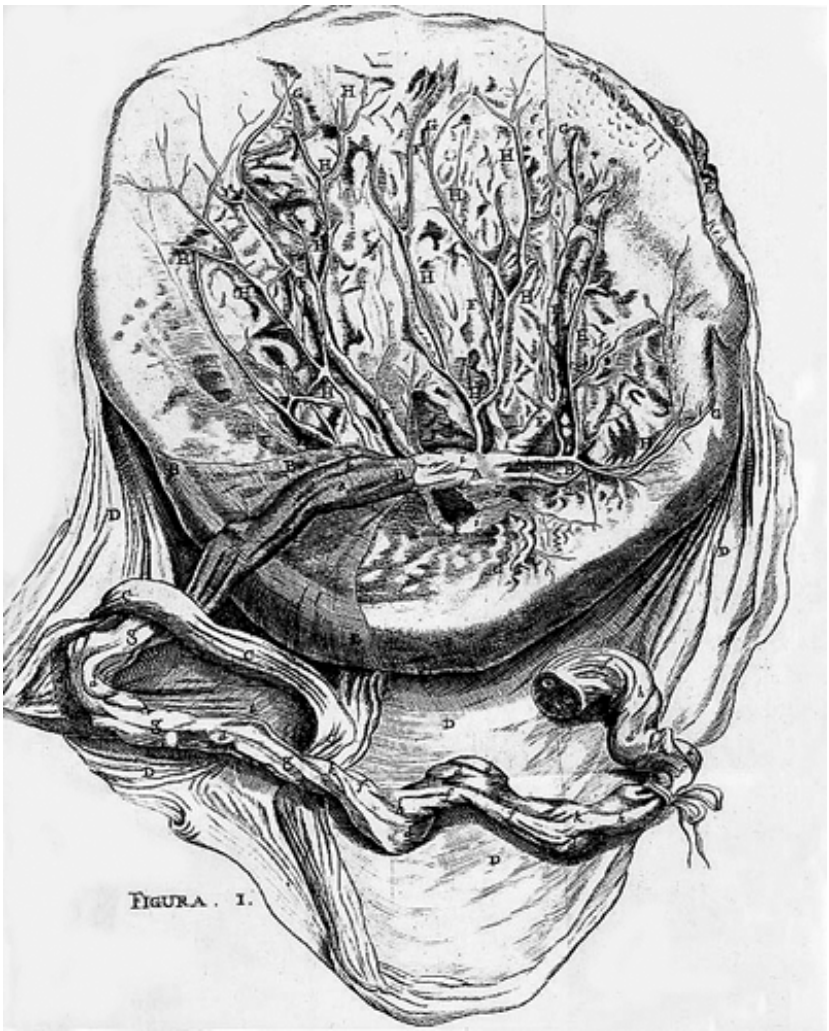

Figure 43.19 As early as the 1600s, Nicholas Hoboken recognized that chorionic arteries (H) overlie veins, and this was beautifully depicted in his painstaking drawings. These are the earliest accurate drawings of the human placenta known to exist.

The primary branches of the umbilical vasculature that course through the chorionic plate periodically dive beneath this stratum to establish the circulation of primary vascular ramifications ending in the terminal villi.

Pathologic Alterations of the Chorionic Vasculature

Abnormalities in the chorionic vasculature are similar to those found in the umbilical cord, the most significant being thrombosis of a chorionic vessel. During the gross examination of placentas so affected, the presence of thrombotic material may readily be identified by noting dilated vessels containing firm thrombotic substance. On the other hand, vascular thrombi may be more subtle and their appearance characterized only by the presence of faintly highlighted linear white streaks that parallel the peripheral

margin of vessels involved (Figure 43.20). These findings can be confirmed histologically.

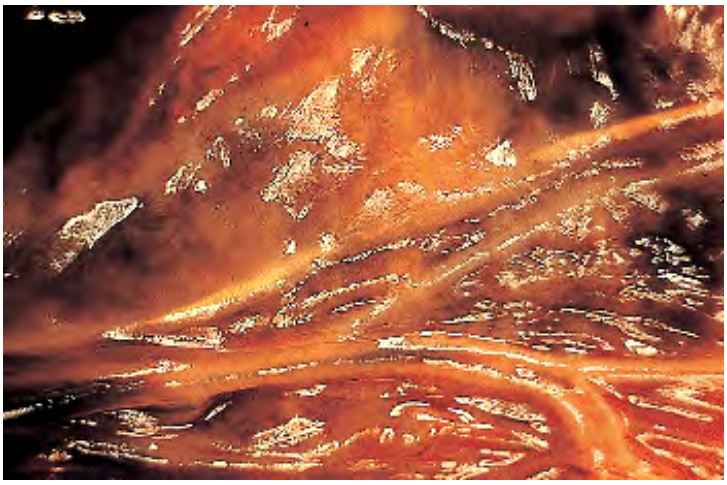

Figure 43.20 Chorionic vascular thrombosis characterized by a linear streak paralleling the vascular course (in this case a chorionic vein). Reprinted with permission from: Benirschke K, Kaufmann P. *Pathology of the Human Placenta.* 3rd ed. New York: Springer-Verlag; 1995.

The presence of polymorphonuclear leukocytes migrating from the chorionic vasculature and from the umbilical vasculature is pathognomonic of chorionitis and umbilical cord funisitis, respectively. Findings of chorionitis are histologically similar to those aforementioned in acute funisitis (Figure 43.16).

Membranes

Embryology

The placental membranes consist of the amnion and chorion. The amnion, which constitutes the innermost aspect of the embryonic cavity, develops from the margin of the embryonic disk. As the embryonic disk begins to take the form of a tube, the amnionic periphery also folds inward and its attachment to the ventral body is defined. The amnionic cavity subsequently develops by the process of cavitation. Elongation of the body stalk coincides with embryonic prolapse into the amnionic compartment. As development proceeds, the resultant cavity expands, and by 12 weeks from the last menstrual period the amniotic cavity completely occupies the chorionic sac. At this point, fusion occurs with the chorionic wall. This event is commonly identified by clinicians via routine ultrasonographic analysis of advancing gestations. At this gestational age, the potential space between the chorion and amnion is visibly obliterated. The amnionic cavity remains filled with amnionic fluid, which by the end of gestation amounts to approximately 1 L.

The chorion forms the base for the peripherally radiating villi and serves to encapsulate the embryo and developing amnion. As the early implantation embryo develops, the embryonic tissues (the trophoblast and its mesodermal investments) continue to expand in a spherical fashion. The inner aspect of the condensation of mesoderm, which forms the inner capsular structure deep to the peripheral trophoblast, is also termed the chorion. In the region that becomes the placental disk proper, chorionic villi continue to develop beneath these structures, and the placenta proper or the chorion frondosum is defined. The region of the chorion that covers the expanded amnionic cavity forms what has been termed the chorionic laeve. This constitutes the reflected membranes and is discerned from the membranous covering of the chorionic plate.

Chorionic villi in the region of the laeve (which delimits the sac containing amnionic fluid) atrophy by pressure, although remnants of villous tissue may be found in association with this structure. In the region of the chorion frondosum, the fetal blood vessels invest the chorionic plate. Such vessels only occur in the chorion; the amnion is an avascular structure.

Amnion and Chorion

Gross Morphology

The fetal membranes have a particular and characteristic appearance in normal deliveries. The sac, when viewed from the fetal surface, is clear and often has a bluish hue, and the amnion is devoid of vasculature. Remnants of atrophied vasculature may be seen in the overlying chorion and appear as filamentous streaks. The chorionic plate also has a characteristic blue sheen and, as described previously, the distribution of chorionic vessels has a characteristic appearance. The membranes of the chorionic plate are distinguished from the laeve as described above. It is not infrequent to find a peripheral nodule on the surface of the disk membranes. This normal nodule is the remnant of the fetal yolk sac (Figure 43.21).

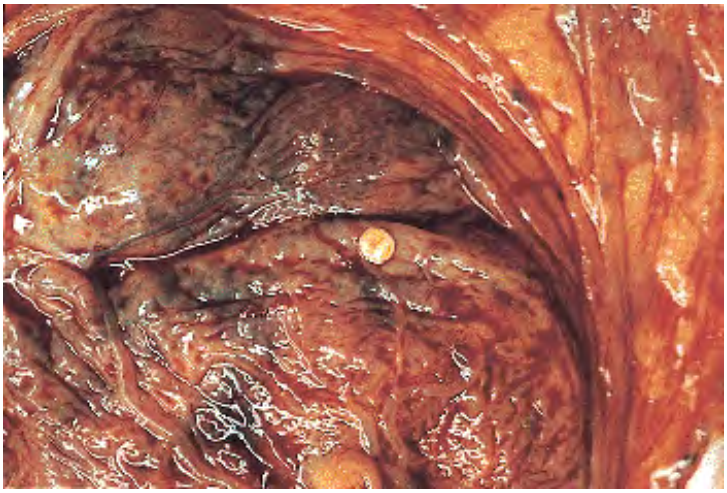

Figure 43.21 White nodule is the residua of the fetal yolk sac.

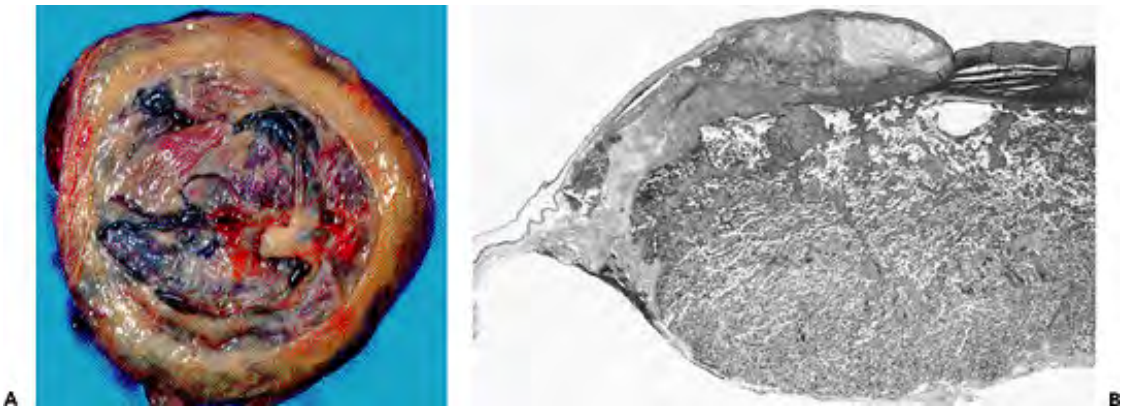

Figure 43.22 A. Circumvallate placenta. B. Note loose association of amnion peripheral to marginal subamnionic fibrin deposition. Reprinted with permission from:
Benirschke K, Kaufmann P. *Pathology of the Human Placenta.* 3rd ed. New York: Springer-Verlag; 1995.

Gross Morphologic Alterations

Although chorionic vessels are normal in the chorion of the chorionic plate overlying the disk, the persistence of functional vasculature in the chorion laeve is aberrant and equates to membranous vessels. These vessels may connect lobes of placenta or relate to the membranous insertion of the umbilical cord (velamentous insertion as described above).

On occasion, the chorionic plate may possess a ring of fibrin that forms a concentric ridge between the insertion of the cord and the margin of the placental disk. This fibrin ring, which lies deep to the amnion, is indicative of an extrachorial placentation. Such a placentation is characterized by two forms: the circumvallate placentation and the circumarginate placentation. In the former, the membranes are reflected upon themselves at the ridge of the

fibrin deposition. They then cover the remaining margin of the placental disk in a loose fashion (Figure 43.22A, B). In the circumarginate placenta, the ring of fibrin is present over the chorion, and the overlying amnion is not reflected upon itself at this fibrinous ring (Figure 43.23). The amnion thus extends to the margin of the placental disk, and its departure to form the amnionic sac occurs at this margin. It is currently felt that this fibrinous ring represents placental migration in conjunction with an enlarging uterus during the second trimester (so-called trophotropism) (1).

Figure 43.23 Circumarginate placenta. Note the close association of amnion to the disk peripheral to the fibrin ring.

The common occurrence of squamous metaplasia on the amnionic surface can be identified grossly by its characteristic appearance. It is a normal finding unless its presence is extensive. Immersion of the placental membranes in water generally defines this area by its failure to become moist as opposed to the normal surrounding amnion. Thus, these areas are more clearly defined. In pathologic conditions, metaplasia

in these regions may be pronounced, and large plaques and nodules may form (Figure 43.24). These nodules are distinguished

from the truly pathologic condition of amnion nodosum by their failure to be easily denuded from the surface of the amnion by slight mechanical pressure.

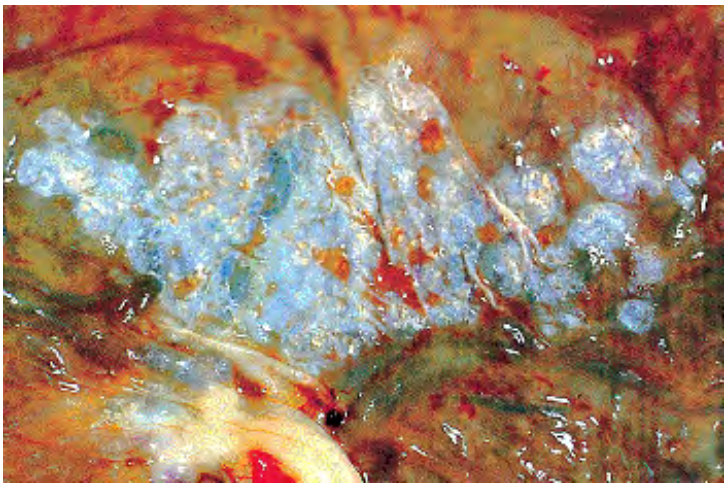

Figure 43.24 Extensive squamous metaplasia on the amnionic surface from a fetus with an encephalocele. It is believed that irritation from the encephalocele in this region produced the extensive metaplasia.

The presence of amnion nodosum is characterized in the gross sense by the presence of multiple small papules on the amnionic surface (Figure 43.25). The clinical history is suggestive, and oligohydramnios characterizes these gestations. The small papules are easily removed from the amnionic surface by excoriation, and their substances are confirmed histologically by the presence of debris and degenerated squames. The origin of these cells is fetal epidermal, and their presence on the amnionic surface is related to apposition of this membrane and fetal skin in conditions where there is diminished amnionic fluid.

Amnionic bands are rare. The condition is responsible for in utero fetal part amputation and trauma and is a phenomenon that occurs in approximately one in 10,000 births. The occurrence is important because it demonstrates potential difficulties from abnormal amnionic membrane development. The precise mechanism is not

known in most cases, but rupture of the amnion (most probably in the first trimester) allows the fetus to enter the chorionic sac. The remnants of amnion form the substance of the resulting amnionic bands. At term these placentas have highly opaque chorionic surfaces that reflect hyperplasia of this uncovered layer. The remaining amnionic epithelium is densely adherent to the umbilical cord from which it cannot be stripped. Only small amounts of amnion are present, which distinguishes this condition from artifactual disruption of the amnion from the chorionic plate during the delivery process (1 ,24 ,25). Occasionally, an abnormal â€œwebâ€• will be present at the base of the cord insertion, and this may limit normal cord movement (5) (Figure 43.26).

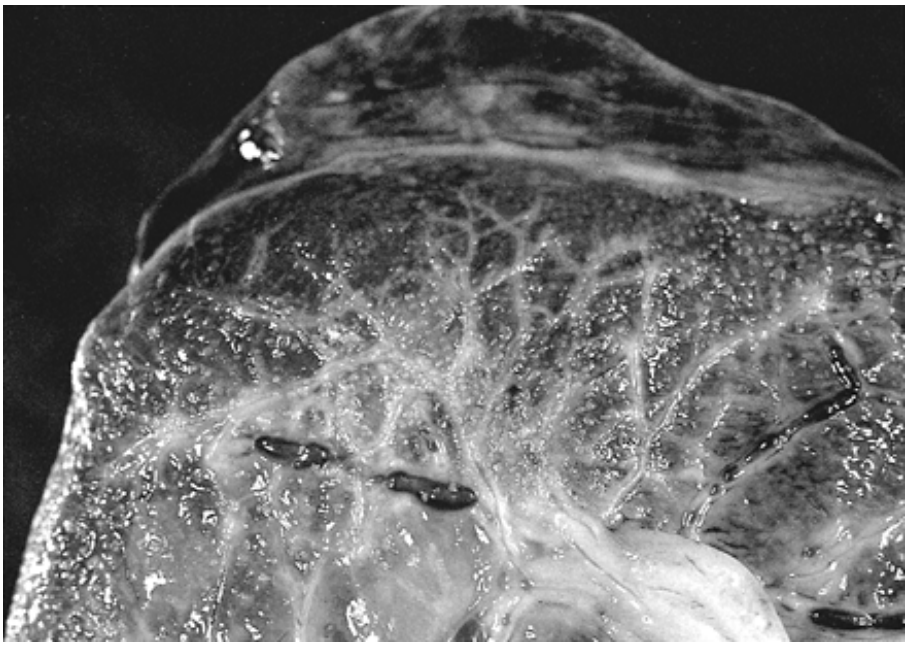

Figure 43.25 Multiple papules of amnion nodosum stipple the amnionic surface of this placenta from a gestation characterized by oligohydramnios.

Figure 43.26 Amniotic web partially immobilizes the cord by limiting its movement at the cord base.

Amnion Histology

The amnion, the innermost layer of the amnionic cavity, is lined by a single layer of epithelial cells that resides on a basement membrane. The basement membrane is attached to an underlying thin layer of connective tissue (26) (Figure 43.27). The amnion, although adjacent to the chorion, is not truly fused to it and may be separated with minimum effort. This juxtaposition of the two membranous layers occurs at 12 weeks' gestational age (27) (Figure 43.28). Before this time, as the amnion develops, it is separated from the chorion by the so-called magma reticulare, which is a viscous and thixotropic gelatinous fluid. Stellate mesenchymal cells may be found within this subtance. These cells also have epithelial characteristics and have been stained immunohistochemically and found to be cytokeratin and vimentin positive (28).

The epithelial cell layer of the amnion is composed of one distinct cytologic type (29). The epithelium is a single layer, squamoid to cuboidal, and devoid of secretory activity. Ultrastructural studies show extensive microvillous projections (30). Multiple vesicular

structures have been identified at the base of these epithelia. It has been postulated that these vesicles represent pinocytotic activity (11). This observation is important because, as stated earlier, the amnion possesses no vasculature. This also pertains to its mesenchymal component. Therefore, the cytologic components of this layer gain their nutrition from adjacent amnionic fluid, which in turn is rich in nutrients from transudation (from fetal vasculature) and fetal excretory products. In early gestation, this nutrition is derived from the magma reticulare. Channels that also have been considered responsible for fluid transmission (31) are felt to be the residua of epithelial cell loss. A postulate relating to cell loss may invoke a newly revitalized theoretical discussion (initiated by Virchow) that describes â€œapoptosisâ€• as a form of programmed cell death. Such epithelial loss or â€œcell death by suicideâ€• also has been noted in placental

components, including the wall of the yolk sac and in the endothelium of umbilical veins. Further investigation in these areas may enhance understanding of developmental biology and with refinement may be used for addressing future methodologies for the treatment of neoplasia (32 ,33).

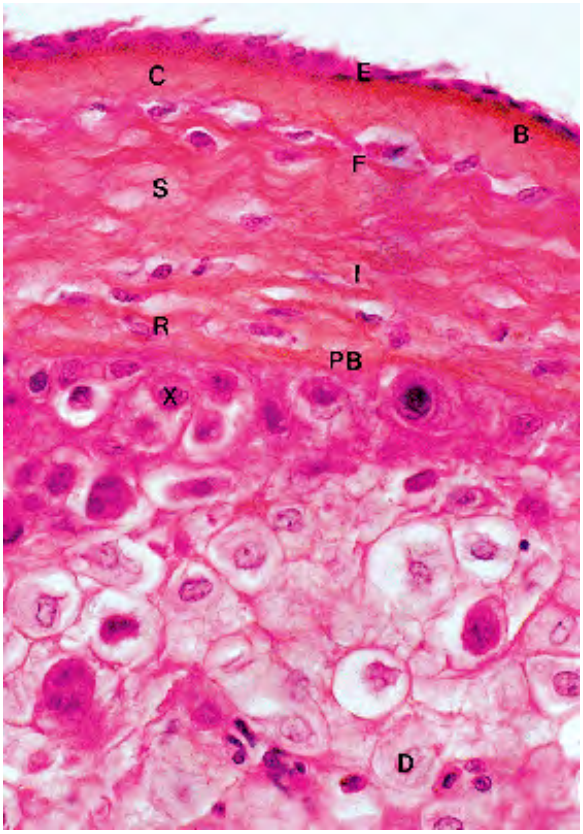

Figure 43.27 Flattened to cuboidal amnionic epithelial cells (E) adhere to their basement membrane (B). Beneath this is the compact layer of the amnion (C), which is acellular and may form a barrier to PMNs. The compact layer is rarely affected by edema and is probably the strongest amnionic layer. A fibroblastic layer (F) lies beneath the compact layer, and macrophages may be found. A spongy layer (S), relatively devoid of fibroblasts, separates the amnion from the chorion, although the two may merge imperceptibly. Often, an artifactual separation may be present near the plane of true fusion. The amnion usually measures from 0.2 to 0.5 mm in thickness (1). The most superficial layer of chorion is usually an incomplete cellular zone (I) that overlies a thick reticular layer (R). This layer is composed of fibroblasts and macrophages. Beneath the reticular layer is a pseudoâ€“basement membrane (PB) overlying trophoblastic X cells (X) and then maternal decidua (D) (HPS stain).

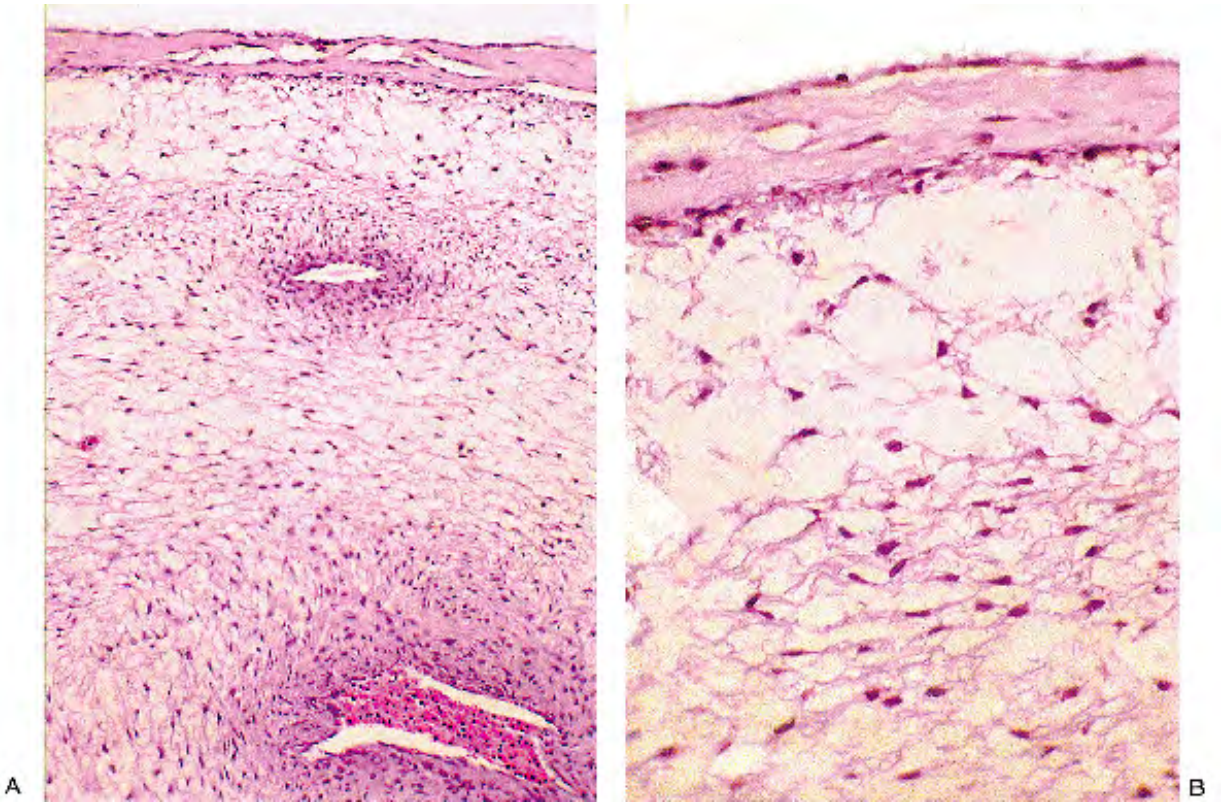

Figure 43.28 The separation between amnion and chorion is more apparent in early gestations as seen in this section from the chorionic plate of a 10- to 12-week placenta. The amnion is readily distinguished from the underlying chorion, which contains the easily identifiable chorionic vessels. Mesynchymal components are prominent (H&E stain).

Amnionic epithelial cells are attached to one another by desmosomes in freeze-fracture experiments (34). Furthermore, the amnionic epithelium attaches to the underlying basement membrane by hemidesmosomes (35).

Amnionic epithelial cells divide by mitosis (36). On occasion, multinucleated cells are identified. Morphometry studies have demonstrated that polyploid cells exist in this layer (37). Other karyotypic anomalies occur, and amniocentesis for chromosomal defects may yield false-positive results when these amnionic cells contaminate preparations (38).

Although the epithelium of the amnion does not actively secrete, lipid droplets have been noted within these cells, an observation that correlates with increasing gestational age (36 ,39 ,40). Glycogen also has been found within amnionic cells.

Squamous metaplasia is a common occurrence in the amnionic epithelium, especially near the insertion of the umbilical cord (Figure 43.29). This epithelium may become keratinized, and keratohyalin granules can be identified. Although this appears to result from irritation of the amnionic epithelial surface, these changes can be found in more than half of all term placentas (1).

Beneath the basement membrane of the amnionic epithelium, an additional component of the amnion is identified. This layer principally is divided into a compact and a fibroblastic region. The connective tissue within this region may harbor macrophages, which have been identified within the first trimester of pregnancy (41).

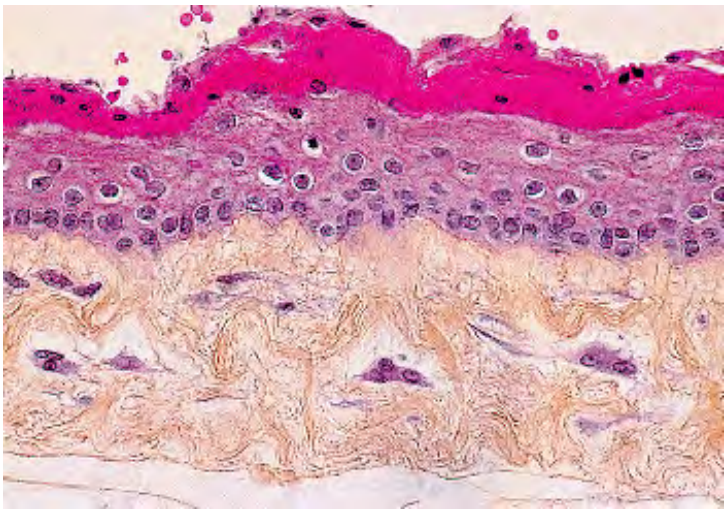

Figure 43.29 Squamous metaplasia of the amnion with hyperkeratosis (HPS stain).

Amnion Histopathology

Histologic abnormalities of the amnion are heralded by an abnormal gross appearance. For example, membranes that are stained green may reflect deposition of meconium. Amnionic membranes that are white may be indicative of polymorphonuclear leukocyte infiltration and acute chorioamnionitis (26) (Figure 43.30A, B).

Abnormalities of amnionic epithelial cells, although suggested by gross examination, can be confirmed by histologic assessment. Abnormalities that reflect degenerative changes are characterized by the presence of vacuolated cytoplasm and elongation to columnar forms. A rather rare and unusual finding associated with gastroschisis carries a pathognomonic histologic aberrancy of the amnion whereby amnionic epithelial cells contain innumerable vacuoles (1) (Figure 43.31).

Amnionic epithelial degeneration (Figure 43.32) is characteristic when meconium is present. Such findings may be confirmed when macrophages, present within the amnionic layer, contain meconium (a coarse brown pigment), which does not stain for iron (Figure 43.33). On the other hand, hemosiderin deposition may be found within the amnionic layer in macrophages, and this can be confirmed by the use of iron stains (i.e., Prussian blue).

Although there are no true tumors of the amnion, occasional cysts representing edema may be identified. Although they may be striking in their gross appearance, it must be recognized that no clinical significance can be identified. Occasional cysts of ectodermal and mesodermal tissue have been identified deep to the amnionic layer, but such findings are not considered true neoplasms. Teratomas have been described (42). These lesions probably represent degenerative acardiac twins (1), but the lack of directed differentiation from pluripotential stem cells could account for the former.

The papules of amnion nodosum are clearly pathologic and reflect, in most cases, decreased amnionic fluid. In such

instances, vernix (desquamated epithelia from the fetus) forms minute nodules on the amnionic surface in this characteristic fashion (Figure 43.34). The lesions are composed of acellular debris and remnants of cells (43). The material within these papules is PAS and alcian blue positive.

(HPS stain).

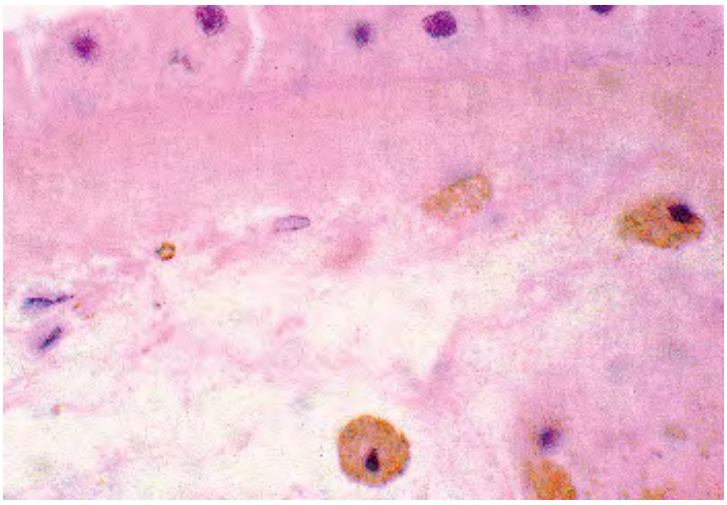

Figure 43.33 Amnionic epithelial degeneration overlies pigment-laden macrophages containing meconium (HPS stain).

Chorion Histology

The chorion is composed of a connective tissue membrane that carries the fetal vasculature. Its inner aspect is bounded by the outer layer of the amnion, and the outer aspect is directly associated with the trophoblastic villi that sprout from its surface. There are two distinct aspects of the chorion: the chorion frondosum and the chorion laeve. The chorion of the reflected membranes (chorion laeve) is composed of an inner cellular layer, a â€œreticularâ€• layer, a â€œpseudo-basement membrane,â€• and an outer trophoblastic layer (44) (Figure 43.27). The precise origin of the mesenchymal component of the chorion is not clear, but it is believed that this connective tissue is derived from the primitive streak and not the trophoblast (45 ,46) (Figure 43.28). Electron microscopy studies have shown the connective tissue cells adjacent to the amnion to be rich in endoplasmic reticulum (47 ,48). Macrophages and degenerative endothelial cells also have been

described as part of the cytologic makeup of this layer (48). Acid mucopolysaccharides are prominent within the connective tissue matrix of the chorion (49). Although present in other regions of the placenta, type VI collagen is a prominent constituent of the chorionic layer (50). The chorion frondosum is similarly constituted but contains functional chorionic vessels and is bordered deeply by functional villi.

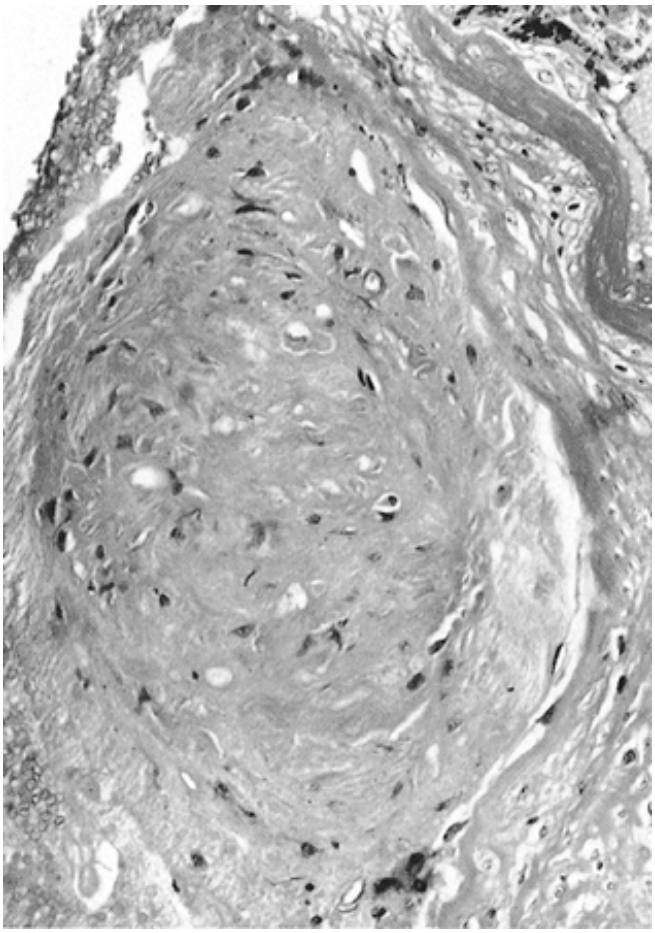

Figure 43.34 Amnion nodosum (H&E stain).

Chorion Histopathology

Pathology of the chorionic vasculature (described above in the context of its umbilical cord continuity) includes chorionitis and

thromboses. The fetal chorionic vessels allow permeation of polymorphonuclear cells (PMNs) in response to intraamnionic bacterial antigens. Maternal PMNs also may be seen in the chorion laeve. In both cases, the amnion is later affected (Figure 43.30).

Chorionic cysts, which do not truly arise from the chorion proper, are derived from trophoblastic cytologic components (X cells). Multiple cysts may be present, bulging the fetal surface of the disk. These may appear terribly abnormal but in fact carry no significance in the form of true pathology (Figure 43.35). These cysts, which are commonly found in the chorionic plate and within placental septa, are discussed further below.

Multiple Gestation

The normal relationship of the placental membranes are germane to the understanding of twin or multiple-gestation placentations. These relationships are described briefly, but for a more complete discussion of twinning and associated pathological conditions, readers are referred to an extensive and detailed review of the topic (1).

The majority of twin placentas (incidences show a dependence on geographic location and ethnic background) are dizygotic. The dizygotic twin placenta has a variety of presentations: separate placentas or fused placentas. In the latter, the intervening membrane should be studied to distinguish dichorionic from monochorionic twin placentas. The intervening membrane of about 70% of monozygotic twin placentas is devoid of a chorion, and the term â€œdiamnionicâ€“monochorionicâ€• (DiMo) is applicable (Figure 43.36). All DiMo placentas are monozygotic. In these gestations (DiMo), the shared chorion invests only the chorionic plate and is not present in the intervening membrane. In DiMo placentas, shared vascular districts between placentas are possible, and vein-to-vein and artery-to-artery anastomoses are the most common. Artery-to-vein anastomoses are relatively

infrequent and are the etiology of the twinâ€“twin transfusion syndrome (Figure 43.37Aâ€“D).

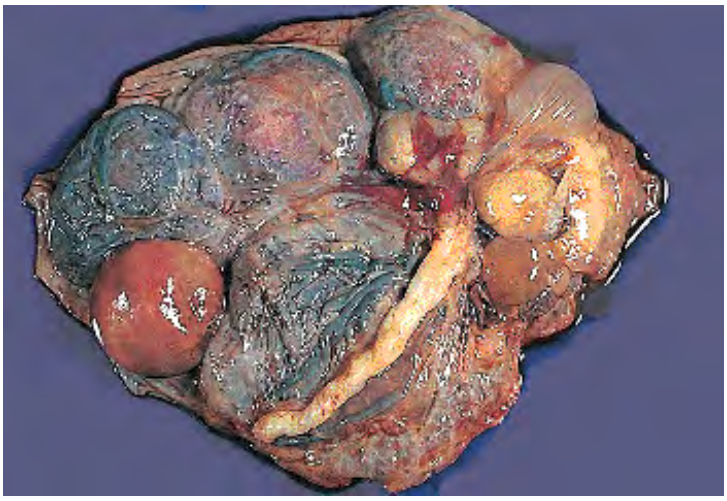

Figure 43.35 Multiple normal chorionic cysts.

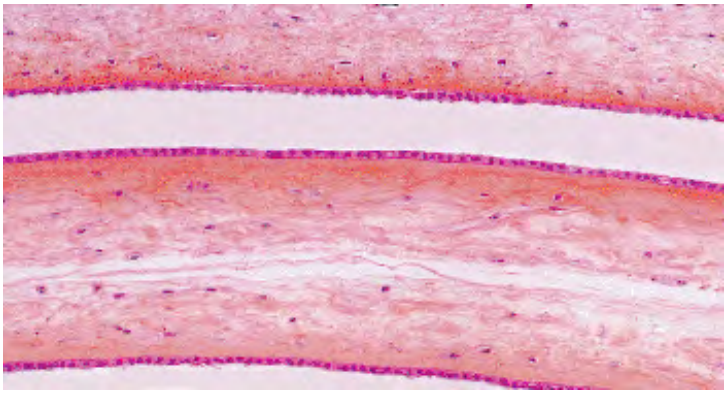

Figure 43.36 Intervening membrane from diamnionic monochorionic twin placenta. Note the absence of an intervening chorionic layer (HPS stain).

The diamnionicâ€“dichorionic (DiDi) placenta is distinguished morphologically by examining the intervening membrane and noting the presence of two fused chorions beneath the two amnionic layers (Figure 43.38A, B). Most of these placentas are dizygotic; however, approximately 30% of DiDi twin placentas result from monozygotic twin implantations and are the result of

splitting within 3 days of fertilization. Vascular anastomoses are reportable.

The complete absence of an intervening membrane (monoamnionicâ€“monochorionic) in a twin gestation is also diagnostic of monozygotic twins. There, splitting of the embryo occurs later in gestation (at approximately 7 days of age), and although twinâ€“twin transfusions can occur, these are less common than in DiMo placentations. The significant pathologic problems from these placentations result from cord entanglements, and fetal death is common. Even later separations result in fused twin fetuses (Siamese twins).

Villi

Embryology

After formation of the blastocyst, the trophectoderm gives rise to extraembryonic trophoblastic villi. The organization of the inner cell mass gives rise to the embryo proper. The trophoblastic derivatives of the early implantation embryo

are best characterized by discussing their structures and cell types. The trophoblastic villus forms the functional unit of the placenta. In the first trimester, trophoblastic villi are composed of an outer syncytiotrophoblastic layer and an inner cytotrophoblastic layer encompassing villous mesenchyme in which the fetal vasculature differentiates. Although the majority of the villus is surrounded by the characteristic two-cell layers, a polarity to the villi can be identified and their basal implantation regions are composed of additional trophoblastic constituents, which make up the trophoblastic cell columns (Figure 43.39). Cytotrophoblast gives rise to syncytiotrophoblast. The origin of X cells (which contribute to the trophoblastic cell columns and â€œpercolateâ€•

into the maternal decidua along with syncytiotrophoblast) is less clearly understood.

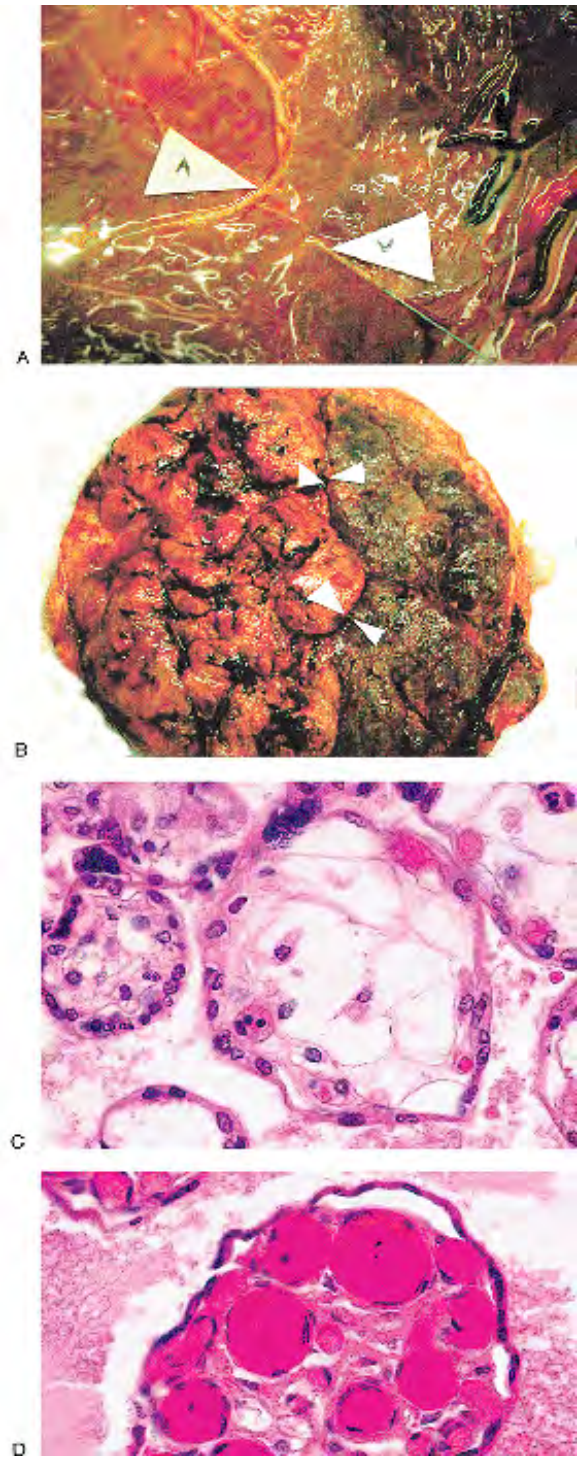

Figure 43.37 A. Twinâ€“twin anastomosis characterized by artery-to-vein transfusion. B. Note pale anemic and edematous

parenchyma of donor (*left*) and dark congested parenchyma of recipient (*right*). The *arrowheads* mark the vascular equator along the maternal surface. C. Villi from the anemic twin are edematous with abundant macrophages, and vascular spaces contain nucleated hematologic precursors denoting high-output failure and increased red cell production, respectively. D. Villi from plethoric twin are markedly congested (HPS stain). Characteristic â€œclassicâ€• twinâ€“twin transfusion outcomes may not always occur. Although one twin may be smaller, hemoglobin may be increased in a paradoxical fashion suggesting shifts in flow before analysis. Reprinted with permission from:

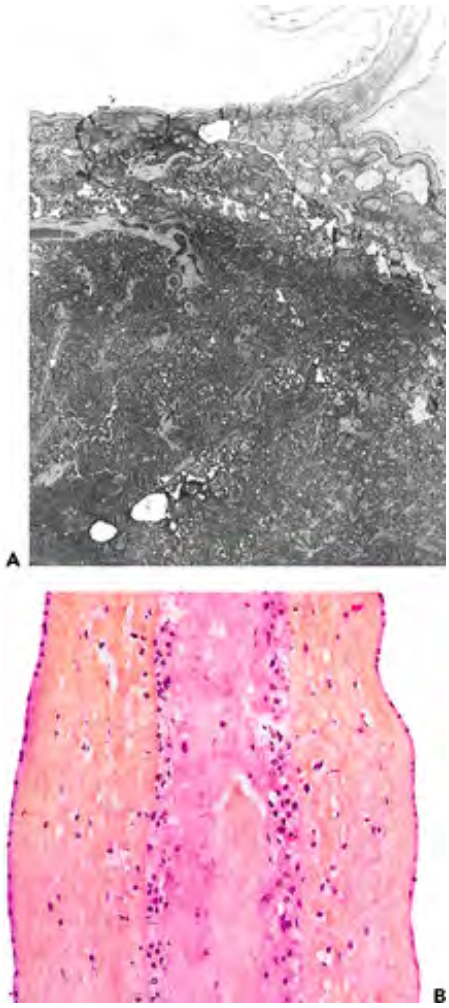

Figure 43.38 A. Diamnionicâ€“dichorionic intervening membrane, site of fusion at chorionic plate (â€œT zoneâ€•) (H&E stain). B. Note the more cellular intervening chorion separating the two layers of amnion (A) (HPS stain).

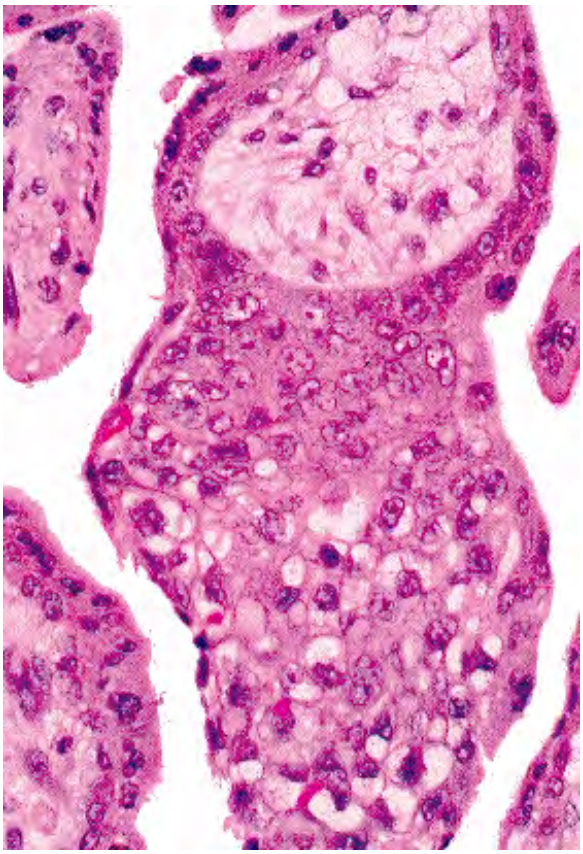

Figure 43.39 Polar trophoblastic proliferation comprising trophoblastic cell column. Many vacuolated X cells are identified (H&E stain).

As gestation progresses, the characteristic elements of the trophoblastic villus, as described from the early implantation, differentiate and develop to form a more functionally efficient unit. This occurs with gradual diminution in the size of peripheral branching villi. The tertiary villi, which stem from secondary villi, which in turn are derived from major stem villi, have a characteristic appearance (Figure 43.40A, B). The previously noted two-cell layer is less apparent, and the cytotrophoblast becomes much more difficult to identify. The overlying syncytiotrophoblast of the villus thins so that a syncytiovascular membrane forms the villous interface with the maternal intervillous blood. Deep to the trophoblast lies a basement

membrane (also present in earlier villi), which in turn surrounds the villous mesenchyme. Deep to the villous mesenchyme, fetal blood courses within capillaries lined by endothelial cells supported on a basement membrane. These are the constituents of the â€œsyncytial vascular membraneâ€• separating fetal from maternal blood across which transport of essential nutrients and waste products must occur.

The course of development also has an impact on the mesenchyme. Early in development, when villi have a pronounced double trophoblastic cell layer, the mesenchyme is prominent. The cytologic constituents of this region alter with development. Before 6 weeks from the last menstrual period, capillary lumina are not readily identified (Figure 43.41). After this point, the development of vascularization within villous tissue becomes more pronounced. The vasculature is derived from branches of the stem vessels that connect with the vasculature of the chorionic plate. By about 8 weeks' gestational age (from the last menstrual period), only nucleated hematologic precursors are evident

within these villous capillary spaces (Figure 43.42). Many of these primitive blood cell precursors have their origin within the yolk sac. As gestational age progresses, there is a decrease in the number of nucleated hematologic precursors, such that between 10 and 12 weeks' gestational age (from the last menstrual period) only approximately 10% of these blood cells are nucleated. The near absence of nucleated hematologic precursors after 12 weeks is readily apparent in histologic sections (Figure 43.43). Surrounding the early villous vasculature, the villous mesenchyme is also prominent early in gestation. The mesenchymal structural units (primitive fibroblastic cells) form about 50% of the cells in this region. The remainder of cells are composed of members of the macrophage family. These cells bear antigens that characterize them as such (CD4, LeuM3, and a variety of other macrophage markers can be identified) (51).

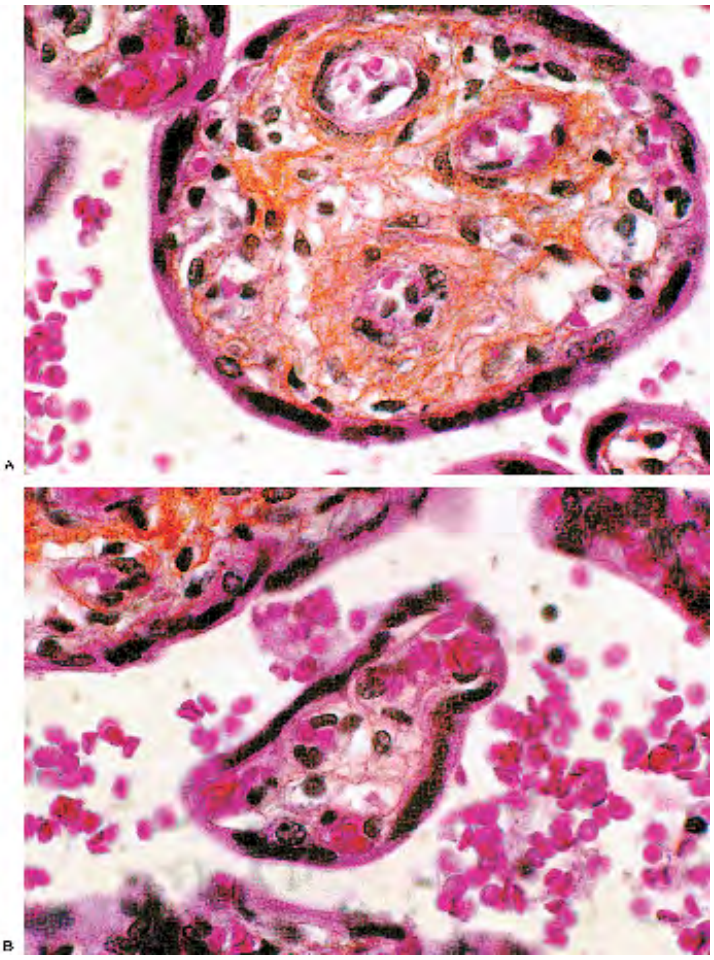

Figure 43.40 Third trimester villi. Secondary villus (A) and tertiary villus (B). Note that capillary lumina are more peripherally located in the tertiary villus. Furthermore, there is less prominent villous mesenchymal substance (HPS stain).

Figure 43.41 Villus from gestation of less than 6 weeks. No capillary lumina are present and no embryonic erythropoiesis is identified (H&E stain).

The villous macrophages or so-called Hofbauer cells lose their prominence as gestation proceeds. The maturing tertiary villus, although it possesses this cell type, has fewer of them at term. The function of Hofbauer cells, although not completely understood, is important in water regulation activities, the transport of various nutrients and waste, and villous homeostasis. This cell type also may be important to immune regulatory functions as an intermediate in the processing of infectious agents that are blood borne.

Chorionic villi may be useful in prenatal diagnosis. Karyotype analysis may be assessed at 10 to 12 weeks' gestational age through chorionic villus sampling (CVS). It should be noted that although early diagnosis is often preferable (to later amniocentesis), several concerns exist. There have been controversies regarding limb reduction abnormalities, but the vast majority of evidence does not confirm this adverse event, especially in â€œexperienced hands.â€• Of genuine concern, CVS is not useful in the diagnosis of neural tube defects (amniotic fluid for Î±-fetoprotein determination is required) and fragile X

syndrome, which also requires amniotic fluid due to alterations in methylation patterns found in trophoblast as compared with fetal squames (52).

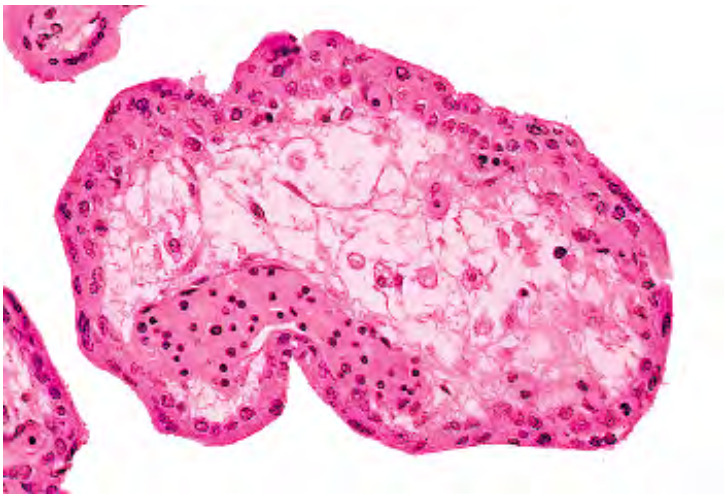

Figure 43.42 Trophoblastic villus at 8 weeks' gestation. Note only nucleated hematologic precursors present within villous capillary spaces (H&E stain).

Gross Morphology

The villous parenchyma is discoid and occupies the space beneath the chorionic plate. The substance of the parenchyma is red and â€œbeefy.â€• On sectioning, it appears homogeneous in contour and texture. Irregularities within the substance denote abnormalities within the villous parenchyma. Many abnormalities so identified are common, and in most instances, due to their frequent occurrence, they should be considered as normal varients (unless they are unduly prominent). Such entities include infarcts and perivillous fibrin deposition.

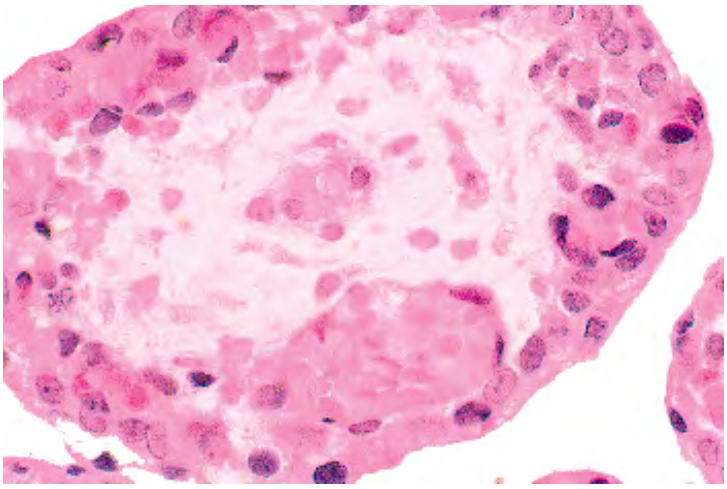

Figure 43.43 Near absence of nucleated hematologic precursors within villous capillaries after 12 weeks' gestation (H&E stain).

In addition to the perivillous fibrin deposition, other fibrinous depositions are common and are generally considered normal within the placenta. The so-called Langhans' stria, located below the chorionic plate, is probably related to alterations of materal intervillous blood flow. By virtue of its distance from the decidual vasculature, it tends to be more static.

Nitabuch's fibrin is present between the floor of the placenta and the maternal decidua. This layer was once believed to prevent allograft rejection, but now the precise nature and functional significance of this fibrin deposition are not clear.

On occasion, the placental parenchyma have spherical defects (usually 1 to 2 cm in greatest dimension), which represent so-called jet lesions. These cleared areas within the villous parenchyma represent pressure heads from maternal decidual vascular flow. It is not uncommon to histologically identify a small zone of acute infarction peripheral to these lesions.

Calcification is a common phenomenon in the mature placenta. Calcification has been used to diagnose placental maturity by ultrasonographic evaluation during pregnancy. Third-trimester

gestations have an increase in the amount of calcium present in the placenta, and when calcifications are prominent, placentas are considered grade 3. A mature placenta detected by ultrasound does not necessarily denote fetal maturity. The appearance of calcium deposition in the gross sense is that of fine, pinhead-sized deposits of yellowâ€“white, gritty material. Calcification of the placenta is a normal physiologic response to development and aging (53 ,54).

Gross Morphologic Alterations

Many placentas normally have some degree of infarction. When infarction roughly exceeds 10 to 15% of the placental surface, or when it is more central than peripheral, this should be considered pathologic. Infarcts are characterized grossly as either acute or â€œold.â€• Acute infarcts are pale, poorly demarcated regions that are slightly granular on palpation. â€œOldâ€• infarcts are white, often triangular, and they too are granular (Figure 43.44).

Infarcts evaluated grossly are distinguished from perivillous fibrin deposition. Upon palpation, infarcts are granular and firm. Perivillous fibrin, on the other hand, tends to be nodular and smooth. Further distinctions are made histologically, and these are described in detail below.

Intervillous thrombi also may be identified during the gross examination of the placenta. These triangular or diamond-shaped lesions within the placenta may consist of soft gelatinous red to white (depending on age of lesion) aggregates of collected blood. The lamellations of fibrin within this thrombotic material may be observed grossly. It is this aspect, as well as the gelatinous soft makeup of this material, that distinguishes these lesions from infarcts and perivillous fibrin deposition upon gross examination.

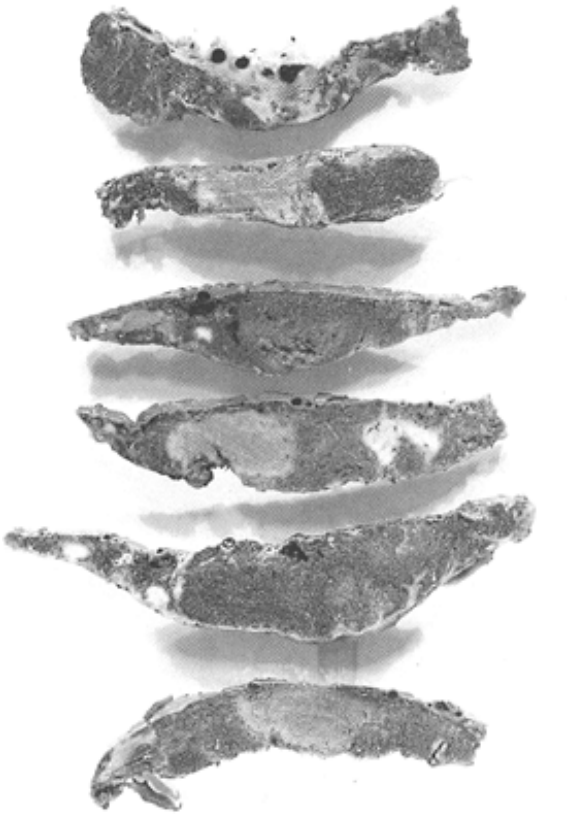

Figure 43.44 Multiple old infarcts from a hypertensive pregnancy.

Histology

The histologic variations in placental architecture are largely dependent on the developmental state at which observations are made. The histology of the individual cell types involved directly in villous implantation is now described.

X cells, also termed intermediate trophoblasts, are major constituents of the cell columns that form the deepest structural components of the implantation site. These cytologic components of trophoblastic origin are unique with respect to other trophoblastic derivatives (syncytiotrophoblasts and cytotrophoblasts). X cells are secretorily distinct and produce human placental lactogen and major basic protein, and are electron microscopically distinct insofar as they contain large

numbers of mitochondria with tubular cristae (55 ,56 ,57). Similar cell types are identified along with the chorion laeve (Figure 43.45A, B), and these cells have been characterized histologically as being eosinophilic or vacuolated; it was suggested that they represent two distinct subpopulations in this region (58). In the implantation site, these cells are morphologically distinguished from decidual elements in that their cytoplasm is generally darker and they

are occasionally multinucleated. Furthermore, these cells tend to be more vacuolated then their neighboring decidual cells. Difficulty in distinguishing these cell types has resulted in some problems with the diagnosis of intrauterine pregnancy when these are the only trophoblastic cells present in currettage specimens. In the absence of villi, most pathologists confirm their diagnosis of intrauterine pregnancy (and hence generally exclude the possibility of a tubal pregnancy) based on the presence of multinucleated trophoblastic derivatives, which are more readily distinguished from the surrounding decidua. Should difficulty arise with morphologic assessment of the true nature of the uninuclear cells in question, immunohistochemical localization of human placental lactogen within X cells is helpful (59). This cell type is of important immunologic interest because it may be responsible for the synthesis of fibronectin (1). An excess of immature intermediate trophoblasts has been associated with preeclampsia and eclampsia (60).

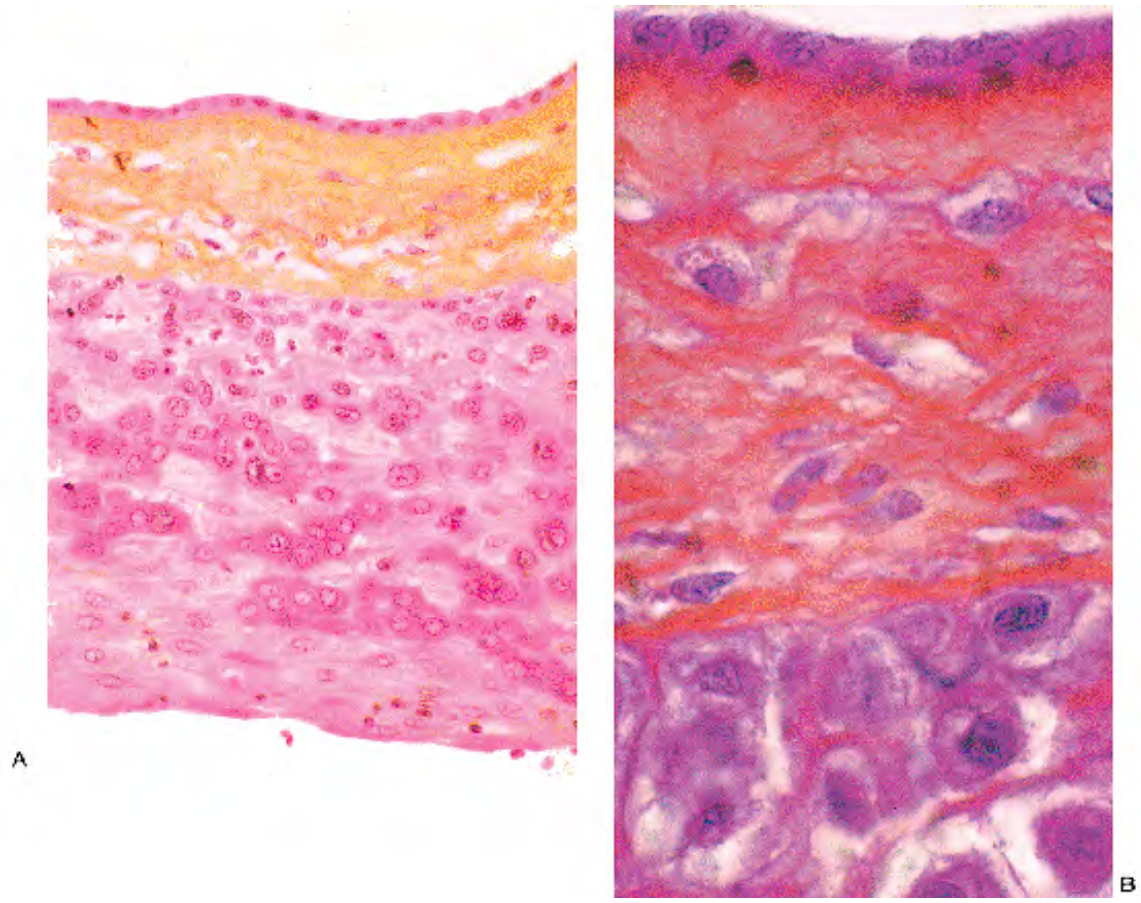

Figure 43.45 Prominent nonvacuolated X cells within the decidua of the chorionic laeve. Note their darker cytoplasm and occasional multinucleation (A) and vacuolated X cells deep in the chorion (B) (HPS stain).

An interesting normal finding within the placenta is the so-called chorionic cyst. These cysts occur in placental septae and are composed largely of decidua and X cells. The cysts are entirely lined by X cells. As noted above, such cysts also may be seen in the chorionic plate (Figure 43.35). On sectioning, gelatinous fluid may be present, and the major constituent of this fluid is one of the substances produced by X cells: major basic protein. The function of these cysts is not known. They should not be considered pathologic when present (1).

The syncytiotrophoblast, the outer cell layer, possesses a brush

border. Microvilli that constitute this border are felt to be involved in pinocytotic activity. Vacuoles within the cytoplasm of these cells are indicative of the absorptive and secretory activities of the syncytiotrophoblast. Syncytiotrophoblasts are composed of pyknotic (often multiple) nuclei that are hyperchromatic. In addition to the multiple vesicles present within this cell type, ultrastructural examinations show a cytoplasm that is rich in endoplasmic reticulum, mitochondria, lipid droplets, and Golgi bodies (61).

The cytotrophoblastic nuclei are more round and open. Tritiated thymidine incorporation experiments have shown that uptake and incorporation are confined to the cytotrophoblastic layer and not the syncytiotrophoblastic layer (62). On occasion, cytotrophoblasts may possess mitotic figures (Figure 43.46). Ultrastructurally, the cytotrophoblast has fewer organelles than does the syncytiotrophoblast. Most prominent are large mitochondria, which may be numerous.

Human placental lactogen may be localized within X cells and syncytiotrophoblasts. Human chorionic gonadotropin can be identified within syncytiotrophoblast cells, but not within cytotrophoblast cells (55 ,63).

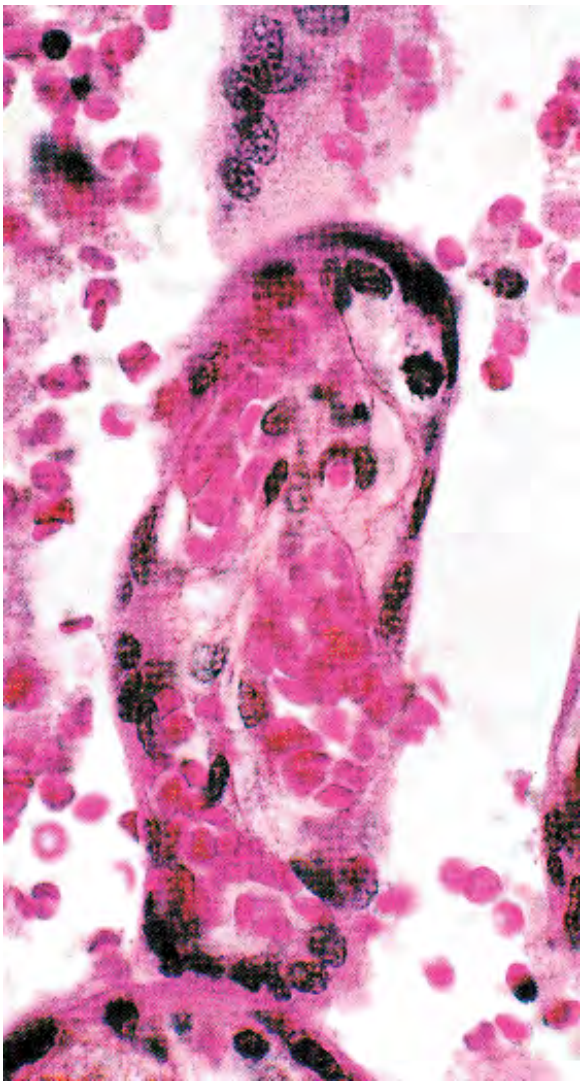

Figure 43.46 Sparse cytotrophoblast with rare mitotic figure in terminal villus from a third trimester placenta (HPS stain).

Histopathology

Various pathologic entities, which may be identified within the villous parenchyma at the histologic level, serve to better illustrate the normal histology of the placenta.

Infarcts, which are common in the placental substance, have a characteristic gross appearance. Acute infarcts are characterized

histologically by the presence of faint staining villi, which are aggregated, compressed, or agglutinated to one another and have interspersed polymorphonuclear leukocytes within the intervillous space (Figure 43.47). (As described below, it is crucial to distinguish this inflammation from that which occurs in an intravellous fashion). Earlier forms of infarction may be characterized by the presence of villous agglutination and congestion, with lysis of intervillous maternal blood (Figure 43.48). In very advanced (â€œoldâ€•) infarcts, complete absence of villous architecture is noted and a fuzzy outline of remaining villous constituents can be identified (Figure 43.49). No viable staining cells are identified, and an acute inflammatory infiltrate may persist. The placenta rarely undergoes â€œorganizationâ€• or fibrosis. When acute infarcts resolve and

become â€œold,â€• fibroblasts are generally lacking. It is for this reason that organization is not a term applied to the placenta. Classic organization as might apply to other organ systems undergoing ischemic change does not occur. The variance probably relates to the two distinct vascular supplies (maternal and fetal). Disturbance in maternal flow results in placental infarction.

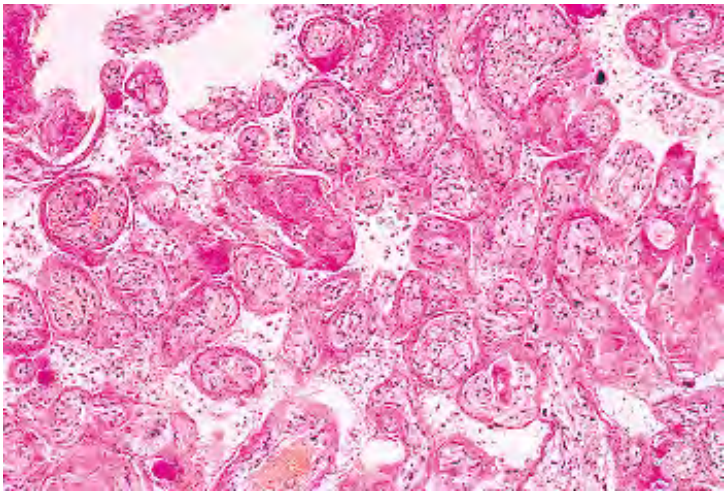

Figure 43.47 Acute infarct (HPS stain).

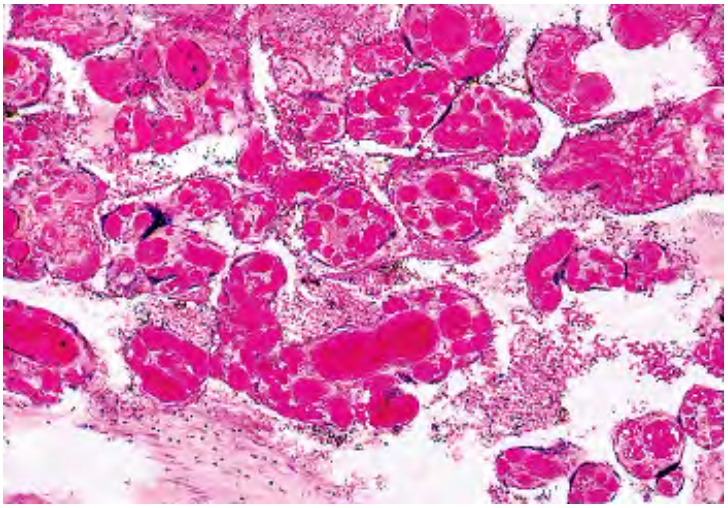

Figure 43.48 Villous vascular congestion may indicate early infarction or need to be more closely examined to exclude chorangiosis (HPS stain).

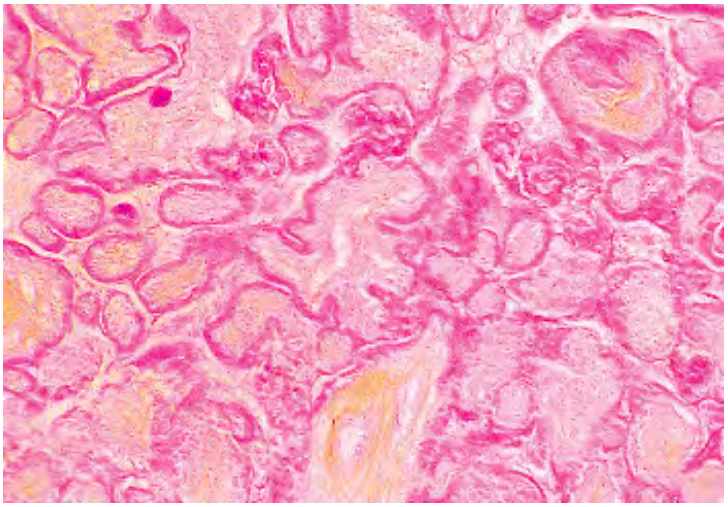

Figure 43.49 â€œOldâ€• infarct (HPS stain).

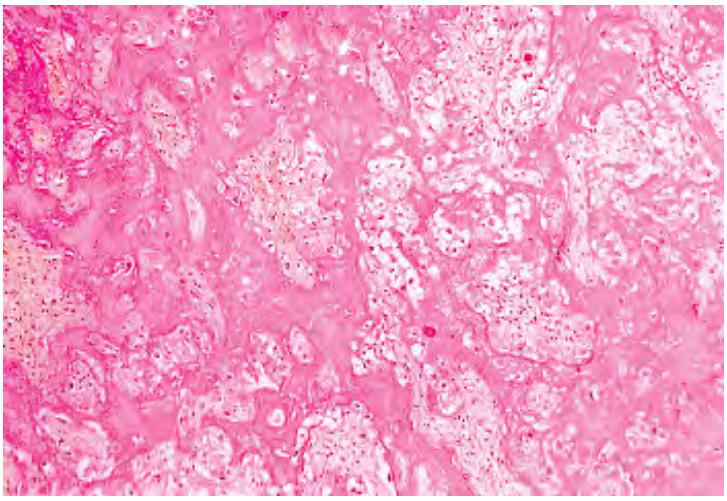

Figure 43.50 Increased perivillous fibrin. Note trophoblastic nuclear remnants encased in fibrin (HPS stain).

Infarcts are distinguished from perivillous fibrin deposition histologically in that regions of the latter contain cytotrophoblastic nuclear remnants that are often prominent (Figure 43.50). Intervillous thrombi are identified histologically by the presence of lamellated thrombotic material displacing neighboring villi (Figure 43.51).

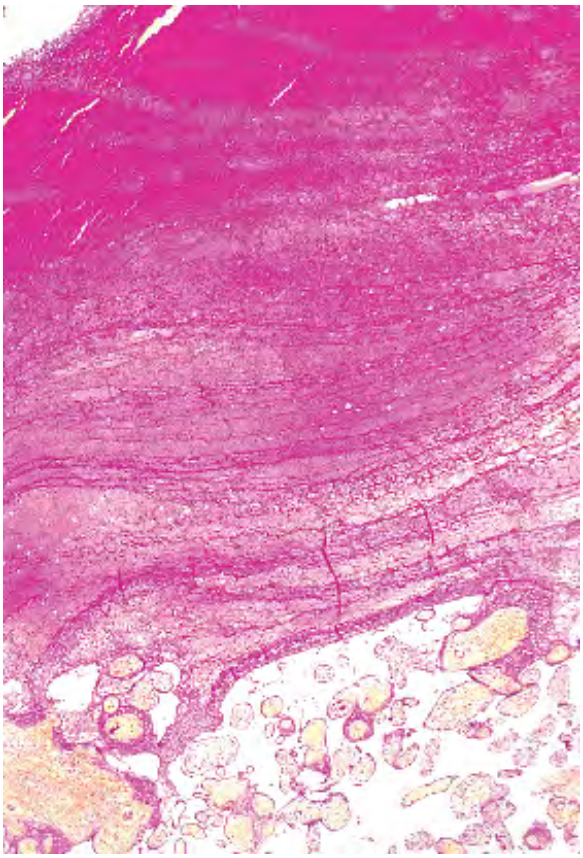

Figure 43.51 Intervillous thrombus. Note lamellated lines of Zahn (HPS stain).

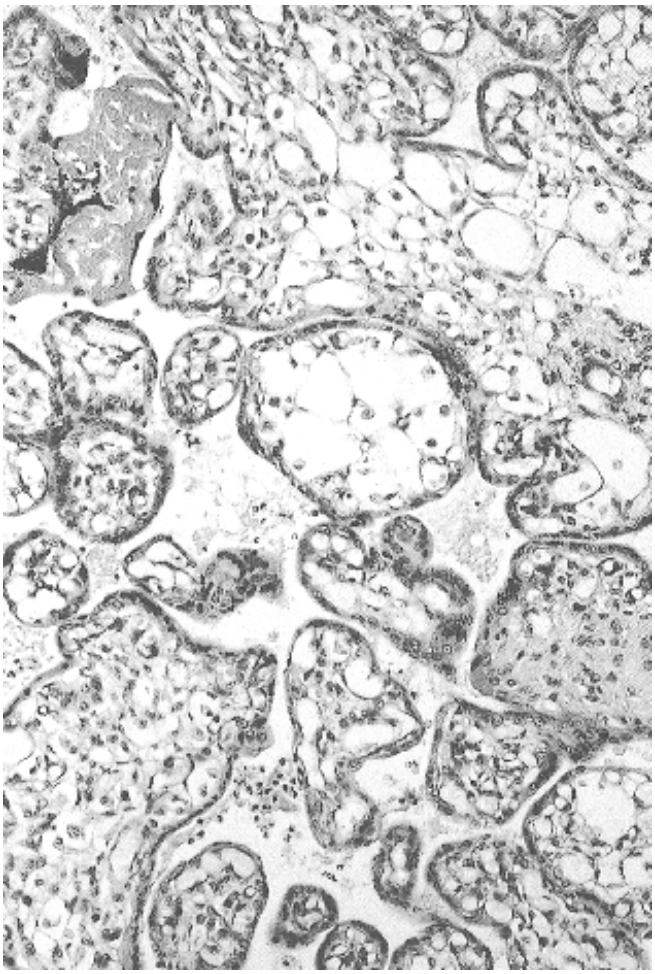

Figure 43.52 Focal edema (H&E stain).

Other abnormalities of the villous parenchyma include villous edema, where edema fluid displaces intravillous cytologic architecture; it is considered pathologic, especially in premature gestations (Figure 43.52) and has been reported as a cause of fetal ischemia. Its etiology is not clear (22). Tenney-Parker change is characteristic of placentas from preeclamptic gestations. This change is characterized by increased syncytial knotting on villi (Figure 43.53). These syncytial knots are best considered failed adaptive responses to low oxygen tension within the intervillous space. As noted above, increased intermediate trophoblasts also may be seen (60). Infarcts are not uncommon (1), and in preeclamptic/eclamptic gestations, decidual

vasculopathy is also encountered and is discussed below.

Unusual appearances of villous vasculature take three unrelated forms. First, villous vasculature may be congested (Figure 43.48), and this may have no pathologic significance or may be indicative of early infarction. Second, increased numbers of villous capillaries, so-called chorangiosis, has been considered to be indicative of chronic hypoxic changes. The definition is precise, and in histologic terms three criteria

(10 vessels/10 villi/10 fields at 10Ã—) need to be met (64). Third, abnormal proliferations of villous vessels that form histologically hemangiomatous nodules, are termed chorioangiomas when present in the placenta (Figure 43.54A, B). These lesions have pathologic significance when prominent and may result in high-output cardiac failure in the fetus or microangiopathic hemolytic phenomena.

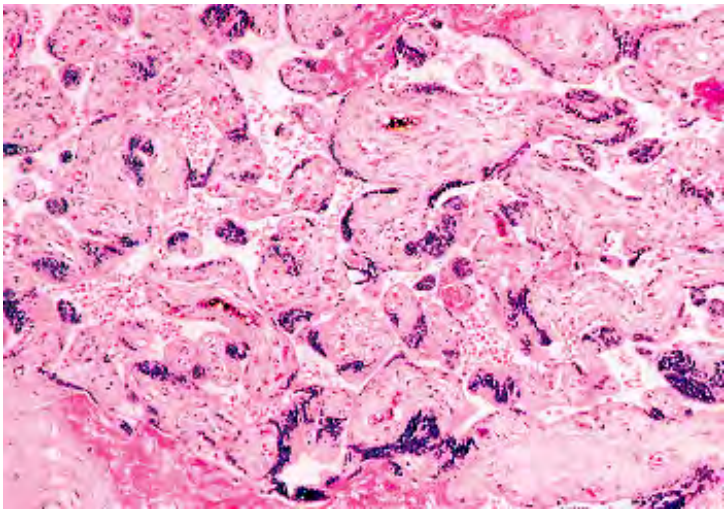

Figure 43.53 Increased syncytial knots in a hypertensive pregnancy (HPS stain).

Dysmaturity of villi is also considered pathologic. Villi that show the characteristic two-cell layer of the first-trimester implantation, when present in third-trimester placentas, are indicative of

abnormal developmental events. This change has been noted to occur in mothers who are diabetic.

Nucleated red blood cells are common in very early gestations, but as gestation proceeds, and especially in the third trimester, nucleated red blood cells should not be present. When present, fetal anemia with increased erythroid production should be suspected. Additionally, recent investigations have addressed the presence of nucleated red blood cells (in advanced-gestation placentas), correlating such findings with erythropoietin secretion by the fetus and concomitant fetal hypoxia (1) (Figure 43.55).

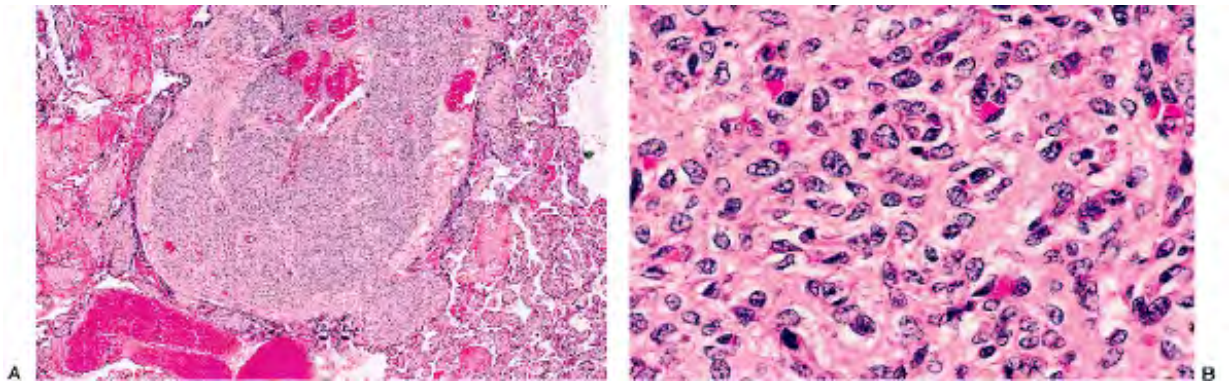

Figure 43.54 Chorioangioma (A) characterized by hemangiomatous proliferation (B) (HPS stain).

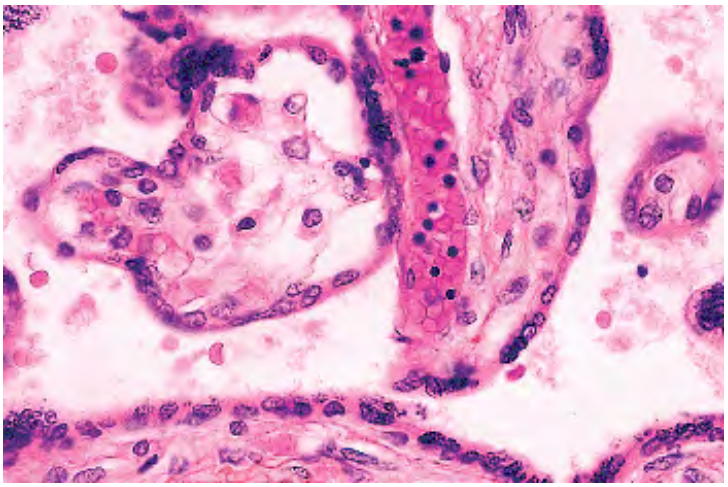

Figure 43.55 Fetal nucleated red blood cells are abnormal at

term. There is associated focal villous edema (H&E stain).

In patients with sickle cell disease, it is not unusual to find sickling of maternal erythrocytes within the intervillous spaces. This is promoted by diminished oxygen tension in the setting of abnormal maternal hemoglobin S. It is wise to correlate histopathologic findings with clinical status in that it has been reported that hypoxia during and after placental separation causes sickling (65) (Figure 43.56).

Inflammatory changes within villi are probably one of the most interesting aspects of placental pathology. These inflammatory changes herald the presence of infectious disease agents in many cases. The presence of syphilis and cytomegalovirus (CMV) should be considered when

infiltrates of lymphocytes and plasma cells are found within trophoblastic villi. Special stains may be confirmatory. It is important to distinguish this chronic inflammation from that of the acute inflammatory infiltrate (surrounding villi) associated with acute infarction. An acute inflammatory infiltrate within villi may suggest *Listeria* infection with extensive microabscess formation throughout the placenta. This often can be seen in the gross as innumerable white dots. The odor has been characterized as â€œsweetâ€• (1). In many instances, inflammatory changes within the villi are limited to an increase in the villous cellularity (increased Hofbauer cells), and no specific infectious disease agent can be identified. Increased numbers of inflammatory cells (without plasma cells) also signify chronic villitis; however, in most instances when this occurs, no infectious disease organism can be identified. These inflammatory changes within the placenta have been termed â€œvillitis of unknown etiology (VUE)â€• (64 ,66) (Figure 43.57A, B). The infiltrate has been identified as maternal in origin (67).

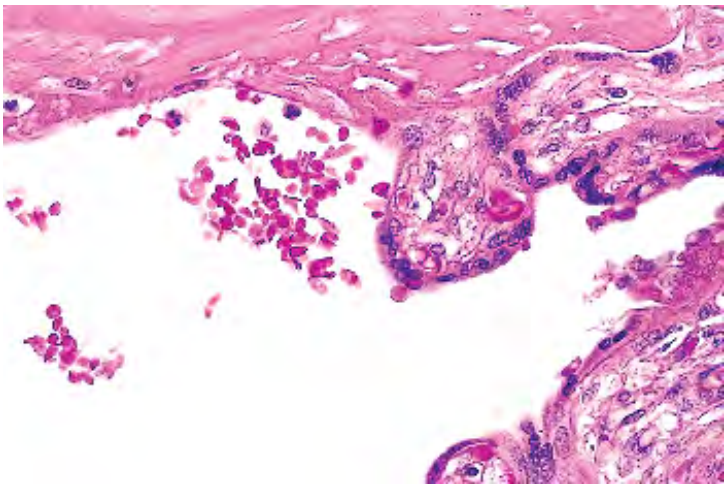

Figure 43.56 Intervillous maternal red cell sickling in patient with sickle cell disease (H&E stain).

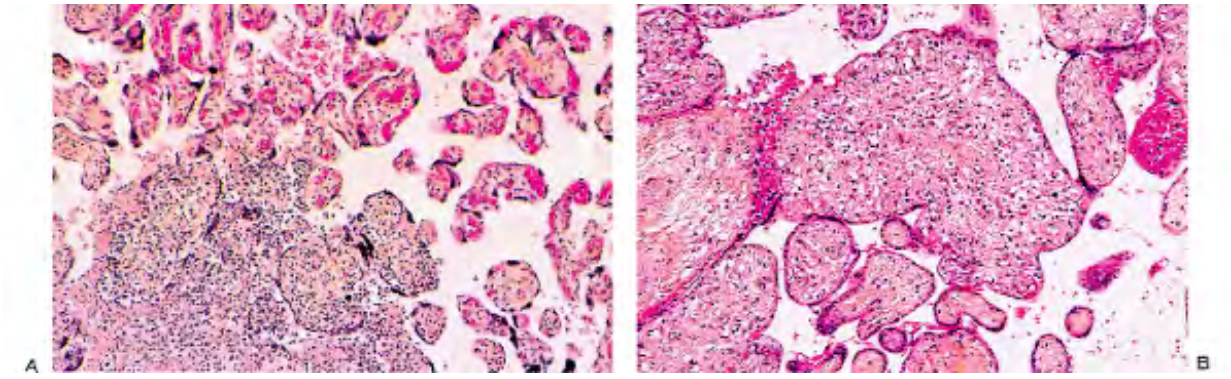

Figure 43.57 Villitis of unknown etiology (VUE) in which a chronic inflammatory infiltrate devoid of plasma cells is present (A) and chronic villitis due to known syphilis infection characterized by the presence of a mononuclear infiltrate containing plasma cells (B) (HPS stain).

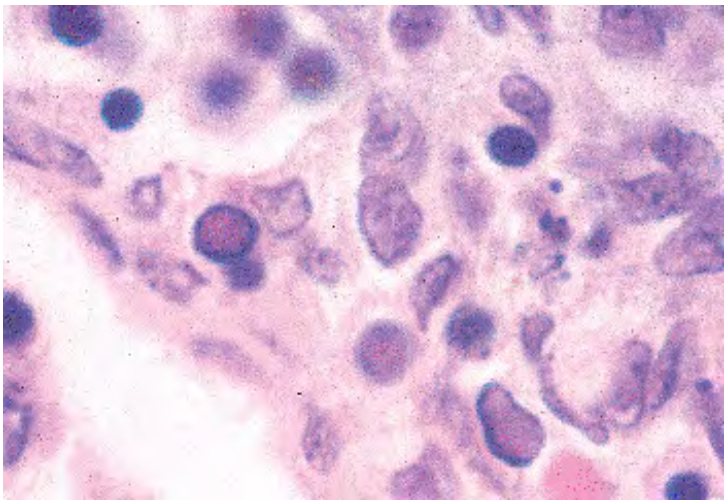

Figure 43.58 Parvovirus B19 infection associated with villous edema and nucleated fetal red cells with characteristic inclusions (H&E).

The absence of inflammation does not always coincide with the absence of infection. For example, in parvovirus B19 infection, hydropic villi and the presence of villous vascular nucleated red blood cells (occasionally with â€œsmudgedâ€• amphophilic intranuclear inclusion bodies) may herald the presence of severe congenital infection even in the setting of absence of maternal symptoms (1) (Figure 43.58).

Confounding the topic of placental and neonatal infection is the entirely normal placenta, by routine examination. Only special molecular studies will detect antigens and nucleic acids indicating the presence of infectious materials (68) (Figure 43.59A, B).

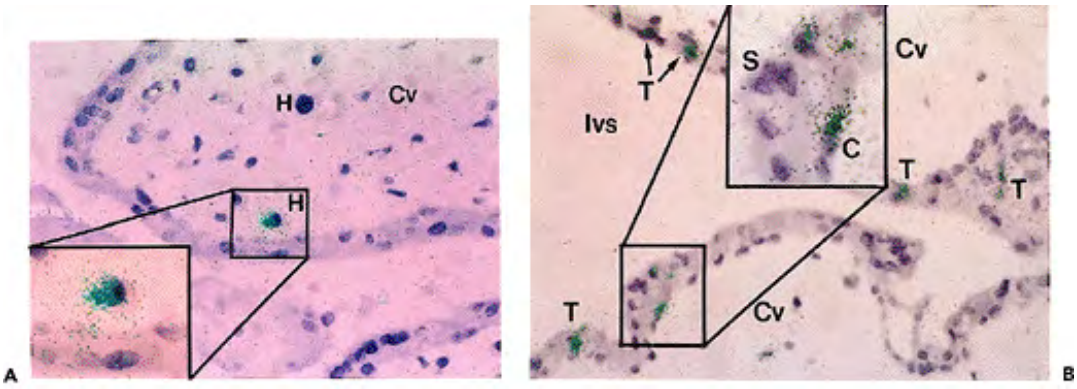

Figure 43.59 In situ hybridization with S^{35} probe detects HIV-1 nucleic acids in Hofbauer (H) cells (A) and trophoblast (C, T) of immature villi (Cv) (B). Villitis of unknown etiology is associated with major infiltration of fetal tissue by maternal inflammatory cells. *Am J Pathol* 1993;143:473â€“479.

Decidua

Histology

The hypersecretory glandular epithelium of the endometrium, which is progestationally induced, affords the proper environment for implantation. At times, these hypersecretory glands may exhibit the Arias-Stella reaction in which cytologic atypia is noted (Figure 43.60). In this condition, nuclei are often polyploid. However, nuclear cytoplasmic ratios remain low, distinguishing this normal finding from neoplasia. In this continued progestational influence, endometrial glands become secretorily exhausted. The endometrial stroma has undergone its characteristic â€œdecidualization,â€• and decidual cells of the endometrium are characterized as epithelioid and polygonal. Their small rounded nuclei are generally situated centrally in abundant pale eosinophilic, often vacuolated, cytoplasm (Figure 43.61). The

cytoplasm is rich in glycogen and glycoproteins. In regions of decidual tissue, where trophoblastic derivatives are not present, nuclear content is diploid (69). Ultrastructural examination of the decidua shows that tight junctions separate these cells (70).

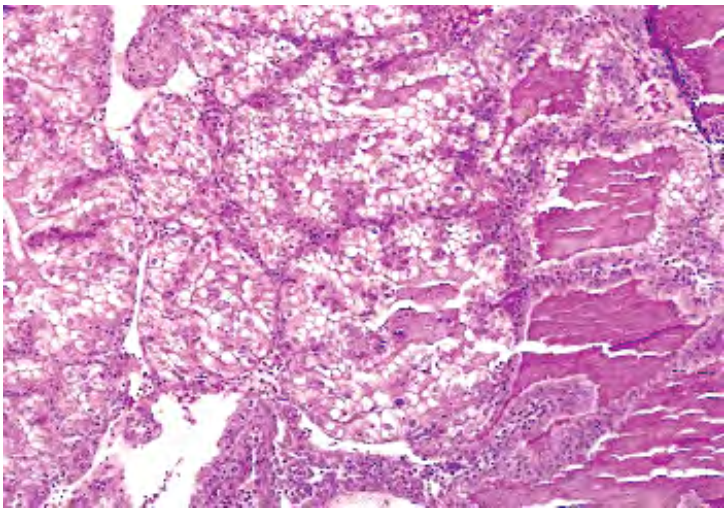

Figure 43.60 Arias-Stella reaction (H&E stain).

In addition to the decidual cells, an admixture of fibroblasts and lymphocytes is also identified. An additional cell type, the â€œgranular cell,â€• has been shown to produce relaxin (71).

The intercellular matrix contains abundant type IV collagen and laminin. Fibronectin and heparin sulfate proteins also have been identified (72). Other collagens are also present throughout the decidual matrix, and these include types I, III, and V.

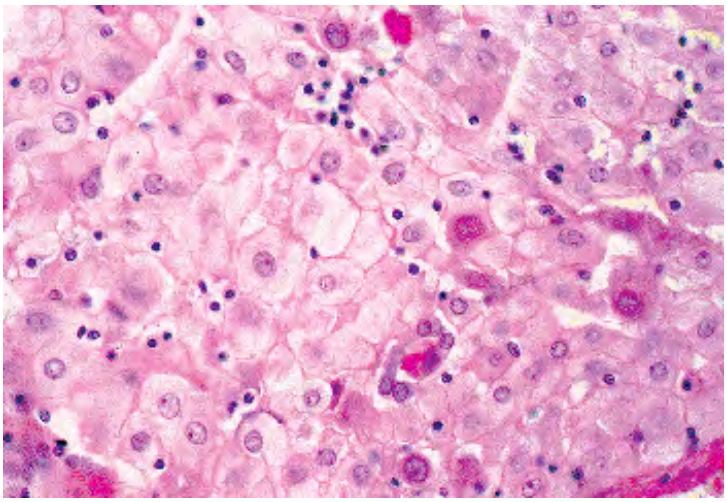

Figure 43.61 Decidua with centrally placed open nuclei and abundant pale cytoplasm with prominent cell borders. Note sparse normal lymphocytic infiltrate and occasional X cell with cytoplasm darker than decidual cytoplasm (HPS stain).

Although prior reports suggested that the secretory activity of the decidua included the production of prolactin and human placental lactogen, it is known that this hormone is produced not by decidual cells but by invading trophoblastic derivatives (principally intermediate trophoblast or X cells) (55). Much of the difficulty in studying decidual tissues and their hormonal production has resulted from the inability of many investigators to distinguish decidual components from invading trophoblastic contaminants (1).

The vascularization of the decidual component of the implantation site is critical to the developing gestation. The major branches of the uterine arteries extend deeply into the myometrial substance, resulting in arcuate arteries that then branch to form radial arteries. These become the spiral arterioles, the terminal components of the endometrial vasculature. These spiral vessels have been shown by injection studies to be responsible for the intervillous blood flow within cotyledonary units (73). The precise

number of spiral arterioles that serve to perfuse the placenta is a debated topic. Estimates range from 25 to 300 vascular openings (74 ,75).

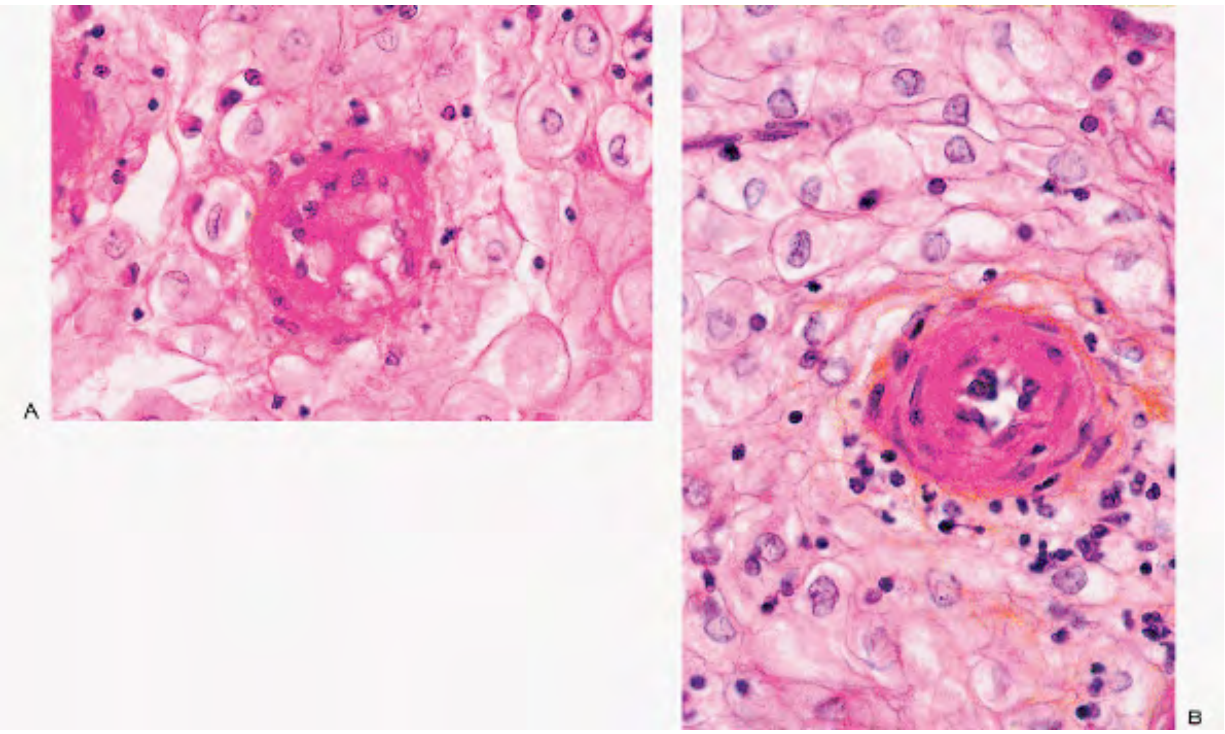

Figure 43.62 Decidual vascular atherosis (A) and concentric medial hypertrophy (B) from a hypertensive gestation (HPS stain).

That trophoblastic cells invade the underlying decidual vasculate is a well-known phenomenon. This finding has been documented within the decidual bed, as well as in systemic maternal vascular compartments, most notably the lung (76). It is important to distinguish these decidual vascular changes from those abnormalities of the decidual vasculature that indicate pathologic conditions.

Gross inspection of the decidua is generally unrevealing, and important attributes and diagnoses are identified histologically. In through-and-through sections of the placenta disk, which includes the chorionic plate and the villous parenchyma, the underlying

decidua is often denuded from the placental implantation site during the delivery process. Therefore, it is not uncommon to find sections of parenchyma devoid of decidual tissue. One region in which decidua is often prominent is on the chorion laeve. Sections of â€œmembrane rolls,â€• which include amnion and chorion, often include sections of adherent decidua, which represent fusion of the decidua capsularis and the decidua vera during development. In some patients in whom decidua abnormalities are suspect, decidual bed biopsies have been performed at the time of delivery. Such biopsies often reveal aberrant vascular relationships of the more proximal vascular tree (radial and basal arteries). The more proximal vessels are characterized by thicker vascular walls, and their arteries often have internal elastic laminae as evidenced by silver stains. The more distal arteries (the spiral arterioles) are thin walled and do not possess any internal elastic lamina.

Histopathology

Principal among decidual pathology is the so-called atherosis of the decidual vascular bed, which is known to accompany preeclampsia and hypertensive conditions of gestation (77). These lesions are characterized by fibrinoid necrosis and hyalinization of the vascular wall along with the deposition of foamy macrophages and should be readily distinguishable from normal trophoblastic vascular invasion. Another abnormality that may characterize hypertensive pregnancies is concentric arteriolar mural hypertrophy (Figure 43.62A, B).

Bleeding (retroplacental) is responsible for premature placental separation or abruptio placenta. This has been related to two maternal conditions: increased maternal blood pressure and decidual vascular necrosis (due to vasculopathies or inflammatory-bacterial decidual infections) (Figure 43.63).

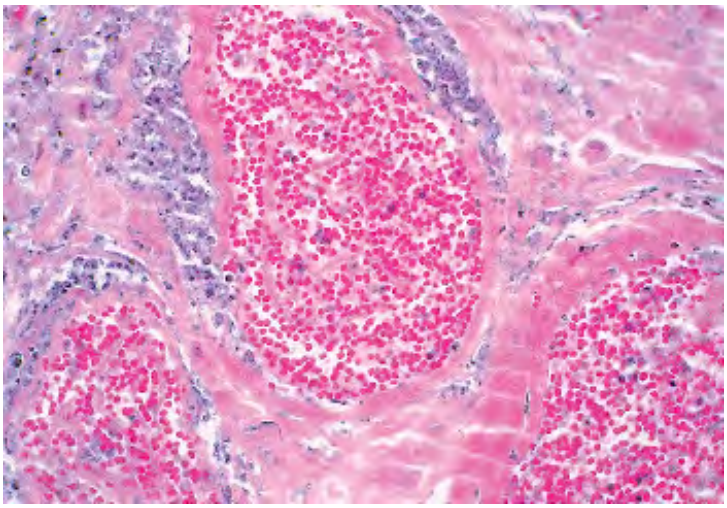

Figure 43.63 Decidual vascular necrosis, in this case due to a severe acute deciduitis. Note vascular wall hyalinization and necrosis, which resulted in adjacent abruptio (H&E stain).

When trophoblastic villi implant directly on myometrial tissue and intervening decidua is absent, the pathologic condition of placenta accreta is present (Figure 43.64). This finding is more common in low implantations of the placenta, especially when prior cesarean sections have been performed. Variations in which trophoblastic villi implanted within the myometrium (placenta increta) and when implantation results in the presence of villous tissue protruding through the uterine serosal surface (placenta percreta) are more severe forms of this condition. Generally, all placental tissue cannot be removed from the uterus at delivery and severe hemorrhage ensues. Heroic measures only rarely save the uterus and may increase morbidity due to persistant hemorrhage (and in latter stages bacterial infection) by delay of definitive therapy, which is hysterectomy. Occasionally, accreta are confirmed by studying the decidua of the chorion laeve. Failure of resolution of villi during capsular expansion may result in myometrial implantation without intervening decidua. Also occasionally, myometrium adherent to frondosum is found without intervening

decidua. In both cases the diagnosis of accreta can be made by the pathologist in the absence of the hysterectomy specimen.

Within the decidua attached to the delivered placenta rare leukocytes may be seen. If these cytological constituents are plasma cells, syphilis or CMV infection should be considered.

In the absence of pathologic alterations (placental, maternal or neonatal) these rare leukocytes within the decidua are likely physiologic or nonspecific.

More destinctive inflammatory processes involving the decidua are deciduitis and can be associated with inflammation elsewhere. Acute chorioamnionitis and acute or chronic villitis should be sought in the further examination of the placenta.

Gestational Trophoblastic Disease

Although the discussion of neoplastic trophoblastic disease is beyond the scope of this chapter, several normal or exaggerated findings of the implantation site or the placenta proper are discussed to distinguish them from more significant pathologic entities.

Degenerative changes of early trophoblastic villi are not uncommon, especially in the presence of incomplete abortus material. Trophoblastic villi from such gestations are often seen in histologic sections to be swollen (hydropic). These findings are distinguished from the gestational trophoblastic neoplasm (complete hydatidiform mole) in several aspects. Principal among these distinguishing characteristics is that no trophoblastic atypia or proliferation is present along the surface of the villi (Figure 43.65A, B). When degenerative changes have taken place and fetal components are blighted, the chorionic vasculature may be absent within the villi. However, if remnants of these vessels persist, the presence of complete hydatidiform mole is essentially not possible. The ease of identifying nucleated hematologic

precursors facilitates this observation. Furthermore, should any fetal parts be identified, this too excludes the presence of complete hydatidiform mole. On the other hand, hydropic villi in the presence of fetal parts may herald genotypically abnormal gestations. This form of

incomplete mole, which is rarely neoplastic, is characterized by scalloped trophoblastic borders and occasional trophoblastic island inclusions (representing tangential cuts of scalloped borders within the villous stroma) (Figure 43.66A, B).

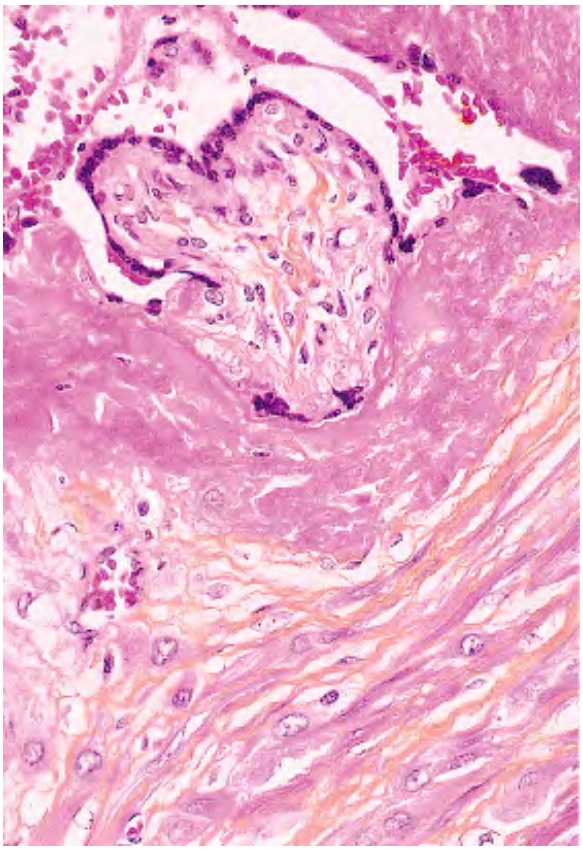

Figure 43.64 Placenta accreta. No decidua is present between the implanting trophoblastic villi and the uterine myometrium. The presence of small amounts of fibrin does not alter the diagnosis.

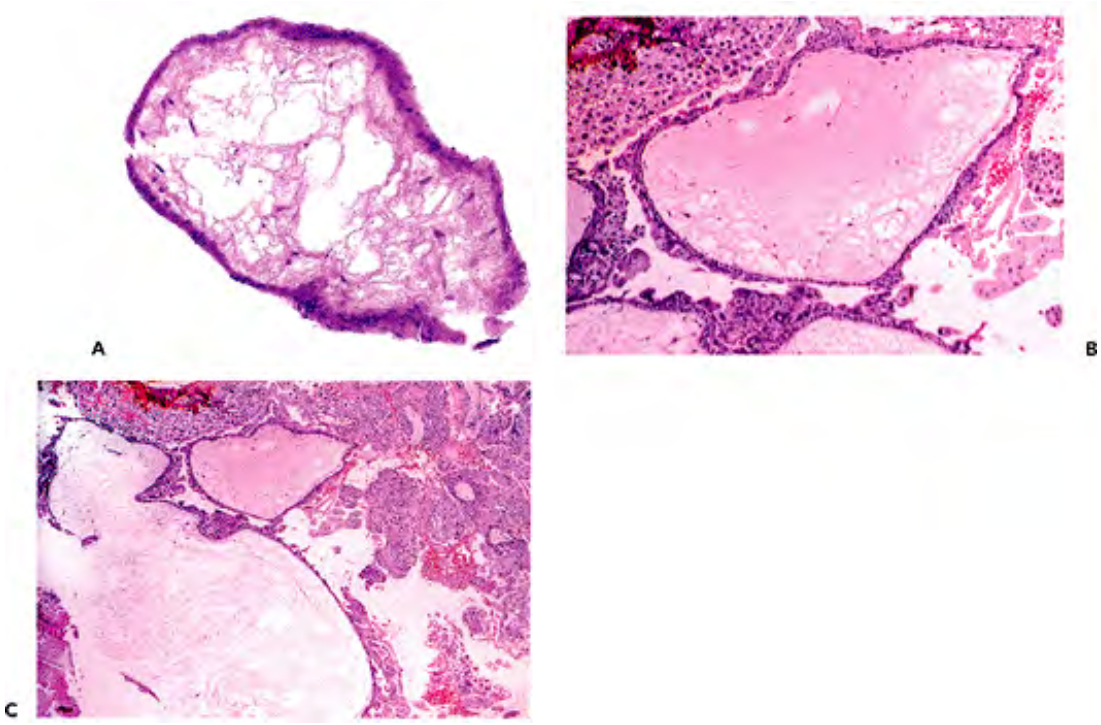

Figure 43.65 Degenerative (nonneoplastic) focal hydropic degeneration (A) and (neoplastic) complete mole (B) with trophoblastic hyperplasia and atypia (C) (H&E stain).

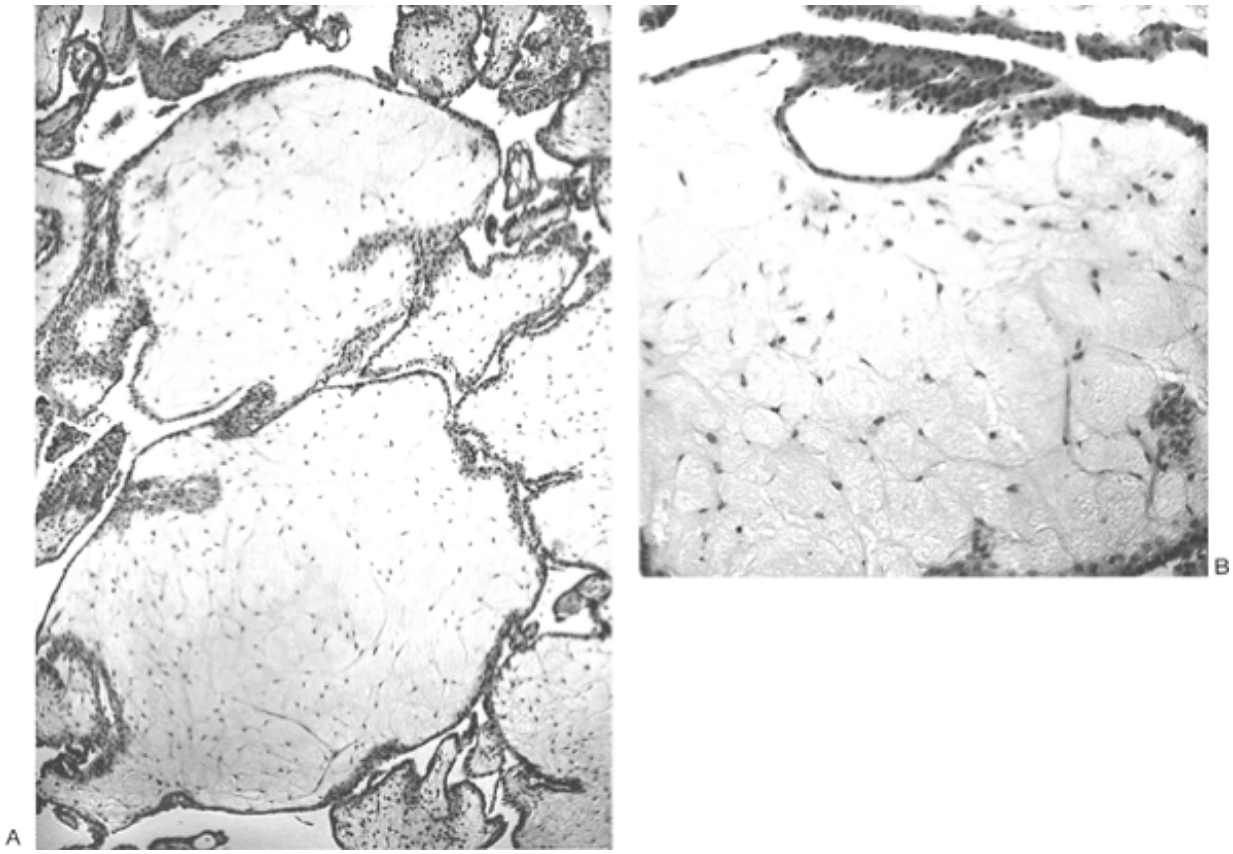

Figure 43.66 Triploid incomplete mole with scalloped trophoblastic borders (A) and trophoblastic inclusions (B), which are actually tangential cuts of scalloped borders (H&E stain).

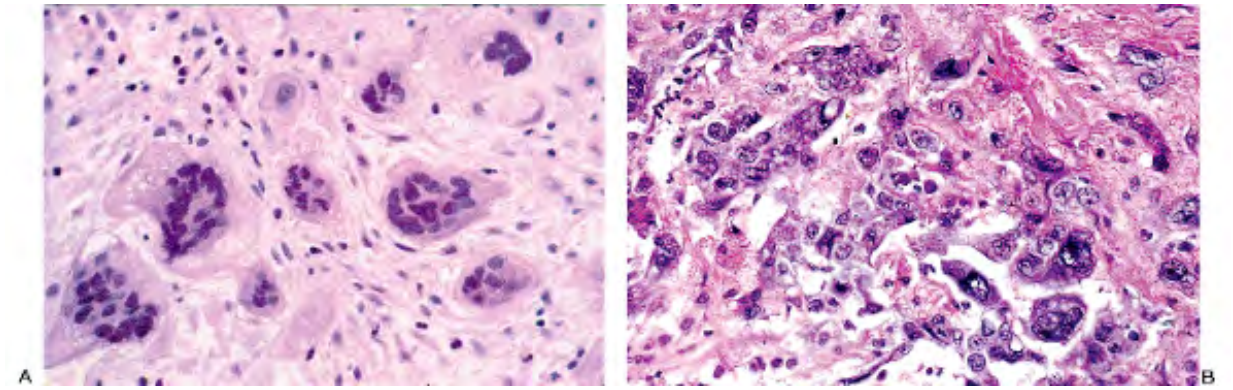

Figure 43.67 Exaggerated implantation site (A) and invading choriocarcinoma (B) (H&E stain).

Abundant trophoblastic derivates, prominent within the nidus of the implantation site, may from time to time need to be distinguished from choriocarcinoma. The so-called syncytial endometritisâ€”a poor term because it is not an inflammatory or infectious conditionâ€”refers to an exaggerated implantation site where syncytiotrophoblastic and other trophoblastic derivative counterparts are prominant (Figure 43.67A, B). In the absence of included trophoblastic villi during examination, the histologic appearance is similar to that of invading choriocarcinoma. The chief distinction is the lack of pronounced cytologic and nuclear atypia that characterizes choriocarcinoma.

Last, an unusual lesion that is neoplastic is the placental site trophoblastic tumor. This neplasm is composed solely of X cells (or, as described by Kurman et al. (55), intermediate trophoblasts) (Figure 43.68).

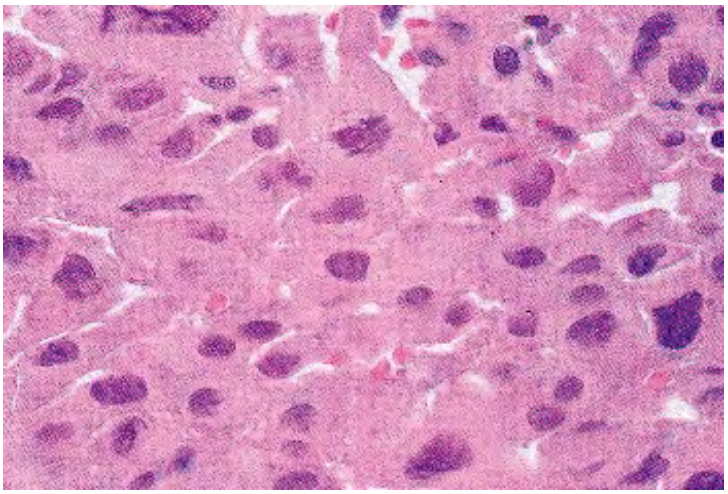

Figure 43.68 Placental site trophoblastic tumor (H&E stain).

Thyroid

Maria Luisa Carcangiu

Embryology

The human thyroid first appears as a median anlage and two lateral anlagen. The median anlage develops in the floor of the primitive pharynx at the foramen cecum (a dimplelike depression at the base of the tongue) from a median ductlike invagination that grows caudally. This formation, known as the thyroglossal duct, contains at its base the developing thyroid gland, which is at first spherical but later, when approaching its final site in front of the trachea at about 7 weeks of gestation, becomes bilobed (1). During this downward migration, the thyroglossal duct undergoes atrophy, leaving as a vestige the pyramidal lobe in about 40% of individuals. Faulty downward migration of the medial anlage or persistence of parts of the thyroglossal duct gives rise to ectopic thyroid tissue, thyroglossal duct cysts, and cervical fistulae.

The initially solid thyroid anlage begins to form cords and plates of follicular cells during the 9th week of gestation. Small follicles appear by the 10th week. Inside these primitive follicles, a finely granular material begins to collect, which by the 20th week acquires the morphologic features of colloid. By week 14 there are well-developed follicles with a central lumen containing colloid. Both the cytoplasm of the follicular cells and the intralumional

colloid are thyroglobulin (TGB)-positive (Figure 44.1A, B). Labeled amino acid studies have shown that TGB synthesis actually begins at a much earlier stage, when the thyroid is still a solid mass at the base of the tongue and long before follicle formation and colloid secretion can be identified morphologically (2,3).

PAX8, a transcription factor expressed in the adult mouse thyroid where it is involved in the maintenance of functional differentiation in follicular cells, has been demonstrated in the human median thyroid anlage, in the tyroglossal duct, and in the ultimobranchial bodies.

Thyroid transcription factor-1 (TTF1), also is expressed in the median thyroid anlage (4,5).

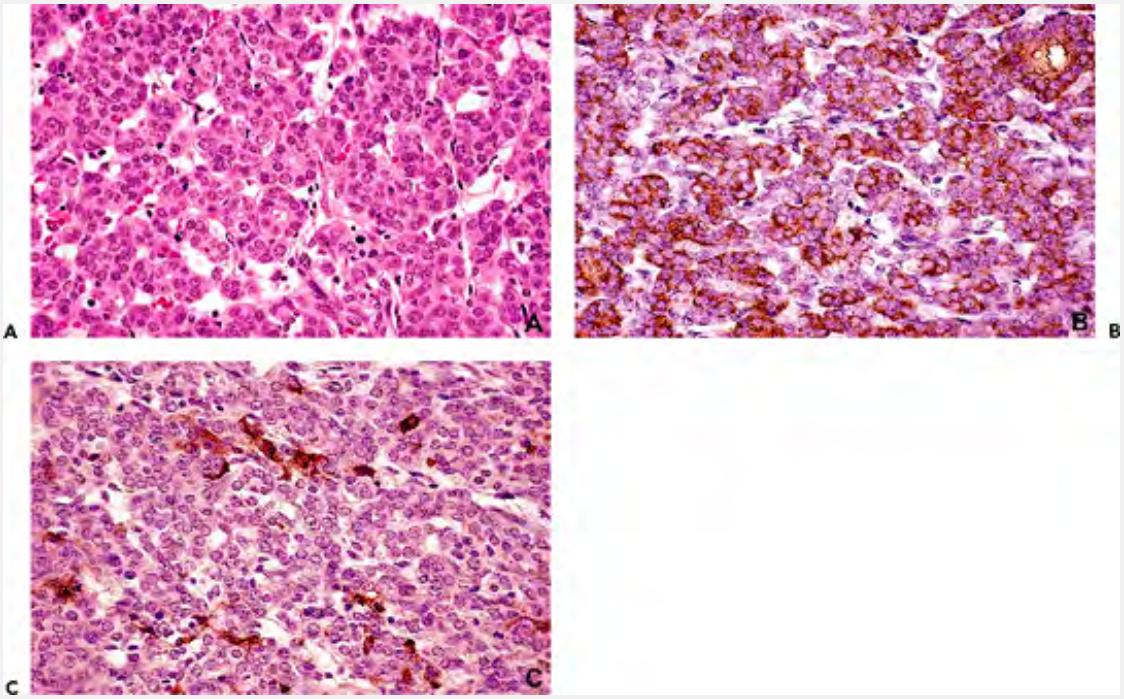

Figure 44.1 Developing thyroid gland in a 14-week fetus. A. Rare primitive follicles are seen within a mostly solid proliferation. B. The cytoplasm of the follicular cells and the

material contained in the lumen of the primitive follicles are immunoreactive for TGB. C. C cells, as seen in a CT immunostain preparation, are scattered within follicles.

Immunohistochemically, ghrelin, a growth hormoneâ€“releasing hormone, has been shown in the follicular cells of fetal thyroid (from 8 to 38 weeks of gestational age) (6). Fetal thyroid stromal tissue is immunoreactive for galectin 1 but not for galectin 3 (7).

The two lateral anlagen of the thyroid derive from the ultimobranchial bodies (UBBs), which in turn originate from the IVthâ€“Vth branchial pouch complex. UBBs, while still connected to the pharynx, start their migration downward on each side of the neck together with the parathyroid IV anlage. At 7 to 8 weeks they separate from the pharynx and the parathyroid. Their lumens become obliterated by proliferating cells, so that at 8 to 9 weeks they appear as solid masses that fuse with the dorsolateral aspects of the median thyroid anlage and become incorporated into the developing lateral lobes (8).

After its fusion with the medial thyroid (at 9 weeks to term) the UBB enters in the dissolution phase and divides into a central thick-walled stratified epithelial cyst and a peripheral component composed of cell groups dispersed among the follicles: the C cells (9,10) (Figure 44.1C). In postnatal life, the central epithelial cyst largely disappears, its occasional remnants corresponding to the so-called solid cell nests (SCNs).

C cells are thought to derive from the neural crest and to migrate to the UBBs before the incorporation of the latter in the thyroid (11,12,13,14). Evidence for a relationship between UBBs and C cells comes from several sources:

- Patients with Di George syndrome, characterized by complete or partial absence of derivatives of the IIIrd and IVthâ€“Vth

pouch complexes, have C cells in their thyroid in only 25% of cases (15,16).

- C cells are completely absent in thyroglossal duct remnants and cysts, as well as in lingual thyroid (17).
- In the adult thyroid gland, C cells and follicles carrying such cells in their walls are especially numerous in the vicinity of the UBB remnants (17).

There is some controversy as to whether the role of UBBs in thyroid development is limited to the production of C cells as described above or whether they also contribute to the follicular cell population. Williams et al. (18) described five cases of maldescent of the medial thyroid anlage in which cystic structures were present in the lateral neck in the region of the upper parathyroids. Four of these cystic structures contained intercystic glandular nodules composed of solid areas of irregularly distributed cells that stained positively for calcitonin (CT) and CT geneâ€“related peptide; these cells were intermixed with follicular structures that were immunoreactive for thyroglobin. On the basis of these observations, the investigators concluded that the UBB contributes both C cells and follicular cells to the

thyroid gland, and they speculated on the possible role of UBB-derived cells in the genesis of so-called intermediate or mixed medullary and follicular carcinomas. This hypothesis, which was independently postulated by Ljungberg (17), is however contradicted by the observation that in humans with thyroid nondescent (or unilateral aplasia) there are no recognizable thyroid follicles in the usual locations (19).

The fetal thyroid gland develops rapidly until the 4th month of intrauterine growth (crownâ€“rump length 18 mm). After birth the thyroid growth rate parallels that of the body, reaching the normal adult weight at around 15 years of age.

Gross Anatomy

The normal adult thyroid has a shape reminiscent of a butterfly, with two bulky lateral lobes connected by a thin isthmus. Each lateral lobe is 2 to 2.5 cm wide, 5 to 6 cm long, and 2 cm deep. Their upper and lower extremities (one having a pointed shape and the other featuring blunt contours) are referred to as upper and lower thyroid poles, respectively. One lobe may be larger than the other, and the isthmus may be exceptionally wide. The pyramidal lobe, a vestige of the thyroglossal duct, is found in about 40% of thyroids; it appears as a narrow projection of thyroid tissue that extends upward from the isthmus to lie on the surface of the thyroid cartilage.

The thyroid gland is located in the midportion of the neck, where it is attached to the anterior trachea by loose connective tissue. The two lateral lobes surround the ventral and lateral aspects of the larynx and trachea, reaching the lower halves of the thyroid cartilage and covering the second, third, and fourth tracheal rings.

The normal weight of the adult thyroid is 15 to 25 g in nongoitrous areas. However, there are significant individual variations, most of them related to gender, age, corporal weight, hormonal status, functional status of the gland, and iodine intake (20). In women, the thyroid volume is known to increase during the secretory phase of the menstrual cycle (21).

A thin fibrous capsule invests the thyroid. Connected to this capsule are numerous fibrous septa that penetrate the thyroid parenchyma and divide it into lobules (so-called thyromeres). The microscopic integrity of the capsule was assessed in a study on 138 thyroid glands from autopsies of adults (age 20â€“40 years) by Komorowski and Hanson (22). Although grossly all of these capsules seemed complete, microscopically they were focally incomplete in 62% of the cases. Furthermore, thyroid follicles were found within the thyroid capsule in 14% of cases and in the

pericapsular connective tissue in 88%. In the latter location, they were mostly seen as nodular aggregates.

The color of the normal thyroid is redâ€“brown. A phenomenon exceptionally seen in normal thyroid glands of elderly individuals is the accumulation in the follicular cells of a melanin-like pigment that imparts to the gland a characteristic coal black stain, easily apparent on gross examination. The terms *melanosis thyroid* and *black thyroid* are used to refer to this phenomenon. These changes are qualitatively identical to those seen in more florid form in thyroids of patients on chronic minocycline therapy (23,24).

Nodularity of thyroid parenchyma is identified grossly in about 10% of the glands of endocrinologically normal individuals (25).

The blood supply of the thyroid gland derives primarily from the inferior thyroid artery (which originates from the thyrocervical trunk of the subclavian artery) and the superior thyroid artery (which arises from the external carotid). A thyroidea ima artery also may be present, which varies widely in size from a small vessel to one the size of the inferior thyroid artery. The superior and medial thyroid veins and the inferior vein drain (via a venous plexus in the thyroid capsule) into the internal jugular and the brachiocephalic vein, respectively (26,27).

An intricate lymphatic network permeates the thyroid gland, encircling the follicles and connecting the two lateral lobes through the isthmus. It empties into subcapsular channels, which in turn give rise to collecting trunks within the thyroid capsule in close proximity to the veins. The lymph vessels draining the superior portion of the thyroid lobes and isthmus collect into the internal jugular lymph nodes, whereas those draining the inferior portion of the gland collect into the pre- and paratracheal and prelaryngeal lymph nodes. The pretracheal lymph node situated close to the isthmus is also known as the *Delphian node* (28). Other lymph node stations are the recurrent laryngeal nerve chain and the

retropharyngeal and retroesophageal groups. The anterosuperior mediastinal nodes are secondary to the recurrent laryngeal nerve chain and pretracheal groups; however, injection studies have shown that dye injected into the thyroid isthmus can drain directly into the mediastinal nodes (29).

Some correlations exist between the site of a thyroid tumor within a given lobe and the location of the initial lymph node metastasis. However, the degree of anastomosing between these various nodal groups is such that any of them can be found to be the site of disease regardless of the precise location of the primary tumor.

Vasomotor nonmedullated postganglionic neural fibers originating from the superior and midline cervical sympathetic ganglia influence indirectly the secretory activity of the thyroid gland through their action on the blood vessels. In addition, adrenergic receptors in follicular cells and a network of adrenergic fibers ending near the follicular basement membrane have been demonstrated (30). It has been hypothesized, therefore, that thyroid secretion is regulated

both by direct neural signals and by indirect vascular nerve signals (31,32,33). A role for direct neural influences in the secretion of calcitonin (CT) and other C cellâ€“derived hormones is supported by the demonstration in chickens of a rich cholinergic network encircling the C cells (34).

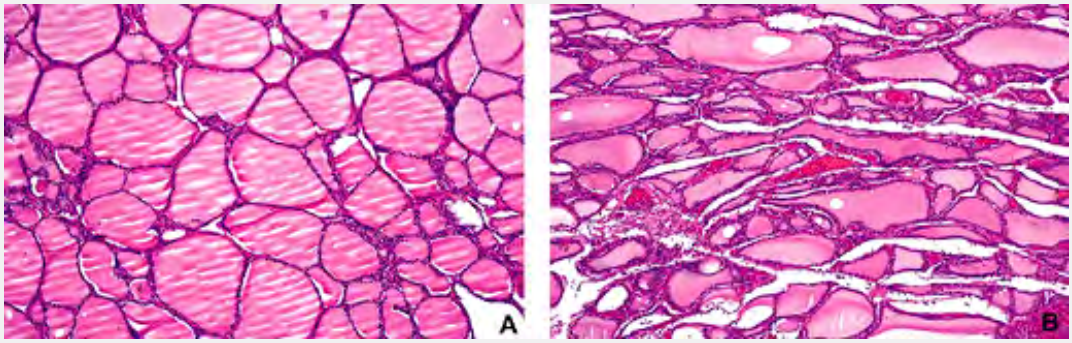

Figure 44.2 A. Low-power view of normal adult thyroid gland. The follicles have a round-to-oval shape. B. Elongated follicles as a result of compression are seen in the vicinity of an adenoma (not shown in this picture).

Small paraganglia are normally present close to the thyroid and are occasionally found beneath the thyroid capsule; their presence explains the rare occurrence of peri- and intrathyroidal paragangliomas.

Microscopic Anatomy

The fundamental unit of the thyroid is the follicle, a round to slightly oval structure lined by a single layer of epithelial cells resting on a basement membrane (Figure 44.2A). The lumen of the follicle contains colloid, a viscous material that is mostly composed by proteins secreted by the follicular cells, including TGB. The follicles, which are separated from each other by a loose fibroconnective tissue, have an average diameter of 200 Âµm. Their size may vary even within the same gland depending on the functional status of the thyroid and the age of the individual. Variations in the shape of follicles exist, but elongated follicles are

a feature of hyperplastic or neoplastic conditions or are the result of compression adjacent to an expansile mass (Figure 44.2B). A characteristic structure present in the normal thyroid but more often seen in hyperplastic conditions, is the Sanderson's polster. (See page 1136.)

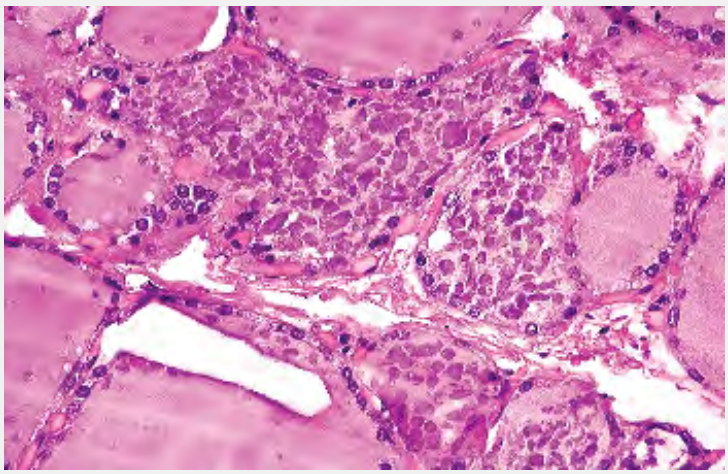

Figure 44.3 Clumps of condensed colloid within follicular lumina.

The colloid, which is pale eosinophilic in the actively secreting gland, acquires a deeply eosinophilic staining quality in resting follicles. Often, numerous clumps with various shapes appear within the colloid of resting follicles, suggesting an artifactual coagulation-type phenomenon (Figure 44.3). In some follicles the colloid may have an amphophilic or basophilic staining quality, probably the result of an increase in the amount of acidic groups in the TGB molecule (Figure 44.4). In the most advanced expression

of this phenomenon, the intraluminal material acquires a distinct mucinlike appearance (Figure. 44.5).

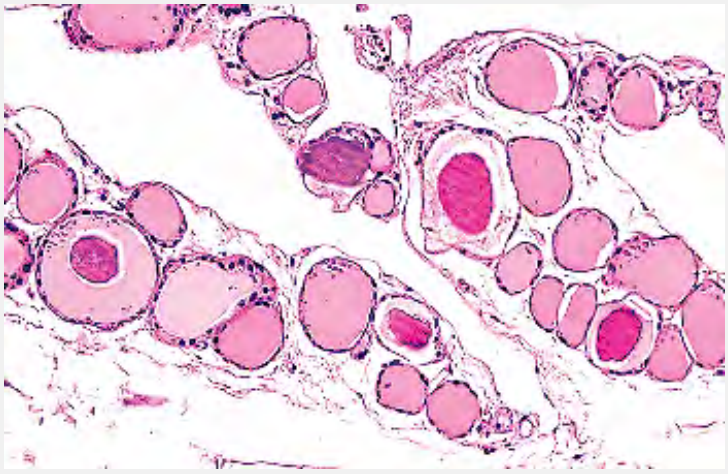

Figure 44.4 The colloid accumulated in these follicles exhibits different densities and tintorial qualities, the latter ranging from acidophilic to basophilic.

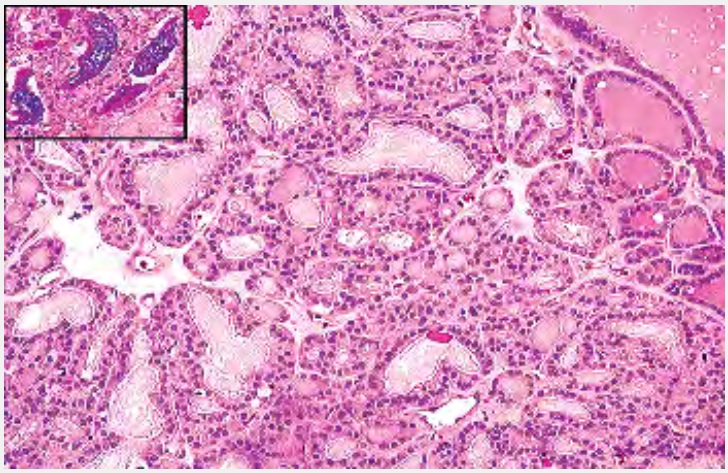

Figure 44.5 The basophilic colloid present in most of these follicles contrasts with the more typical red colloid present in the follicles on the right upper corner. Inset: Alcian blue-PAS highlights the mucinous character of the basophilic colloid.

The glycoproteic material present within the follicles stains for periodic acid-Schiff (PAS) and alcian blue and is immunoreactive for TGB. A row of small vacuoles is seen at the interface between follicular epithelium and the colloid in actively functioning glands; these are referred to as resorption vacuoles. In addition, it is not unusual to find a large round or oval clear space within the colloid; this often appears empty but it may contain birefringent calcium oxalate crystals (See page 1137.)

Another morphologic variation of the colloid is represented by collections of round basophilic corpuscles clustering at one pole of the follicle.

The epithelial glandular cells lining the follicle are known as follicular cells or thyrocytes; among them, there is a second cellular component known as C cells.

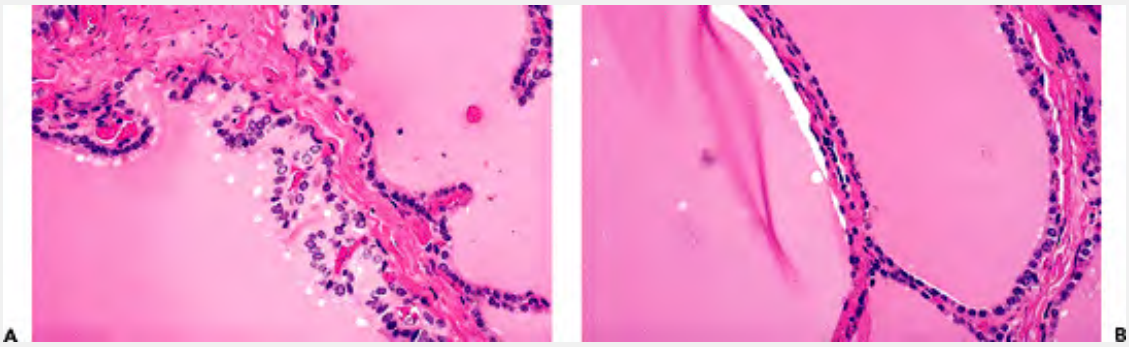

Figure 44.6 A. The epithelium of one follicle is low cuboidal and relatively inactive. The adjacent follicle shows a taller epithelium and reabsorption vacuoles. B. The epithelium of the same follicle is flattened on one side and cuboidal on the other, as an expression of functional polarization.

Follicular Cells

The cells lining the folliclesâ€”follicular cells or thyrocytesâ€”show variations in their shape and size according to the functional status of the gland. Three major types, expressions of a morphologic continuum, are described: flattened (endothelioid), cuboidal, and columnar (cylindrical) (Figure 44.6A). Flattened cells are relatively inactive. Cuboidal cells (their height equaling their width) are the most numerous and their major function is to secrete colloid. The rarer columnar cells resorb the TGB-containing colloid, liberate the active hormones, and excrete these hormones into blood vessels; they may feature an apical cuticle, apical lipid droplets, and one or more basilar vacuoles (vacuoles of Bensley).

Functional polarity is apparent at the level of the follicle and the follicular cell. A single follicle may have flattened cells on one side and cuboidal or low columnar cells on the other (Figure 44.6B), the best expression of this phenomenon being the already mentioned Sanderson's polster.

At the cellular level, all follicular cells manifest a definite polarity, resting with their bases on the basement membrane and having the apexes directed toward the lumen of the follicle. Size and position of the nucleus and some components of the cytoplasm may vary considerably. In the resting thyroid, the nucleus is round or oval, is located toward the center of the cell, and usually contains one nucleolus that is eccentrically located. Its chromatin may be finely granular or clumped. In actively secreting cells, the nucleus is enlarged; because of the mostly apical enlargement of the cytoplasm, it acquires a basal position. The cytoplasm is usually weakly eosinophilic; only exceptionally in an otherwise normal thyroid, does it appear granular and intensely eosinophilic; that is, oncocytic (so-called Hurthle cells). In contrast to parathyroid cells, little or no intracytoplasmic glycogen is present. Occasionally, the

follicular cell cytoplasm contains a golden brown pigment of lipofuscin type (Figure 44.7A), which should be distinguished from the melanin-like pigment already mentioned (Figure 44.7B).

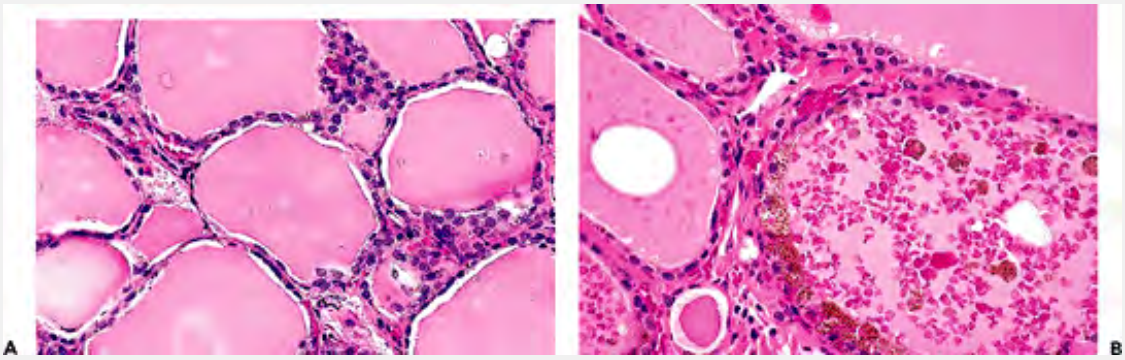

Figure 44.7 A. Lipofuscin in the cytoplasm of the follicular cells. B. Granular black pigment in the follicular epithelium and colloid of the thyroid of a 73-year-old patient who was not on minocycline therapy.

Ultrastructurally, the follicular cells are arranged in a single layer around the colloid and rest on a basement membrane, approximately 35 to 40 nm in thickness, that separate them from the interstitial stroma. Microvilli emanate from the surface of the cells, their number being increased and their length greater in actively functioning cells. Cell membranes of adjacent cells interdigitate in a complex fashion and are joined by junctional complexes toward the apex (35,36). The cytoplasm contains variable amounts of endoplasmic reticulum, mitochondria of usually small size, and lysosomes. When the number of mitochondria is highly increased, the cell acquires at the light microscopic level an intensely eosinophilic granular cytoplasmic appearance (corresponding to the above mentioned Hurthle cells).

Immunohistochemistry

A wide variety of markers with various degrees of specificity and diagnostic significance are expressed by the normal adult follicular cells.

Thyroglobulin (TGB)

This is the most specific immunohistochemical marker for normal follicular cells and the tumors composed of them. It can be demostrated with either monoclonal or polyclonal antibodies and the reactivity is both in the cytoplasm and in the colloid (37,38). Oncocytes show a much lesser degree of positivity. Despite its high specificity, TBG can give rise to a common pitfall. Because of its tendency to leak out of the cytoplasm of the follicular cells and to diffuse into the adjacent tissues, where it can then be incorporated into the cytoplasm of other types of cells (e.g., metastatic carcinoma), it can cause a false positivity (39).

Thyroid Transcription Factor-1 (TTF-1)

This is another very useful marker for thyroid follicular cells and tumors composed of them. This nuclear transcription factor, first identified in thyroid follicular cells and later in pneumocytes, is necessary for the development of thyroid and pulmonary tissues. In the normal adult thyroid its distribution is related to that of thyroglobulin and thyroperoxidase (40,41).

Keratins

Normal follicular cells are immunoreactive only for low-molecular-weight keratin, whereas high-molecular-weight types have been found to be expressed in inflammatory and neoplastic conditions (42,43,44).

Vimentin

Some normal follicular cells occasionally express this intermediate filament in conjunction with keratin, although less commonly than in neoplastic conditions (45).

Epithelial Membrane Antigen (EMA)

Follicular cells are variably positive, with accentuation of the cell membranes.

Triiodothyronine (T3) and Thyroxine (T4)

These hormones can be detected immunohistochemically both in the cytoplasm of the follicular cells and in the intraluminal colloid but their use for diagnostic purposes is negligible.

Estrogen and Progesterone Receptors

Estrogen and progesterone receptors positivity, restricted to the follicular cell nuclei, shows some correlation with the age and sex of the individual (46,47).

S-100 protein

This marker, which is mainly detected in inflammatory/hyperplastic and neoplastic thyroid conditions, is only focally and weakly expressed by normal follicular cells (48,49).

Epidermal Growth Factor Receptor (EGFR)

In normal follicular cells, and because of their functional polarization, the location of this receptor is mainly basal or basolateral (50).

Thyroid Peroxidase

This enzyme is responsible for the oxidation of iodide to iodine. At the immunohistochemical level it shows a pattern of staining correlated with the age of the individual. A cytoplasmic pattern of staining with apical membrane accentuation is seen in children and young adults, and a perinuclear ring distribution is seen in older individuals (51).

Sodium Iodide Symporter

At the immunohistochemical level this molecule, responsible for the active iodide intake into the follicular epithelium, is localized mainly to the lateral basal portion of the cells (52,53).

Physiology

The main function of the thyroid gland is the production of thyroid hormones, the most important being thyroxin (T4) and triiodothyronine (T3). These hormones regulate metabolism, increase protein synthesis in every tissue of the body, and increase O_2 consumption. Thyroid hormones are particularly important for body development and for the normal maturation of the central and peripheral nervous system.

Steps in thyroid hormone biosynthesis include ingestion of iodine ions from water and food, their absorption and transport as iodide into the extracellular fluid and their concentration within the thyroid where their intracellular levels are 30 times higher than in peripheral blood. The active iodide uptake across the basement membrane is mediated by human sodium iodide symporter (hNIS) in a process coupled with the flow of sodium (52). The intrathyroidal iodide is then oxidized to iodine. This last step is dependent on the action of iodide peroxidase, which oxidates the iodine ion to a highly reactive form of iodine, which in turn binds to tyrosine. The results are monoiodotyrosine (MIT) when one

iodine molecule is attached, or diiodotyrosine (DIT) when two iodine molecules are attached. The iodotyrosine residues are condensed to form the biologically active thyroid hormones thyroxin (T4) and triiodotyronine (T3). Thyroxin results from the coupling of two molecules of DIT, and triiodotyronine from the coupling of one molecule of MIT with a molecule of DIT (33).

Thyroid hormones are stored in TGB, with numerous iodinated tyrosine residues, including biologically active T4 and T3. TGB, a large protein with a 19 S sedimentation coefficient and a molecular weight of 670,000, is formed by two identical subunits with a 12 S sedimentation coefficient to which many oligosaccharides are linked. Variations in the sugar chains of the thyroglobulin molecule have been evaluated by analysis of reactivity to various lectins and found to differ between the normal gland and various pathologic states, including neoplasms (54).

Thyroglobulin is encoded by a gene spreading over more than 200 kilobases in the bovine genome (55). The molecular mechanisms involved in the tissue-specific and hormone-dependent expression of the thyroglobulin gene have been studied in follicular cells in primary cultures and cell lines (56,57). TGB is collected at the center of the thyroid follicles and is the main constituent of colloid.

Ultrastructural studies have correlated the morphologic changes that accompany thyroid hormone production and secretion. The synthesis of TGB begins in the endoplasmic reticulum and continues in the Golgi apparatus, where the end sugars of the carbohydrate site are incorporated; it is then packaged in small apical microvesicles, the contents of which are discharged into the follicular lumen after fusion of the vesicle membranes with the luminal side of the plasma membrane.

Resorption of TGB takes place through cytoplasmic pseudopodia (streamers) that engulf minute portions of colloid, which are then drawn into the cell in the form of membrane-bound colloid

droplets. These subsequently fuse with lysosomes, and their content is digested by the lysosomal enzymes (58,59,60,61). The breakdown products, including T3 and T4, diffuse in the blood stream, where they are transported primarily by the specific carrier protein, thyroxin-binding globulin (TBG). TBG normally transports more than 70% of thyroid hormones. Approximately 20% of circulating thyroid hormones is carried by transthyretin (prealbumin) and albumin (62). Only a small portion of circulating thyroid hormones (approximately 0.05% of T3 and 0.015% of T4) is unbound and, therefore, biologically active. Free, circulating, biologically active T3 and T4 are in equilibrium with the hormones bound to the carrier proteins. The amount of circulating T4 is much larger than that of T3; however, T3 is about four times more active biologically; as a result, the final contribution of T3 to the biologic activity of thyroid hormones equals that of T4 (63).

Thyroid hormones stimulate metabolism, increase oxygen consumption, and cause a rise in heat production, cardiac output, and heart rate. They are essential for normal development, growth, and maturation. The acceleration of growth may result from a direct action on the cells to increase their rate of division, by acting permissively for other hormones, or by inducing the synthesis of a variety of growth-promoting hormones (58,62,64,65,66,67,68).

Thyroid biosynthetic and secretory activities are controlled by the blood level of thyroid stimulating hormone (TSH), a glycoprotein synthesized and secreted by the anterior pituitary gland (69). TSH binds to a specific receptor located on the basolateral surface of the follicular cell membrane, and by activating the adenylate-cyclase pathway regulates the complex mechanism responsible for T3 and T4 synthesis (70,71).

Stimulation of the thyroid gland by thyrotropin increases its secretory activity and vascularity and results in both hypertrophy

and hyperplasia of follicular cells, accompanied by reduction of colloid storage. At the functional level, this is reflected by an increase in iodide concentration and organic binding, hormone synthesis, and hormone secretion (63,72). TSH release is in turn regulated by a tripeptide secreted by the hypothalamus, thyrotropin releasing hormone (TRH). TSH and TRH release are regulated by the circulating levels of free T3 and T4, via a negative feedback on the pituitary and hypothalamus (low levels of free T3 and T4 stimulate the release of TSH and TRH). In contrast, TSH and TRH releases are inhibited by high levels of circulating free T3 and T4 (69,72,73).

Microscopic Variations

Sanderson's Polster

A characteristic structure, present in the normal thyroid but accentuated in hyperplastic conditions, is the so-called Sanderson's polster. This refers to an aggregate of small follicles lined by flattened epithelium and covered by an undulating layer of columnar epithelium that is seen bulging into the lumina of larger follicles (Figure 44.8). This perfectly benign and to some extent physiologic change, most likely the morphologic expression of the functional polarization of the thyroid follicle, needs to be distinguished from papillary microcarcinoma.

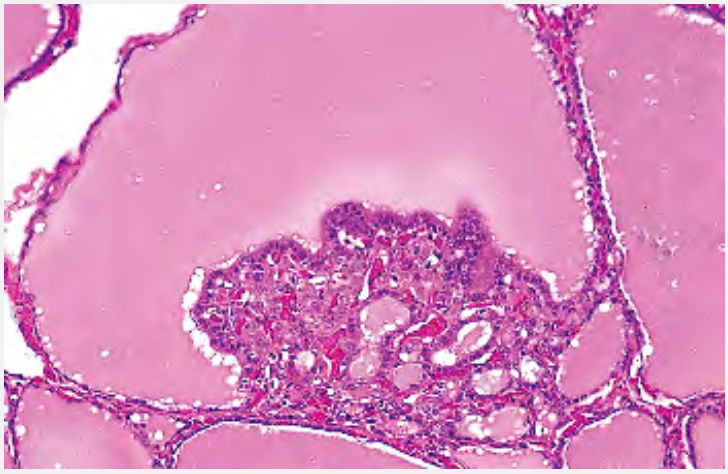

Figure 44.8 Sanderson's polster protruding into the lumen of a follicle.

Granulomas

Granulomas are a relatively common finding in otherwise normal surgically resected thyroids and in autoptic specimens. Both foreign material and colloid may elicit this process. Suture material is the most frequent cause of formation of granulomas in completion thyroidectomy specimens. Larger foreign body granulomas sometimes clinically simulating a thyroid nodule have been reported in thyroids of patients who underwent laryngeal injection of Polytef (polytetrafluoroethylene) (74,75). This material may migrate through the lymphatics into adjacent tissues, where it may start the inflammatory process.

Rarely, interstitial granulomas are seen as a reaction to oxalate crystals that have been released by broken follicles (76).

Granulomatous lesions originated by the rupture of follicles and their invasion by macrophages and leukocytes as a reaction to the extruded colloid are a common incidental finding in surgically

resected thyroids. Carney et al. (77) referred to this process as palpation thyroiditis (and also as multifocal granulomatous folliculitis) and attributed it to the minor trauma resulting from physical examination. Support for this interpretation comes from the observation that the number and size of the granulomas is related to the intensity of the palpation and the fact that similar changes have been described in individuals engaged in martial arts (so-called martial-arts thyroiditis) (77,78).

Grossly, a gland affected by palpation thyroiditis appears normal or shows tiny foci of hemorrhage. Histologically, multiple small granulomas centered in a disrupted follicle and composed of histiocytes, lymphocytes, and plasma cells are seen scattered in the thyroid gland (Figure 44.9A). Some of the histiocytes are foamy, while others have the appearance of multinucleated giant cells. The appearance depends on the stage of the process, a common picture being a cluster of foamy macrophages hanging from the follicular epithelium into the lumen (Figure 44.9B). Necrosis, hemosiderin, and iron deposition are seen only rarely. Sometimes up to four or five follicles are involved in a single granuloma.

Immunohistochemically, most of the lymphocytes are T cells; among the plasma cells, K-positive cells predominate (79).

Palpation thyroiditis seems to represent a variation in the theme of colloidophagy, a process described many years ago and characterized by a granulomatous reaction to colloid in follicles allegedly undergoing spontaneous rupture in thyroids affected by goiter or thyroiditis (80).

Palpation thyroiditis needs to be distinguished from interstitial giant cell thyroiditis (in which the granulomas are centered not in the follicles but in the interstitium), necrotizing granulomas following surgical procedures (similar to those more commonly seen in the bladder and the prostate and characterized by a central area of necrosis surrounded by a palisading of epithelioid

cells), and aggregates of C cells (which are immunoreactive for CT) (81,82).

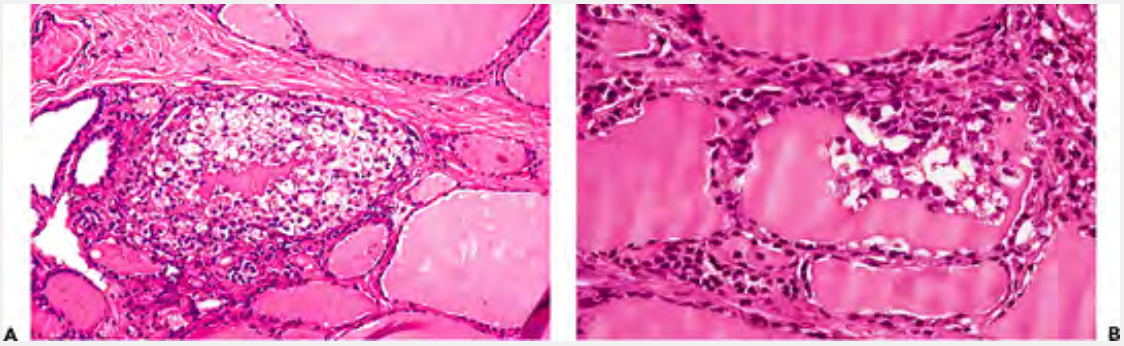

Figure 44.9 Palpation thyroiditis. A. The thyroid follicle in the center is packed with histiocytes and other inflammatory cells, with a clump of residual colloid in the center. The follicular epithelium is barely discernible. B. In this case the follicle is only partially involved. Inflammatory cells and desquamated follicular cells protrude into the lumen.

Crystals

Anisotropic crystals of calcium oxalate may be present within the colloid in normal adult thyroid glands. They may be seen in ordinary light, but are more easily identified under polarized light (Figure 44.10). Their shape varies from rhomboid to irregular plaques and their size shows wide variations (83).

In autoptic studies they have been found with a frequency of up to 85% of thyroids examined (84). Their number appears to increase with age; this, together with the observation that the crystals have been found more frequently in colloid with low positivity for

TGB, has prompted the suggestion that they result from variations in colloid and calcium concentration in the gland secondary to a low functional state of the thyroid (83,84,85).

In one study the number of crystals was markedly elevated in glands with subacute thyroiditis, where they were found in the giant cells, in remnants of colloid, and in the thyroid stroma. In the same study crystals were identified only rarely in thyroids with chronic thyroiditis or glandular hyperplasia (86).

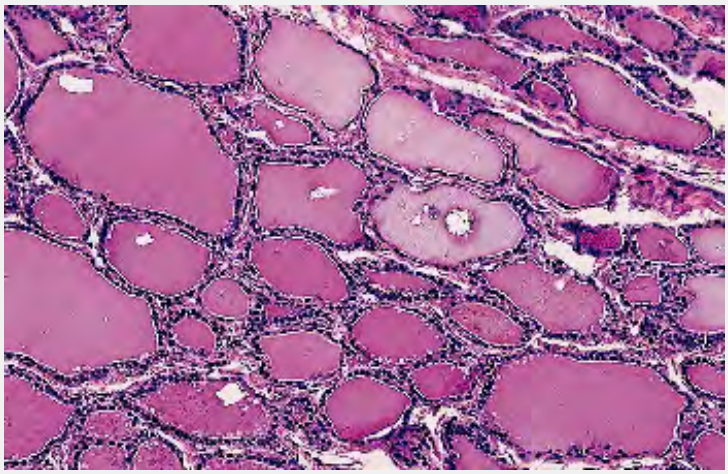

Figure 44.10 Multiple birefringent calcium oxalate crystals are seen in the lumina of normal thyroid follicles (polarized light).

Oxalate crystals in the thyroid are also seen in large number in patients undergoing dialysis for renal failure. In this setting, the thyroid is just another site of oxalate deposition, together with the kidney, myocardium, and other sites (87). Rarely, crystals released by follicular breakdown may elicit a granulomatous reaction in the nearby thyroid stroma (76).

At the time of frozen section, their identification within a follicular structure can be useful in distinguishing thyroid from parathyroid

gland tissue (88).

Squamous Metaplasia

Benign squamous cells occur as an expression of squamous metaplasia of follicular cells in various benign and malignant thyroid lesions and, under exceptional circumstances, in an otherwise normal thyroid (89,90,91). They need to be distinguished from transversally cut follicles and from the SCNs of UBB derivation. It also should be mentioned that squamous epithelium is regularly observed as a component of the epithelium of thyroglossal duct cysts.

C CELLS

C cells (parafollicular cells) represent a minor component of the thyroid gland. It has been estimated that they comprise not more that 0.1% of the glandular mass. They have a neuroendocrine function, being responsible for the production of the peptide hormone CT. The term â€œC cellsâ€• was introduced by Pearse (92) to underline their role in secreting and storing this hormone. More recently, other hormones have been found to be produced by C cells, but only in small quantity and not in every cell.

C cells are identified only with difficulty in sections stained with hematoxylin and eosin, where they appear polygonal and with a granular weakly eosinophilic

cytoplasm that is larger and paler than that of follicular cells. The nucleus is round to oval, pale, with a centrally located nucleolus.

C cells are located, individually or in small groups, within thyroid follicles. Specifically, most are found at the periphery of the follicular wall (hence the qualifier parafollicular), within its basement membrane and without contact with the follicular lumen. Electron microscopy has shown that C cells occupy an

intrafollicular (rather than interfollicular) position, and that they are separated from the thyroid interstitium by the follicular basal lamina. The presence of C cells in the interfollicular stroma has never been convincingly demonstrated ultrastructurally (93).

Occasional C cells have prominent cytoplasmic processes that extend beyond the adjacent follicular cells. In normal adults and neonates, C cells are restricted to the midupper and upper thirds of the lateral lobes of the thyroid, in the area where UBBs (from which they derive) fuse with the thyroid median anlage. The number of C cells varies with the development of the gland, being more numerous in early age. In one study, up to 100 C cells per low-power field were demonstrated in neonates and children; whereas in adults only a maximum of 10 cells per low-power field were counted (94). In another study, no difference in the number of C cells was found between young and middle-aged groups, but in the elderly the number of such cells was variable, with groups of up to 20 or more cells sometimes being observed (95). However, no statistically significant differences among the various age groups in adults were demonstrated. Other studies have since confirmed that normal adult thyroid glands may contain numerous C cells, sometimes in the form of small nodules (22,96) (Figure 44.11). Gibson et al. (96) suggested that such clusters of C cells, in the absence of disturbances in calcium metabolism and of a family history of medullary carcinoma, do not constitute a precursor of medullary carcinoma but may be instead the expression of either a partial failure of embryonic C-cell migration and dispersion within the gland or of age-related hyperplasia. It needs to be mentioned that C-cell hyperplasia of presumed reactive nature has been observed in the immediate periphery of nonmedullary thyroid neoplasms (97,98), in association with lymphocytic thyroiditis (99,100,101), and in secondary hyperparathyroidism (102). As already mentioned, C cells tend to aggregate in the vicinity of SCNs.

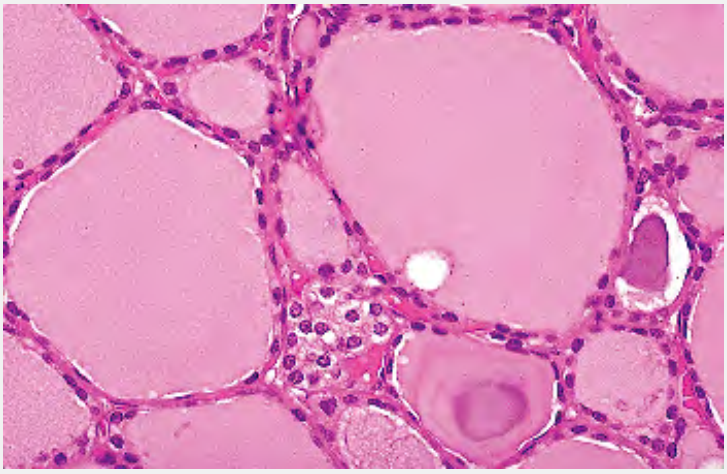

Figure 44.11 Clusters of C cells in the thyroid of an elderly individual with no known clinical or laboratory evidence of calcium disturbance.

The main ultrastructural characteristic of C cells is the presence of secretory granules, which range in diameter from 60 to 550 nm (103). Two main types of granules have been identified. Type I granules have an average diameter of 280 nm and a moderately electron-dense, finely granular content which is closely applied to the limiting membranes of the granules. Type II granules are smaller (average diameter of 130 nm) with a more electron-dense content, which are separated from the limiting membranes by a small but distinct electron-lucent space. Most normal C cells are filled with type I secretory granules, with no or few type II granules. Immunocytochemical studies performed at the ultrastructural level have shown that both type I and II secretory granules contain immunoreactive CT (104).

Histochemistry and Immunohistochemistry

Histochemically, normal C cells are characterized by the following:

Argyrophilia

- In sections stained with argyrophil techniques such as the Grimelius reaction or analogous stains, the cytoplasm of the C cell is characterized by the deposition of fine silver-positive granules (103).

Lead hematoxylin

- The cytoplasm of C cells is selectively stained by this type of hematoxylin (105).

Toluidine blue and coriophosphine 0

- These dyes confer marked metachromasia to C cells after acid hydrolysis of tissue sections (105).

Lectin Ulex europaeus agglutinin I

- Selective reactivity to this marker has been demonstrated (106).
- These methods, widely used in the past for the identification of C cells, have been largely replaced by the use of immunohistochemical techniques.

Immunohistochemically C cells have been found to be reactive to:

- *Calcitonin* (Figure 44.12) (103,104,107,108).
- *Calcitonin geneâ€“related peptide (CGRP)* (109)
- *Katacalcin* (110)
- *Somatostatin* (111,112,113), *substance P* (114), *helodermin* (115) and *gastrin-releasing peptide* (116,117). A small proportion of CT-positive cells are also positive for these

neuropeptides.

- *Thyrotropin-releasing hormone*. In some species, C cells have been found to contain this hormone as detected immunohistochemically (118).
- *Serotonin* and other biologically active amines (119).
- *Cytokeratins.* C cells are immunoreactive only for low-molecular-weight keratin.
- *Pan-endocrine markers*, such as neuron-specific enolase, chromogranin A, and synaptophysin (120).
- *Carcinoembryonic antigen* (CEA) (103).

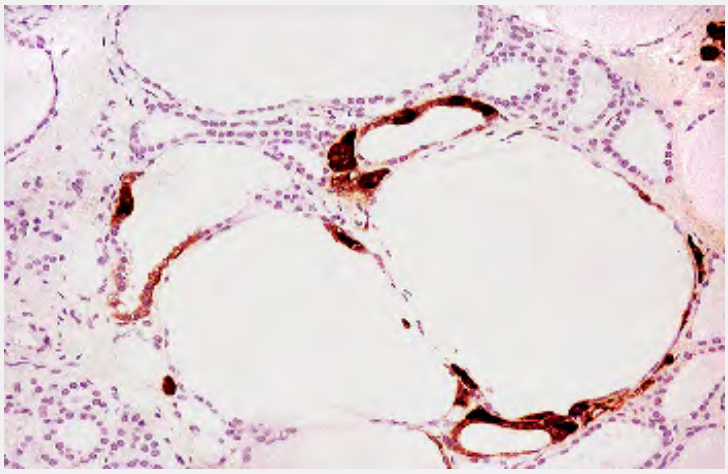

Figure 44.12 Immunoperoxidase stain for CT demonstrates C cells within follicles, arranged either individually or in small groups.

It is possible that neuroendocrine cells other than C cells exist in the thyroid and that they represent the cells of origin of the rare thyroid â€œneuroendocrine carcinomasâ€• having histologic and

immunohistochemical features different from those of medullary carcinoma.

Physiology

CT is a 32â€“amino acid peptide whose main function is the regulation of the level of calcium in the plasma by a feedback mechanism. This is brought about by the inhibition of osteoclastic activity. When calcium plasma levels are increased, CT is released from the thyroid. CT also acts in the kidney to enhance the production of vitamin D.

The major physiological role of CT is most likely the protection of the skeleton during periods of calcium stress such as growth, pregnancy and lactation (121). However, absence of CT is not associated with hypercalcemia, nor does a marked excess of the hormone (as seen in patients with medullary thyroid carcinoma) produce hypocalcemia. In addition to calcium, both gastrin and cholecystokinin induce the secretion of CT, as does the chronic administration of estrogenic hormones.

The CT gene is located on the short arm of chromosome 11 and consists of six axons that encode katacalcin (C-terminal flanking peptide) and CGRP (110,121,122). The primary transcript of the CT gene gives rise to two different mRNAs by tissue-specific alternative splicing events, leading to the production of CT and CGRP mRNAs. The CT-CGRP gene is expressed both in thyroid and nervous tissues, but CT is produced in large quantities only in the thyroid.

In normal male adults, basal CT levels range from 3 to 36 pg/ml (0.9 to 10.5 pmol/L). Plasma levels in females range from 3 to 17 pg/ml (0.9 to 5.0 pmol/L). Normal values after pentagastrin stimulation are less than 106 pg/ml (30.9 pmol/L) for males and less than 29 pg/ml (8.5 pmol/L) for females.

Katacalcin, the C-terminal flanking peptide of CT, is a 21â€“amino

acid peptide that is cosecreted with CT in equimolar amounts (110). Its function, however, is unknown. CGRP is a 37â€“amino acid peptide that is an extremely potent vasodilator and also serves a neuromodulator or neurotransmitter function (121).

Stroma

Lymphocytes

In thyroids surgically resected because of a mass, it is not uncommon to observe in the interstitium of the normal portion of the gland a few collections of lymphocytes, sometimes admixed with rare plasma cells. Simple chronic thyroiditis and focal lymphocytic thyroiditis are the names given to this process that most likely does not represent a nosologic entity but rather the epiphenomenon of etiologically different conditions. Similar changes may in fact be seen in the proximity of neoplasms, in thyroids of patients taking lithium, or in individuals who have received low-dose external radiotherapy (123).

Fibrous Tissue

The usually thin fibrous septa that separate the thyroid lobules may exhibit microscopic variations. In a study on normal thyroids collected at autopsy from young adults, Komorowski and Hanson (22) found that 8% of the thyroid glands showed extensive fibrosis. According to their description, dense and largely acellular collagen fibers divided the thyroid into small nodules, giving it an appearance akin to micronodular cirrhosis of liver.

Another change that may occur in the interstitium, albeit rarely, is so-called multifocal sclerosing thyroiditis. It is characterized histologically by numerous microscopic foci of stellate-shaped fibrosis composed of cellular fibroblastic tissue frequently entrapping few thyroid follicles in the center. Even if at low power

the individual lesions appear similar to those of papillary microcarcinoma, the epithelial component of such lesions lack the cytoarchitectural features of a papillary neoplasm (Figure 44.13A, B). Furthermore, the number of lesions in multifocal sclerosing thyroiditis greatly exceeds that seen in the usual case of papillary microcarcinoma. The etiology and pathogenesis of this process are not known.

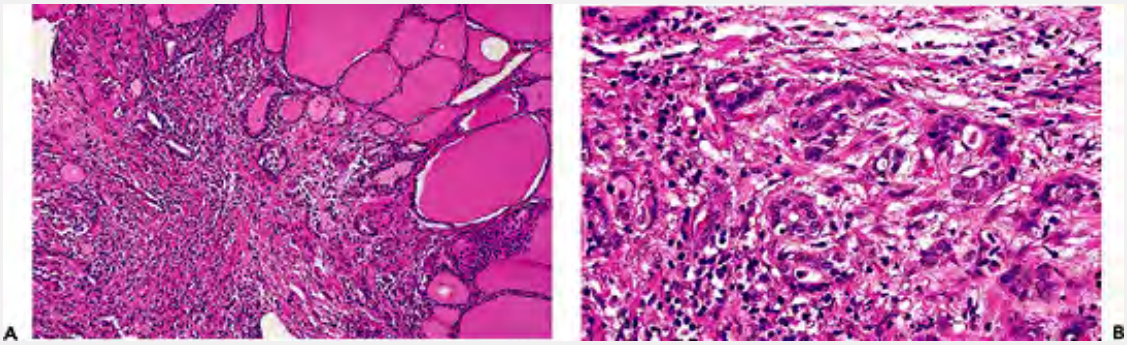

Figure 44.13 A. Multifocal sclerosing thyroiditis. On low power, the appearance resembles that of a papillary microcarcinoma. B. At higher power, the follicles entrapped in the fibrosis are irregularly shaped but do not show any of the cytologic features of papillary carcinoma.

Adipose Tissue and Skeletal Muscle

Thyroid stroma may undergo adipose metaplasia, resulting in the presence of islands of mature adipose tissue between follicles (Figure 44.14). Mature fat also occasionally may be seen in proximity to the thyroid gland capsule, its presence in this location most likely resulting from the close relationship of fat and thyroid

tissue during fetal life (124).

Other tissues that grow in close proximity to the thyroid gland during their development and that can be found within the capsule of adults are cartilage and muscle.

In one study, striated muscle was found within the thyroid parenchyma of 19 glands, usually in the region of the isthmus or in the pyramidal lobe of the gland (22). Conversely, in 10 specimens thyroid follicles were found within fascicles of strap muscle from the same areas (Figure 44.15). Follicles entrapped in perithyroidal skeletal muscle are more easily identifiable when they undergo hyperplastic changes (125).

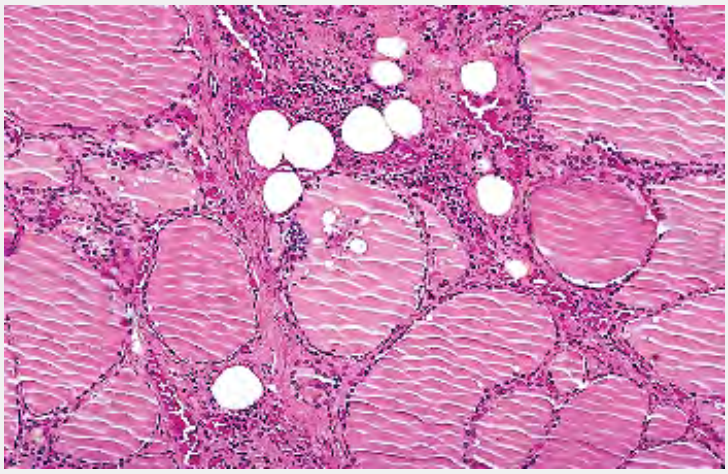

Figure 44.14 Adipose metaplasia of thyroid stroma. Mature adipocytes are seen between follicles.

Calcification

Dystrophic calcifications may be seen in normal thyroid of old age, particularly in relation to vessels. They can easily be distinguished from psammoma bodies because of the lack of laminations and the

irregularity of their contours.

Psammoma bodies rarely have been described in benign thyroid lesions but not in normal thyroids (126,127,128). Finding psammoma bodies in an otherwise normal thyroid or in a cervical lymph node should always prompt a careful search for an occult papillary carcinoma (Figure 44.16).

Branchial Pouchâ€“Derived and Other Ectopic Tissues

Branchial pouch-related structures are found within the thyroid in various forms: solid cell rests (a remnant of the

ultimobranchial body or branchial pouch complex IVâ€“V), epithelium-lined cysts, parathyroid glands, thymic tissue, salivary glandâ€“type tissue, and heterotopic cartilage.

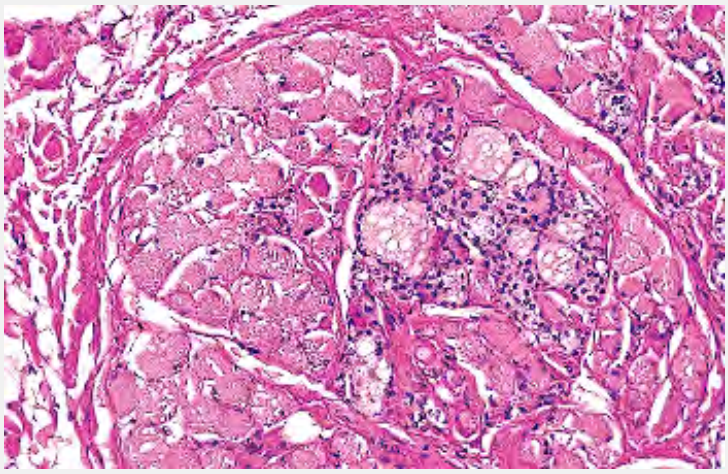

Figure 44.15 Clusters of thyroid tissue intimately admixed with bundles of skeletal muscle adjacent to the thyroid gland.

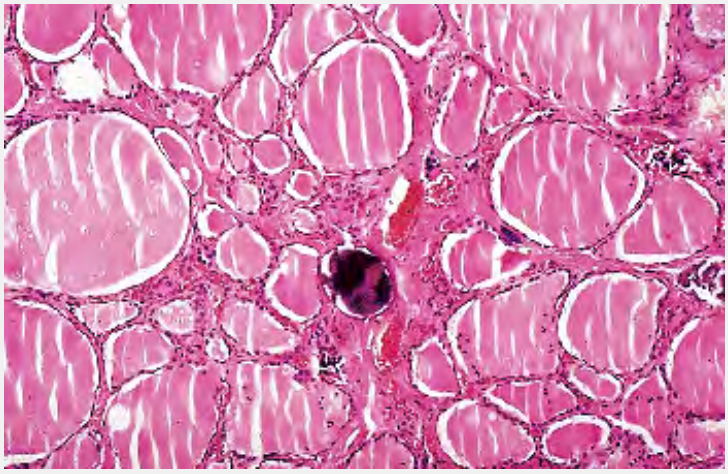

Figure 44.16 Psammoma body in nonneoplastic thyroid tissue adjacent to a papillary carcinoma (not shown in the picture).

Solid Ultimobranchial Body Remnants (Solid Cell Nests)

So-called solid cell nests are clusters of epithelial cells interspersed among the follicles. Because they may exhibit squamous differentiation, they have sometimes been misinterpreted in the past as foci of squamous metaplasia in follicles (91). However, a UBB origin, for what in retrospect are clearly the same formations, had already been suggested by Erdheim in 1904 (129) and Getzowa in 1907 (130), following their demonstration of clusters of epithelial cells with solid or rarely cystic appearance in individuals with thyroid aplasia. Additional evidence along these lines was provided by the demonstration of marked similarities of human SCNs with the normal UBB of the rat and the hyperplastic or neoplastic UBB remnants in bulls (131,132,133).

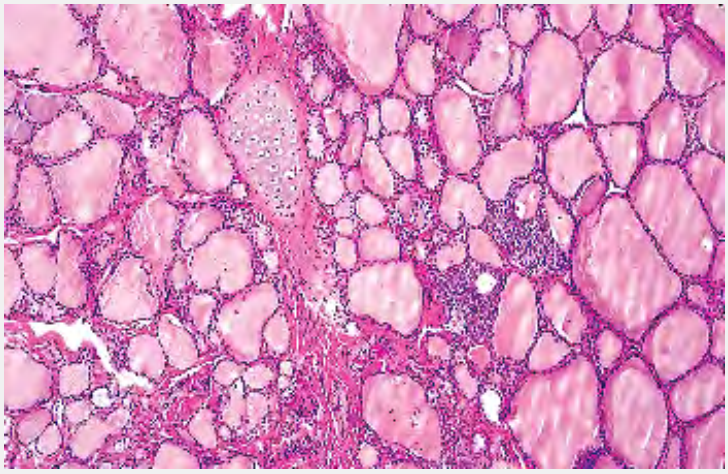

Figure 44.17 Cartilage island is seen in the proximity of SCNs.

SCNs are relatively common in normal thyroid, the probability of finding them increasing with the number of sections examined. In one study, SCNs were found in only 3% of routinely examined thyroids but in as many as 61% of specimens when the gland was blocked serially at 2- to 3-mm intervals (134). For unknown reasons SCNs are more common in males than in females. Most SCNs measure an average 0.1 mm in diameter, but occasionally they can reach 2 mm or more. They may be single or multiple. They are usually surrounded by stroma and more or less demarcated by the adjacent thyroid follicles. Adipose tissue and cartilage may be present in their vicinity (Figure 44.17). Most SCNs are found along the central axis of the middle and upper third of the lateral lobes (i.e., in the same area where C cells usually occur); this constitutes additional proof for their origin from the UBB, as it does the fact that the number of C cells is increased in the vicinity of SCNs (135,136).

SCNs are often grouped in clusters featuring a multilobed shape on low-power examination (Figure 44.18A). They have a dual cell

population. The main component is made

up of cells of polygonal-to-oval shape, elongated nuclei with finely granular chromatin, and acidophilic cytoplasm. Some of these cells show clear-cut squamous differentiation. Immunohistochemically, they are reactive for high- and low-molecular-weight keratins, carcinoembryonic antigen (CEA) and p63 (Figure 44.18B). Ultrastructurally they feature bundles of tonofilaments, desmosomes, and intraluminal cytoplasmic projections (137,138,139). The positivity for p63 (a p53 homolog that is expressed in basal/stem cells of stratified epithelia), together with the expression of basal cell-type keratins (such as 34betaE12), telomerase and bcl-2, is compatible with a basal/stem cell phenotype for this cellular component (140,141). The second cell population, numerically less conspicuous, is characterized at the light microscopic level by clear cytoplasm and round nuclei, at the ultrastructural level by dense-core secretory granules, and at the immunohistochemical level by immunoreactivity to CT, CGRF, and chromogranin (135,137,138,142). All of these features are indicative of a C-cell nature for this population and constitute a further link between SCNs and the UBBs. Cystic cavities containing acid mucin are frequently observed in association with SCNs (see next section). A variation in the theme is represented by the admixture of SCNs (pure or admixed with a cystic component) with groups of small follicles lined by low cuboidal TGB-immunoreactive epithelium, forming the so-called mixed follicles (Figure 44.19). The fact that a similar admixture is seen in mixed medullary-follicular carcinomas has led some investigators to suggest that these rare tumors may arise from uncommitted stem cells of the UBBs that have the potential to differentiate into C cells, follicular cells, or both (143).

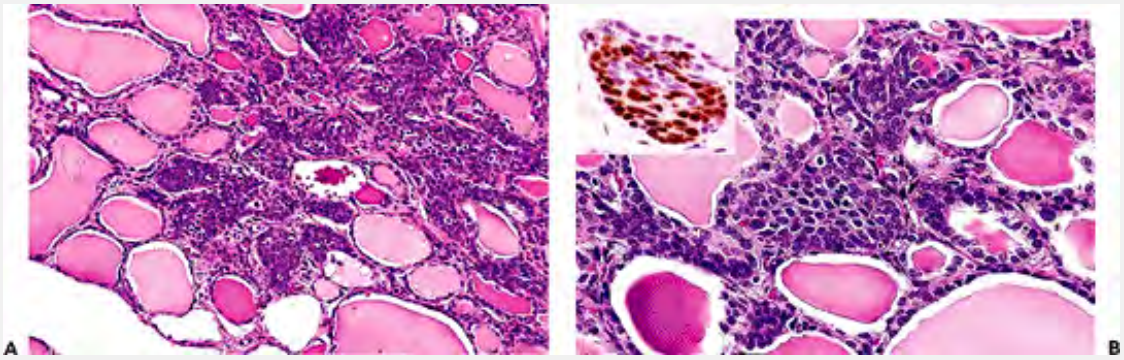

Figure 44.18 A. Low-power view shows the multilobed shape often exhibited by groups of SCNs. B. SCN in normal thyroid. Note the uniform appearance of the epithelial cells. Inset: Strong nuclear immunoreactivity for p63.

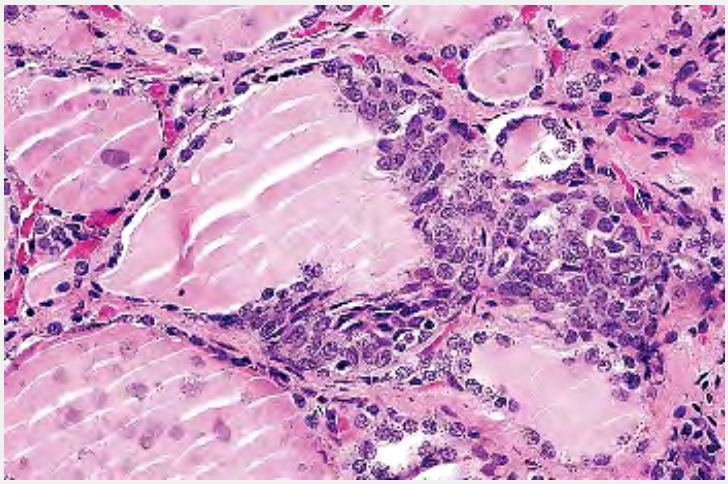

Figure 44.19 So-called mixed follicle. An SCN merges with a follicle lined by a flattened epithelium with colloid in the lumen.

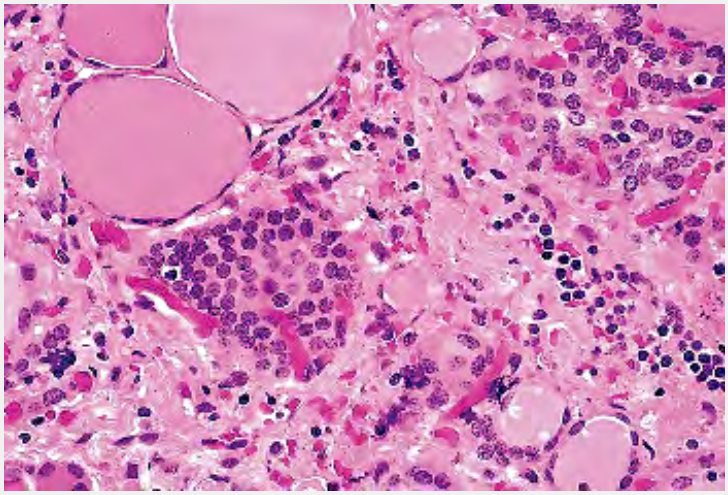

Figure 44.20 Tangential cut of a follicle. This should not be misinterpreted as an SCN.

SCNs need to be distinguished from collections of C cells, follicles with squamous metaplasia, and tangential sections of normal follicles (Figure 44.20).

Cystic Ultimobranchial Body Remnants

UBB remnants also may take the form of cysts. These occur most commonly in the soft tissues of the neck adjacent to the thyroid. Indeed, it is possible that some of the clinically evident branchial pouch cysts located in close proximity to the thyroid gland and sometimes confused clinically with thyroid lesions or lymph nodes are of UBB origin.

Cystic UBB remnants may also develop within the thyroid itself (144). In the latter instance, they may occur by themselves, may be adjacent to SCNs, or may be intimately admixed with them (Figure 44.21). The cysts are lined most frequently by a flattened multilayered epithelium of squamous type, and less commonly by a ciliated columnar epithelium (Figure 44.22) and often contain

clumps of eosinophilic material in their lumen. They are especially common in neonates. Cystic UBB remants may have an associated lymphoid component (lymphoepithelial cysts) and are more commonly seen in glands with Hashimoto's thyroiditis (145,146,147,148). Pancreatic tissue, a representative of foregut remnants, has been described in the wall of perithyroidal epithelial cysts by Langlois et al. (149).

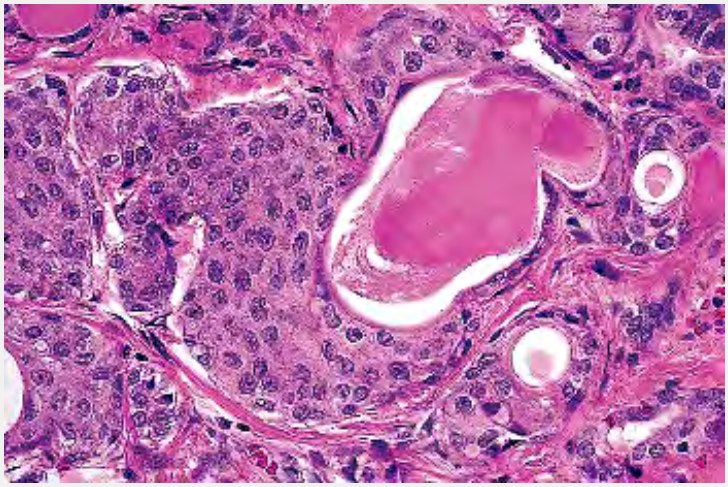

Figure 44.21 SCN with associated cystic formation. A dense eosinophilic material fills the lumen of the cyst.

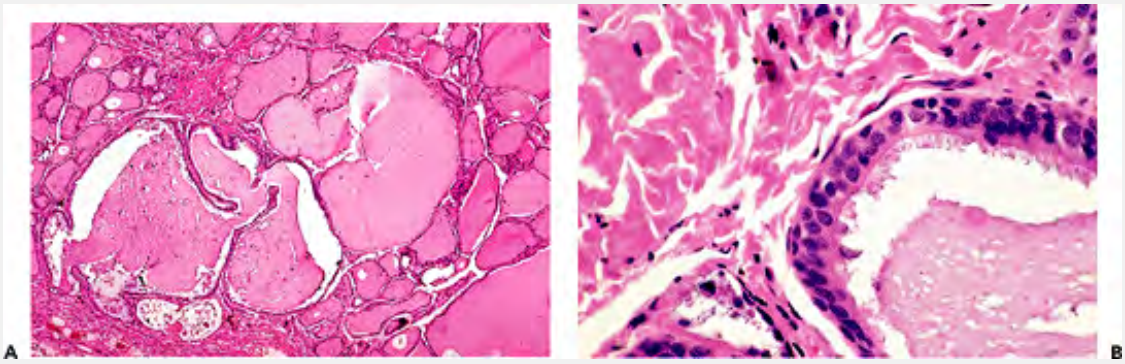

Figure 44.22 A. Intrathyroidal cyst of probable branchial pouch derivation. B. Higher-power view showing ciliated epithelium.

Parathyroid Tissue

The development of the parathyroid glands and the thymus from the branchial pouches in close proximity to the thyroid gland explains why these organs occasionally may be found adjacent to the thyroid capsule or even within the thyroid itself (Figure 44.23).

True intrathyroidal parathyroid glands in adults are rare. However, in a study where 58 human fetal thyroid glands obtained at autopsy were systematically studied for the presence of intrathyroidal parathyroid tissue, the latter was found in 13 thyroid lobes from 12 fetuses (22.4%). It was located subcapsularly in nine of 58 cases (15.5%), and it was lying deep in thyroid tissue in four (68%) (150). These intra- and perithyroidal parathyroid structures can be affected by primary or secondary chief cell hyperplasia, adenoma, or carcinoma and represent an

often overlooked cause of surgical failure in primary hyperparathyroidism (151).

Thymic Tissue

Most of the thymus derives embryologically from the third branchial pouch, together with the lower pair of parathyroid glands. There is also a small and inconstant portion that derives from the fourth branchial pouch together with the upper pair of parathyroid glands and the UBB, which form the lateral thyroid anlage. It is from the latter source that the islands of thymic tissue occasionally found in or around the thyroid are thought to derive (Figure 44.24) (152). The fact that ectopic thymic tissue is observed more frequently in neonates and infants supports this hypothesis. Harach and Vujanic (153) searched systematically for the presence of intrathymic tissue in 58 thyroid glands obtained at autopsy from fetuses with proven retrosternal thymus. Subcapsular thymic tissue was found in two cases (3.4%) and intrathyroid thymic tissue in one (1.7%). An entire thymic gland within the thyroid of an infant has been described by Neill (154). Mizukami et al. (155) reported thymic tissue in the interlobular septum of the thyroid of a patient with Graves disease. Damiani et al. (156) found thymic rests in 1.4% of 2,575 adult thyroid glands that they examined.

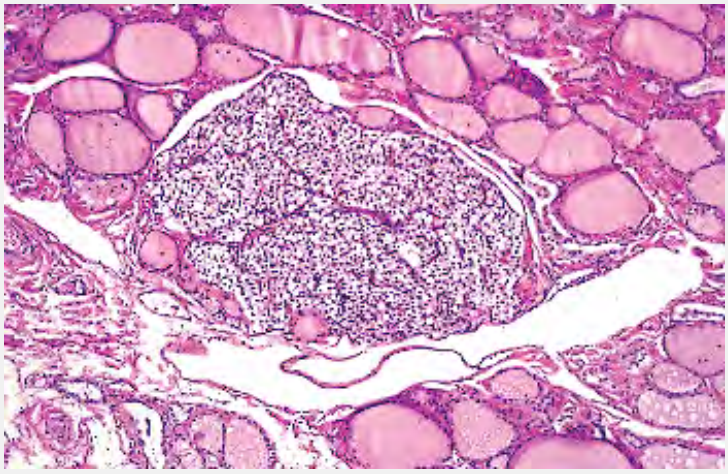

Figure 44.23 Parathyroid gland entirely located within thyroid.

Ectopic thymic tissue may show cystic changes and present clinically as a cystic neck mass. It also may be the source of peri- and intrathyroidal thymomas (157).

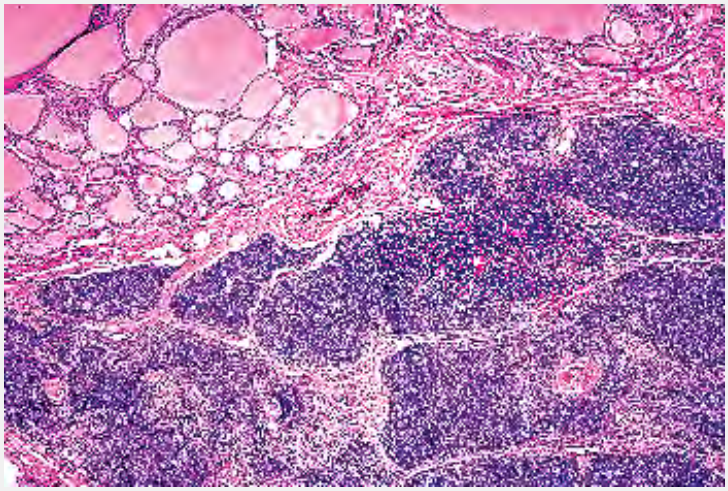

Figure 44.24 Intrathyroidal thymic tissue.

Salivary Glandâ€“Type Tissue

Rarely salivary glandâ€“type tissue has been found within the thyroid. Most of the reported cases have been seen in association with a benign thyroid condition, such as multinodular goiter (158).

Heterotopic Cartilage

Most intrathyroidal islands of mature cartilage probably represent remnants of the branchial pouch apparatus (18,159).

Thyroid Tissue in Abnormal Locations

The presence of nonneoplastic thyroid tissue outside the normal anatomical confines of the gland may be caused by a variety of mechanisms, ranging from congenital abnormalities to acquired processes. Their main practical interest resides in the fact that lack of knowledge of their occurrence may lead to a mistaken diagnosis of metastatic thyroid carcinoma.

In Midline Structures

Ectopic thyroid is derived from abnormalities in migration patterns of the medial anlage and is therefore more commonly found in the neck in a midline position, at any point in the normal pathway of descent of the thyroglossal duct from the foramen cecum to the lower neck (160,161,162). In most cases the ectopy is partial, clinically insignificant, and discovered accidentally. The base of the tongue (lingual thyroid) and the hyoid bone and its surroundings

(as a component of a thyroglossal cyst) are the most common sites. The opposite phenomenon is represented by exaggerated descent of the median anlage into the mediastinum, which may lead to location of thyroid tissue substernally in the preaortic area, in the pericardial cavity, and in the substance of the heart (163,164,165). However, the majority of mediastinal goiters represent a dislocation downward of normal glands that have been pulled down by the hyperplastic changes that occurred in them.

Lingual thyroid is a relatively common incidental microscopic finding. The follicles appear normal but because of their intimate relationship with the surrounding skeletal muscle they may raise the differential diagnosis with carcinoma (166). Sauk (167) and Baughman (168) found thyroid tissue in the tongue in 10% of individuals examined at autopsy, with the sex distribution being equal. The tongue is the most common location of ectopic thyroid tissue in the rare cases of total ectopy (169). In this condition ectopic glands are prone to functional insufficiency, frequently followed by compensatory hyperplasia, which may be the cause of dyspnea or dysphagia. Acute hypothyroidism may follow the removal of this ectopic tissue.

The other site where ectopic thyroid tissue is found more commonly is the wall of thyroglossal duct cysts. It appears in the form of small groups of follicles and is present in 25% to 65% of cysts examined histologically, its frequency being related to the number of sections submitted for histologic examination (170). The medial location and the presence of thyroid tissue in the wall distinguish thyroglossal duct cysts from the rarer branchial pouch cysts. Ectopic thyroid derived from abnormalities in migration of the medial anlage typically does not contain C cells. In one study of median anlage anomalies including 23 cases of thyroglossal cysts with adjacent thyroid tissue and one case of lingual thyroid, not a single C cell was found in either the thyroid tissue or the epithelium lining the cysts (17).

In Pericapsular Soft Tissues and Skeletal Muscles

As already discussed, the presence of thyroid tissue in these locations is not a rare event. It most likely results from the intimate relationship of the thyroid gland with the mesodermal structures of the neck during development.

In the Lateral Neck

This phenomenon, frequently referred to as lateral aberrant thyroid, has different pathogeneses. It has been suggested that surgery and trauma may cause implantation of thyroid tissue in the lateral neck. Typically when this is the case, a few nodules of normal-appearing thyroid tissue, always of microscopic size and frequently surrounded by a fibrous capsule, are seen in the lateral neck close to the cervical lymph nodes (171,172,173). History of previous trauma or surgery on the neck, the presence of suture material (in cases of previous surgery), and the benign appearance of the dislocated thyroid tissue are useful in distinguishing them from metastatic carcinoma. It has to be kept in mind that the latter may appear deceptively benign on microscopic examination. Spontaneous separation of thyroid tissue with subsequent implant in the lateral neck may occur in nodular goiter or Hashimoto's thyroiditis (174,175). In both of these conditions, nodules of thyroid tissue extrude and separate from the surface of the gland and deposit in the extrathyroidal soft tissue, where they may acquire an autonomous blood supply (so-called parasitic nodules). The differential diagnosis with metastatic lymph nodes may be very problematic, especially in the presence of Hashimoto's thyroiditis.

In Cervical Lymph Nodes

Normal-appearing thyroid tissue in medially located cervical lymph

nodes is rarely the result of a developmental

anomaly (176). When this is the case, a few microscopic nests of benign-looking follicles are seen in the marginal sinus of the lymph node (Figure 44.25). The follicular cells that compose them should lack all of the cytologic features typical of papillary carcinoma (177). Psammoma bodies and papillae should also be absent. Numerous sections are sometimes needed to rule out a metastasis from a papillary microcarcinoma, which is by far the most frequent cause of thyroid tissue in cervical nodes.

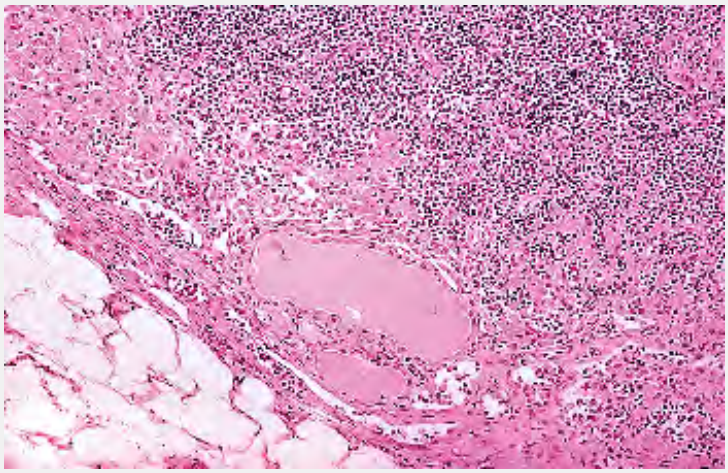

Figure 44.25 A group of benign-appearing thyroid follicles is seen close to the marginal sinus of a cervical lymph node. This patient did not have a carcinoma in the thyroid gland.

In Other Sites

Rarely, one can find thyroid tissue in locations outside its place of embryonic development and occasionally quite distantly from it. These locations include the sella turcica, larynx, trachea, esophagus, heart, diaphragm, gallbladder, common bile duct,

region of the porta hepatis, retroperitoneum, inguinal region, adrenal gland, uterus, vagina, andâ€”last but not leastâ€”the ovary. In the latter site, the thyroid tissue represents a component of a teratoma and sometimes is the only evidence for it *(struma ovarii)* (178,179,180,181,182,183,184,185).

Introduction

The surgical pathology of the parathyroid glands largely involves interpretation of their histology in patients with hyperfunction due to neoplastic or primary hyperplastic processes;[1] that is, primary hyperparathyroidism (1,2,3,4,5,6,7). Secondary hyperparathyroidism, in contrast, is a consequence of stimulation of parathyroid gland growth (secondary hyperplasia) and hormone secretion by hypocalcemia due to diseases of other organs, such as renal insufficiency, malabsorption (8,9,10), or genetic defects in the parathyroid or other organs (11). Secondary hyperplasia is histologically indistinguishable, but clinically easily distinguishable from primary hyperplasia. Since other disorders, such as hypoparathyroidism, pseudohypoparathyroidism, and familial hypocalciuric hypercalcemia (12), are not treated surgically and neonatal severe hyperparathyroidism (12) is rare, the parathyroid glands are rarely available for examination in these diseases. In order to adequately interpret the pathology of the parathyroid glands, the surgical pathologist must have a thorough knowledge and understanding of calcium metabolism, the biochemistry of the

parathyroid glands, the differential diagnosis and pathobiology of parathyroid disease, and the normal and pathologic anatomy of the glands (13). This chapter presents the normal histology, the embryology and its molecular biology, the alterations of the parathyroid glands that occur with age, and a brief discussion of normal calcium metabolism.

Historical Review

In 1850 Professor Richard Owen (14), before the Royal College in London, first described the parathyroid glands in the Indian rhinoceros as â€œa small, compact yellow glandular body â€¦ attached to the thyroid at the point where the veins emerge.â€• Interestingly this paper (14) was not published for twelve years after its initial presentation. Remak (15) in 1855 and Virchow (16) in 1863 described similar glands in cats and humans, respectively. However, it was not until 1880 that the anatomy and histology of the parathyroid glands of several species, including humans, were clearly established by a medical student, Ivor SandstrÃ¶m (17,18). He demonstrated that the glands, which he named â€œglandulae parathyroidae,â€• were structures separate from the thyroid. He used this terminology to suggest the physical, as well as the

possible embryologic, relationship to the thyroid. Kohn (19,20) proposed the term *EpithelkÃ¶rperchen* after he demonstrated by animal experiments that the glands originated independently from the thyroid. However, this terminology has survived only in the German literature.

Embryology

Although an ectodermal origin of the glands has been suggested (21,22), the consensus is that the glands arise from the endodermal region of the branchial pouch (23). Neural crest cells participate in the formation of the mesenchyme of the glands (24). Embryonic

parathyroid hormone production has been demonstrated by immunohistochemical studies (Roth, unpublished data). At 8 3/7; weeks gestational age (3.1 cm crown-rump length) a few positive cells are seen in the glands. By 17 to 20 weeks (Figure 45.1) (25,26,27,28,29,30) abundant parathyroid hormone is present in the glands.

The parathyroid glands arise as diverticula of the endoderm of the third and fourth branchial pouches (31,32,33,34). They make their first appearance as bilateral localized proliferations along the anterodorsal surface of pouch III and the lateral portion of the dorsal extremity of pouch IV during the 5th week of gestation (9-mm embryo). The glands are thus referred to as parathyroid III or parathyroid IV, depending on their pouch of origin (the singular is used because of the symmetrical growth). Parathyroid III, along with the thymus, forms as the third pouch separates from the pharynx. At this stage parathyroid III lies cephalad and lateral to parathyroid IV, and the two are separated by the medial thyroid. Differential growth rates of the thymus and the adjacent medial structures determine the final position the glands occupy after birth. The thymus, the most lateral of these structures, attaches to the pericardium and comes to lie largely in the thorax. The attached parathyroid III also develops a more caudad position as the more medial structures grow cephalad. In the 18 mm embryo, when parathyroid III is at the level of the lower pole of the thyroid, it usually separates from the thymus, forming the lower parathyroid gland. Variations in the level at which this separation takes place are frequent and account for the marked anatomic variations in the final position of the adult glands. Parathyroid IV and the lateral thyroid (the ultimobranchial or postbranchial body) derive from the caudad part of the fourth branchial pouch (Figure 45.2). Together they form a bilobate complex and, as they separate, parathyroid IV acquires its adult position as the upper gland, near the intersection of the recurrent laryngeal nerve and the medial thyroid artery. Due to its medial position, closer association with midline structures, and shorter

embryonic migrations, parathyroid IV has a more constant location and is usually cephalad to parathyroid III. During development, small portions of the gland may become separated from the main gland or a gland may separate into two or more parts (see below).

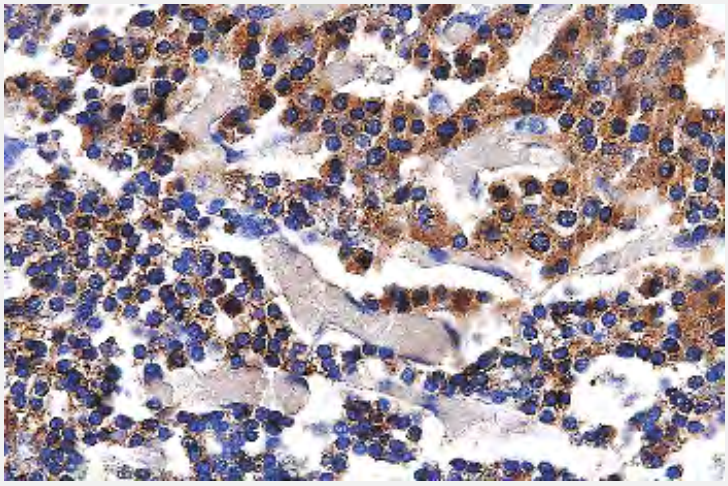

Figure 45.1 Immunohistochemical stain demonstrating PTH in the gland of a 20-week fetus.

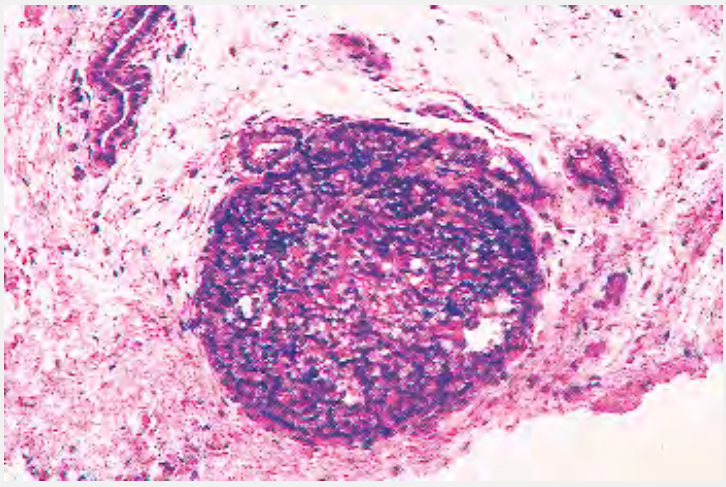

Figure 45.2 An embryonic parathyroid gland still attached to the

remnant of the branchial pouch. The chief cells are closely packed and uniform. No stroma is visible.

Molecular Biology

The successful differentiation, development, and migration of the parathyroid glands require multiple genetic events. These events, though not fully understood, are largely known by identification of the genetic defects in various forms of human hypoparathyroidism, particularly DiGeorge Syndrome/velocardiofacial syndrome[2], and by studies on mouse animal models (35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55). Though early studies (53) proposed an origin of the parathyroid glands from neural crest cells migrating into the pharyngeal pouches, it is now recognized that parathyroid epithelial

cells develop from the third pharyngeal pouch endoderm. Gene products from neural crest cells in the parathyroid mesenchyme are required for modulation of the branchial cleft endoderm into the parathyroid cells (53,54). The development and migration of the parathyroid glands requires a proper balance between epithelial cell death (apoptosis) and proliferation, as well as the appropriate interaction of endoderm with the associated mesenchyme.

Several genes and their products have been identified which are required for normal differentiation, development, and migration of the parathyroid glands (37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,55), though undoubtedly there are many other not yet identified genes and signaling factors vital to these events. The known factors include genes encoding transcription factors, *Hoxa3, Pax9, Tbx1, GATA3, Glial cell missing (Gcm) 2,* and *Eyes absent (Eya)1,* as well as genes encoding secreted signaling molecules, *fibroblast growth factor (Fgf) 8, Chordin (Chrd), bone morphogenetic proteins (BMP*s), TGFÎ²(A)

and *Sonic hedgehog (Shh).* The signaling molecules act by modulating the expression of the respective transcription factors. In homozygous mutant mouse models for many of these genes, amongst multiple pharyngeal and cardiac developmental anomalies, the parathyroids are often aplastic or hypoplastic (37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53).

Hoxa3, a member of the *Hox* family, is a gene that encodes a transcription factor present in the third pharyngeal pouch endoderm as well as the neural crest cells. Mice knockout studies for *Hoxa3* highlight its function in the development of the organs arising from the third and fourth pharyngeal pouches and their dependence on mesenchymal neural crest cells for differentiation (38,39,40). *Hoxa3* mutants develop multiple anomalies involving the throat, heart, and thyroid and fail to develop the thymus and parathyroids. The failure to develop parathyroids is thought to stem from a defect in the neural crest cells' ability to induce proper differentiation of the pharyngeal pouch endoderm (38,39).

Mammalian *gcm2* (*GCMB* in humans) encodes a transcription factor also found in the third pharyngeal pouch endoderm, but is specifically expressed in a domain restricted to the parathyroid. *Gcm2* deficient mice lack parathyroid glands, demonstrating the crucial role of *gcm2* in the differentiation and function of the parathyroid (41). Interestingly, although *gcm2* expression is restricted to the parathyroid, *gcm2* knockout mice showed parathyroid hormone production originating in the thymus driven by *gcm1*, another homolog of the Drosophila gcm family that functions in placental development. Expression of *gcm* is absent in *Hoxa3* mutant mice, suggesting it acts downstream of *Hoxa3* (41,42).

GATA-3 and *Pax9*, additional transcription factors expressed in the third pharyngeal pouch, also result in hypoparathyroidism when absent. In humans with mutations in *GATA-3*, the resulting disease includes hypoparathyroidism manifest by hypocalcemia and low parathyroid hormone (43). Mice deficient for *Pax-9* show initial

formation of the pharyngeal pouches, but have arrested formation of the epithelial buds of the third pharyngeal pouch (44).

Eya1 is expressed in the third pharyngeal endoderm, mesenchyme and ectoderm as well as the organs derived from these structures. In order to investigate the role of *Eya1* in animals, mice knockout experiments were carried out and studied at gestational days 11.5â€“12.5 (45). In contrast to the wild-type embryos that formed epithelial buds of the thymus and parathyroid primordia at gestational day 12, the *Eya1*$^{-/-}$ mice failed to form these epithelial buds. In addition, g*cm2* expression was down-regulated, suggesting an upstream control by *Eya1*. *HoxA3*, *Pax1* and *Pax9* expression were not affected. Since *HoxA3* and *Pax1* have been shown to regulate *Gcm2* expression (45), the control of *Gcm2* by *Eya1* suggests *Eya1* may lie in a pathway downstream from *HoxA3* and *Pax1* (46).

The close relationships of the endoderm, ectoderm and neural crest cells are demonstrated by the signaling protein FGF8. The protein is expressed in the pharyngeal endoderm and ectoderm; however, the severe developmental anomalies caused by its deficiency are a result of its effect on the neural crest cells (47,48). Decreased FGF8 causes increased apoptosis of the cranial and cardiac neural crest cells, resulting in improper development of the heart and pharynx, mimicking DiGeorge syndrome (48). Studies showed dependence of this secreted molecule on the transcription factor *Tbx-1*, a gene mapped to the microdeletion of chromosome 22 associated with DiGeorge syndrome (49,50).

Antagonistic secreted signaling molecules, *Chrd* and the *BMP*s, regulate the dorsal and ventral developmental organization respectively. *Chrd* is present in the pharyngeal endoderm and acts antagonistically by binding the *BMP*s. Loss of *Chrd* results in an expansion of the allantois (ventral) and reduction in the embryonic mesoderm (dorsal). In addition, the mutant mice show features similar to those found in DiGeorge syndrome, including parathyroid hypoplasia, indicating a role of *Chrd* in not only positioning

information but differentiation as well (51). Its role in parathyroid development may be due to decreased expression of *Tbx1* and *Fgf8* caused by loss of *Chrd* (49). An additional gene, *Sonic hedgehog* (*Shh*), also contributes to the balance between *Chrd* and *BMP*s. *Shh* encodes a secreted protein expressed in the pharyngeal endoderm that acts as a negative regulator. *Shh* $^{-/-}$ mutant mice showed abnormal third pouch development thought to be due to an overexpression of *Bmp4* (52). The normal repression of *Bmp* by *Shh* in the third pharyngeal pouch is lost in the mutant mice, upsetting the dorsal/ventral balance in favor of ventral expansion of the thymus and absence of the dorsal parathyroid. Although the gland primordium initially formed appropriately, *Gcm* expression was later absent in these mice, correlating with the lack of parathyroid glands (52).

Aside from organogenesis, numerous genes have been implicated in parathyroid disease (55,56,57,58,59,60,61). Most neoplastic

diseases of the parathyroid, primary chief cell hyperplasia, adenomas and carcinomas, result from alterations in tumor suppressor genes, including *Rb*, *p53*, and *HRPT2*, or cell cycle regulators such as *cyclin D1* (55,56,57,58,59). In addition, genetic mutations involving proteins specific to the parathyroid gland's role in calcium homeostasis have been identified (60), specifically the calcium receptor gene which encodes a gene located in the parathyroid as well as the kidney (61). Although not located in the parathyroid, mutations in vitamin D receptors and PTH receptors indirectly affect the proper functioning of the parathyroid, leading to alterations in calcium homeostasis (62).

Calcium and Parathyroid Metabolism

Calcium is one of the most closely controlled ions in mammals (63). Ninety-nine percent (99%) of the calcium is in the hydroxyapatite of the bones and 1% is in the extracellular fluids and soft tissues (64).

The serum level of ionized calcium (Ca^{2+}) is maintained within the limits of laboratory error in most individuals. The serum calcium concentration ($[Ca^{2+}]$) is commonly measured as the total calcium, although it is the ionized calcium, approximately 50% of the total serum calcium (64), that is meaningful. In normal humans, calcium ions are bound, primarily to proteins (~40%) such as albumin, but also to chelating agents such as citrate. The serum $[Ca^{2+}]$ is regulated through five organs: the parathyroid glands, the C cells of the thyroid (probably of minimal importance in humans), the bones, the kidneys, and the gastrointestinal tract (65). In humans the two primary hormones responsible for control of $[Ca^{2+}]$ are the parathyroid hormone (PTH) and the metabolites of vitamin D, primarily 1Î±,25 $(OH)_2$ vitamin D (66).

Acute control of the serum $[Ca^{2+}]$ is the primary responsibility of PTH (31). PTH operates through a cell surface receptor, primarily found in the proximal convoluted tubule of the kidney and the osteoblasts of the bone. PTH acts to increase the serum calcium. It promotes tubular reabsorption of calcium in the kidney, increases the activity of the 1Î± vitamin D hydroxylase [thus increasing the synthesis of the active form of vitamin D (1Î±,25 $(OH)_2$ vitamin D) and increasing bone resorption and gastrointestinal calcium transport]. The effect on bone requires the osteoblasts and the osteoclast precursors (see Chapter 4), which have PTH receptors. These cells produce paracrine factors that stimulate osteoclastic bone resorption since the osteoclasts lack PTH receptors. PTH also operates through the osteocytes, resulting is osteocytic osteolysis of the perilacunar bone.

The most active metabolite of vitamin D, 1Î±,25 $(OH)_2$ vitamin D, increases calcium resorption from the gastrointestinal tract and acts in synergy with PTH to increase bone resorption (67). 1Î±,25 $(OH)_2$ vitamin D also acts as a negative feedback on PTH synthesis and secretion. This action is mediated by inhibiting translation of prepro-PTH messenger through a vitamin Dâ€“responsive element related to an upstream promotor of the PTH gene (68).

PTH synthesis and secretion are controlled by the ambient [Ca^{2+}]. Increased ambient [Ca^{2+}] decreases PTH synthesis and secretion and intracellular [Ca^{2+}], whereas decreased serum [Ca^{2+}] increases PTH synthesis and secretion. This is in contrast to other organs, where increased intracellular [Ca^{2+}] increases hormone synthesis and secretion, whereas decreased [Ca^{2+}] decreases synthesis and secretion.

A calcium ionâ€“sensing cell surface receptor has been identified (69,70,71). This receptor is a member of the superfamily of guanine-nucleotide-regulatory G proteins. The gene for this receptor is located on the long arm of chromosome 3 (69,70,71). The receptor has been identified on the cell membrane of the parathyroid glands and is thought to be responsible for mediating the effect of calcium on the synthesis and secretion of PTH, much as vitamin D acts through its receptor.

Mutations of the calcium receptor gene have been identified in familial hypocalciuric hypercalcemia and severe neonatal hyperparathyroidism (69,72,73,74). These heterozygous and homozygous mutations result in inactivation of the receptor. The chief cell is thus stimulated to hypersecrete. In some cases of hypoparathyroidism, hyperactivity mutations have been identified in this gene (75), resulting in decreased synthesis and secretion of PTH.

Paracrine control of PTH secretion has been demonstrated in tissue culture, with decreasing cell density resulting in decreasing hormone secretion (76). Chromogranin A, which is cosecreted with PTH and its proteolytic products pancreastatin and parastatin, also inhibit PTH secretion (77,78,79).

Number and Location

Ninety percent (90%) to 97% of patients have four parathyroid glands (80,81,82,83,84,85,86). However, the number has been reported to vary between two and 12 glands (80,81). The incidence

of supernumerary glands in adults varies between 2 and 6.5% (86). Supernumerary glands are most commonly intrathymic and are thought to result from embryonic division of one or more glands (Figure 45.3). Small accumulations of parathyroid tissue as a result of parathyroid cell dispersion during embryonic migration may result in the presence of numerous small nests of cells. Proliferation of these nests, especially in the presence of secondary hyperparathyroidism, [i.e., parathyromatosis (88)], results in multiple accumulations of parathyroid â€œimplantsâ€• that

must be distinguished from metastatic implants from a carcinoma. Ectopic glands are one of the factors responsible for persistent hyperparathyroidism after surgical therapy of primary hyperplasia of the parathyroids (86,87) and must be distinguished from other causes of recurrent or persistent hyperparathyroidism such as parathyroid carcinoma and parathyromatosis (88). It is probably rare for there to be less than four glands in the absence of other abnormalities such as thymic aplasia. Because studies of the number of glands are based on autopsy material, we feel that most of the cases with fewer than four glands are due to failure to locate aberrant glands in unusual locations. Despite the known variation in the adult position of the parathyroid glands (20,28,29,30,69,70), there is a definite pattern in their anatomic distribution, which is related to their embryonic derivation (Figure 45.4). The most common location of the upper or superior (parathyroid IV) glands (77%) is at the cricothyroid junction posteriorly or just above the intersection of the recurrent laryngeal nerve and inferior thyroid artery (70%) (70,82). The second most common location is behind the upper pole of the thyroid (22%) (82), in which case the glands are often within the surgical capsule of the thyroid (Figure 45.5). Other uncommon locations include a more caudad position near the inferior thyroid artery, within the thyroid capsule or parenchyma (Figure 45.5), within or near the pharyngeal wall, a retropharyngeal or retroesophageal position, or within or near the carotid bifurcation.

Abnormal upper glands can descend into ectopic locations as low as the posterior mediastinum (70).

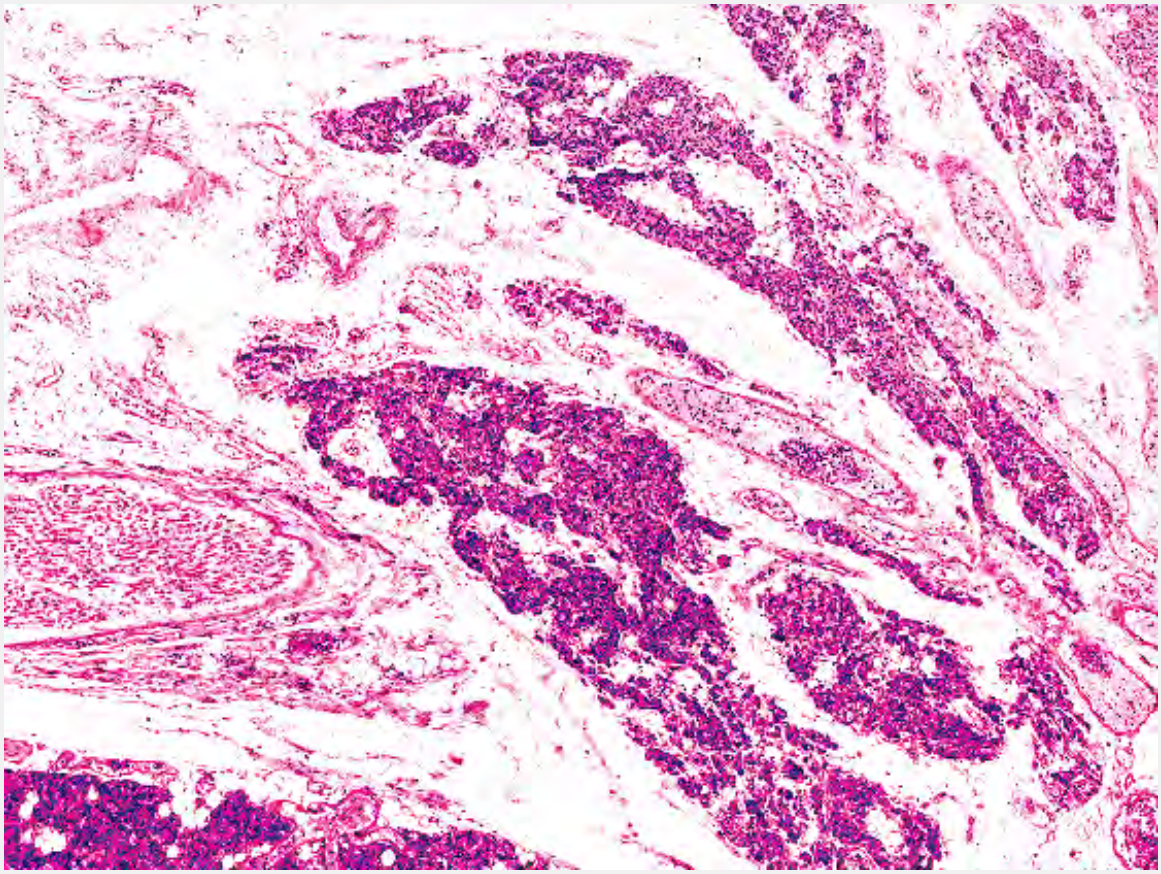

Figure 45.3 Parathyroid gland from a 60-year-old female, divided into several portions by the vascular bundle and recurrent laryngeal nerve.

The lower or inferior parathyroid glands (parathyroid III) have a more diverse distribution but are most commonly located between the lower pole of the thyroid and the thymus (Figure 45.6). They can occur as high in the neck as the hyoid bone, the pharynx, or the pyriform sinus, or as low as the pericardium (89,90). In 42 to 61% of the cases they are located on either side of the lower thyroid or in a

juxtathyroidal location. Another common location is the â€œthymic tongueâ€• or â€œcervical extension of the thymus.â€• Uncommon locations are the mediastinal thymus and the anterior mediastinum (82,83,84,85,86). Ectopic intravagal parathyroid tissue has been reported (91). The gland locations are symmetrical in 80% of patients.

)

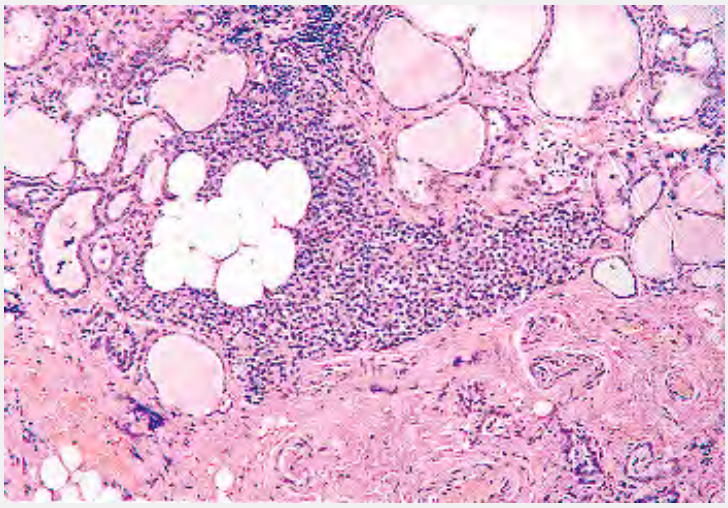

Figure 45.5 A parathyroid gland from a 21-year-old male just below the thyroid gland capsule in the thyroid parenchyma. A large accumulation of adipocytes is present within the parathyroid. Only chief cells are seen within the parathyroid.

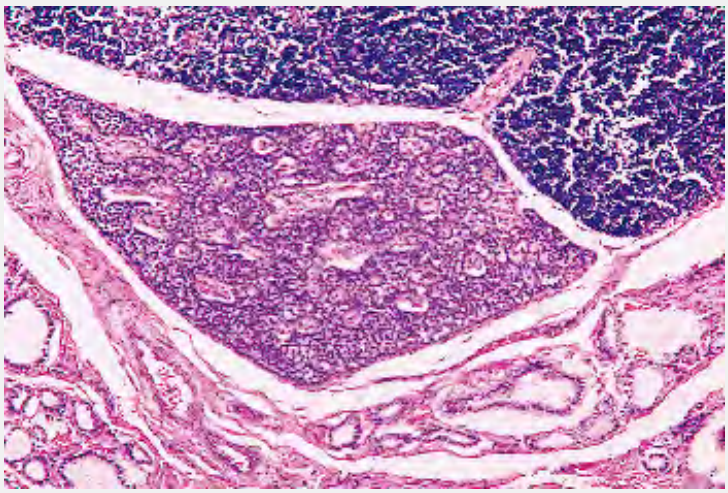

Figure 45.6 A fetal parathyroid (33 weeks' gestation) is seen between the thymus (top) and lower edge of the thyroid

(*bottom*). A small amount of stroma surrounds the parathyroid vessels. The gland is composed of pure tightly packed chief cells.

Gross Appearance, Size, and Shape

Each adult gland measures 3 to 6 mm in length, 2 to 4 mm in width, and 0.5 to 2.0 mm in thickness (Figure 45.7). The shape of the gland varies because it is molded by the adjacent structures. The glands are a flattened, ovoid pancake with â€œsharpâ€• edges. The capsule is grey and almost transparent often with a fine network of small vessels. The underlying parenchyma is yellow to orangeâ€“tan, depending on the amount of stromal fat, the number of oxyphil cells, and degree of vascularity (5). The glands are soft and malleable, although they may show a marked increase in firmness, swelling, and a dark red color if surgical manipulation causes intraglandular hemorrhage. Abnormal glands are usually more bulbous, with rounded edges, and have a firmer consistency and a darker redâ€“tan color (5).

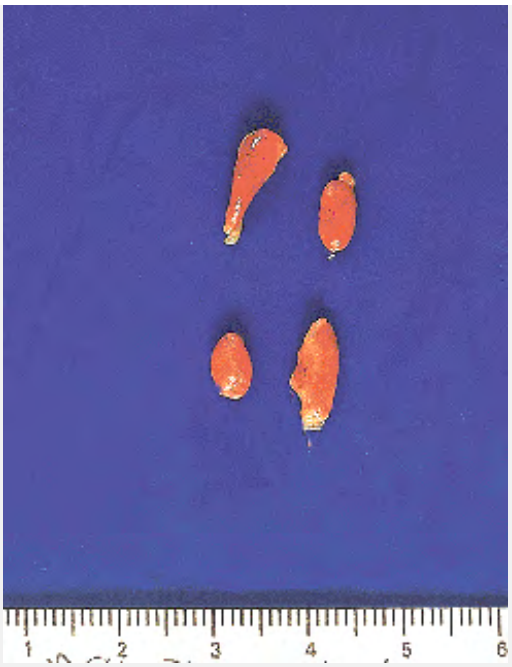

Figure 45.7 Four normal parathyroid glands removed at autopsy from a 53-year-old man.

Gland weight and parenchymal cell content are important parameters used in the histopathologic assessment of the parathyroid gland (92,93,94,95,96,97,98,99,100,101,102), and all parathyroid glands or part of glands removed at surgery must be carefully dissected free of capsular fat or thymic tissue, measured and weighed to the nearest milligram. The total parathyroid weight gradually increases throughout embryonic life, reaching a mean total of 5 to 9 mg at the postpartum age of 3 months (97,98,99). This is followed by a steep linear increase in total parathyroid weight until the third or fourth decade of life, when it levels off at a mean of 120 Â± 3.5 mg in men and 142 Â± 5.2 mg in women (5). The mean weight per gland is 31.1 mg in men and 29.8 mg in women (100). The lower parathyroid glands are larger then the upper glands (97,101). The parenchymal cell content of the glands is extremely variable and difficult to evaluate. It is reported to average 74% of the weight of the gland in

adults (85). It is a somewhat better indicator of gland function than gland weight alone but requires careful morphometric analysis in conjunction with careful evaluation of the total gland weight. The average parenchymal weight per gland is 21.6 mg for men and 18.2 mg for women (100), whereas the mean total parenchymal weight for four glands is 82.0 Â± 2.6 mg for men and 88.9 Â± 3.9 mg for women (96,97,98). The total gland weight has been reported to be higher in blacks than in whites (102). In a selected series of patients with primary hyperparathyroidism due to a single adenoma, who had a second gland totally removed because the surgeon felt the gland was enlarged, 15 histologically normal glands weighed over 60 mg (103). The largest gland weighed slightly over 160 mg. The total (10) and parenchymal (101) gland weight are inversely related to serum calcium concentration in patients with secondary hyperparathyroidism. In these patients a direct relationship has been found between the total gland weight and the serum phosphorus and renal function as expressed by serum urea nitrogen (10).

Histology

The normal parathyroid gland has a thin fibrous capsule that separates it from the adjacent thyroid thymus or adipose tissue (Figures 45.8 and 45.9), which, except for those glands embedded in the thyroid or its capsule, is adipose tissue or thymus. At the vascular pole, an artery and vein are present surrounded by fibrous tissue. These branch into smaller arteries and veins, which form a complex readily visible in the capsule. The capsular arteries and veins are connected by arterioles, capillaries, and venules located in

the fibrous septa between the parenchymal cells (102). This capillary network abuts every chief cell. Due to the rich capillary network, the cut surface bleeds readily, providing an easy way for the surgeon to distinguish the parathyroid from lymph nodes, adipose tissue, thymus, and thyroid, which do not show such prominent bleeding from their cut surfaces. The capillary endothelial lining cells have

pores or fenestrations resembling those seen in other endocrine glands (104,105). Dense bodies, Weibel-Palade bodies, pinocytotic vesicles, tight junctions, or zonulae occludens are constituents of the parathyroid capillary endothelium. Two interconnecting plexuses of lymphatic capillaries in the capsule surround the parathyroid glands. From the inner plexus, loops of lymphatics dip into the gland parenchyma, whereas the efferent lymphatics arise from the outer plexus via special lymphatics or those of the thyroid (106). The interstitial space is limited by the basement membranes of the chief cells and capillaries and contains collagen bundles and elastic fibers (104). Nerve bundles in close proximity to chief cells suggest autonomic innervation (107,108,109,110). In the rabbit the nerves have been shown to originate in the medulla oblongata, the dorsal nucleus of the vagus, and the vagus nerve (107,110).

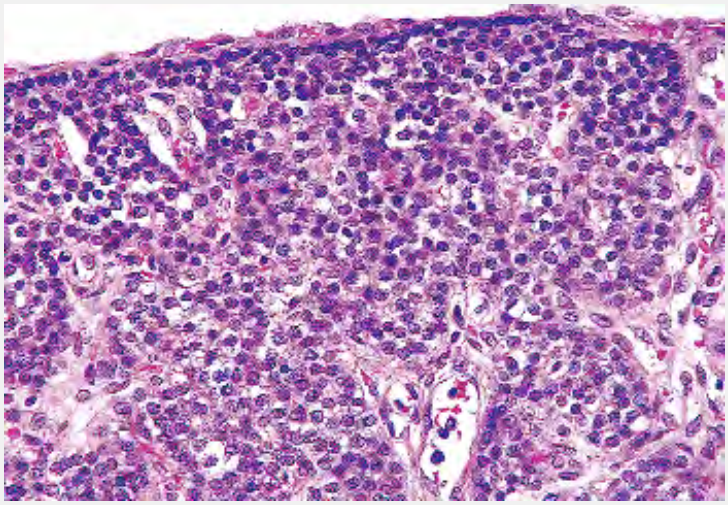

Figure 45.8 A parathyroid gland from a 7.5-month-old girl. The chief cells are the only cell type seen and are arranged in sheets, between the large vascular channels. The capillaries are present between individual chief cells. The chief cells show central regular nuclei and a clear amphophilic cytoplasm. A thin fibrous capsule separates the gland from the stroma.

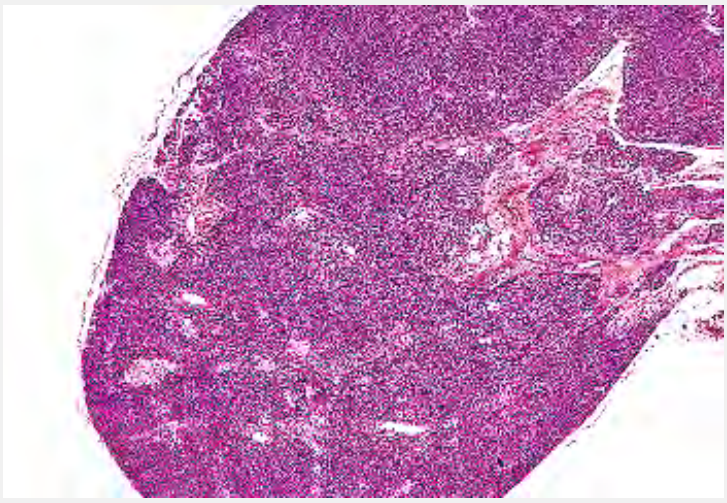

Figure 45.9 A parathyroid from a 27-year-old woman showing only sheets of chief cells and no stromal fat. The vascular pole can be seen at the right margin of the micrograph. A thin fibrous capsule is seen.

In infants and children the interstitium consists only of the capillary network and the extracellular space. Little or no collagen or stroma is present (Figure 45.8). With age, there is focally increasing collagenization of the perivascular stroma. This forms a delicate fibrous septa in adult glands, imparting to them a somewhat lobulated appearance. Surrounding the capillaries and lymphatics are interstitial cells that consist of fibroblasts, pericytes, mast cells, and a few lymphocytes. Adipocytes are sparse in the stroma of infants and children. Stromal fat cells begin to appear late in the first decade of life and increase throughout life. At puberty, especially in women, there is an increased rate of accumulation of adipocytes. Stromal fat cells increase in number with increasing age, reaching a maximum in the third to fifth decades of life. There is a marked variation in the amount and distribution of stromal fat within a single gland, between glands in the same individual, and among individuals

of the same age (Figures 45.8,45.9,45.10,45.11,45.12,45.13,45.14,45.15). Recent studies (96,111,112) confirmed the initial reports of Gilmour (32) that, in adults, adipocytes occupy an average of 50% of the stromal volume rather than of the total parathyroid volume. Women have a higher percentage of stromal fat than do men. The amount of stromal fat is affected by the same factors that affect total body fat; for example, diet, nutrition, chronic illness (such as malignancy), and genetics. These variations make interpretation of the level of parathyroid function difficult to assess on the

basis of the stromal fat. In normal glands, the stromal fat appears to â€œcompressâ€• the surrounding parenchyma; whereas, in hyperplastic or adenomatous glands, the fat cells appear scattered among the parenchymal cells. In the fourth decade there is a relative decrease in parenchymal adipocytes.

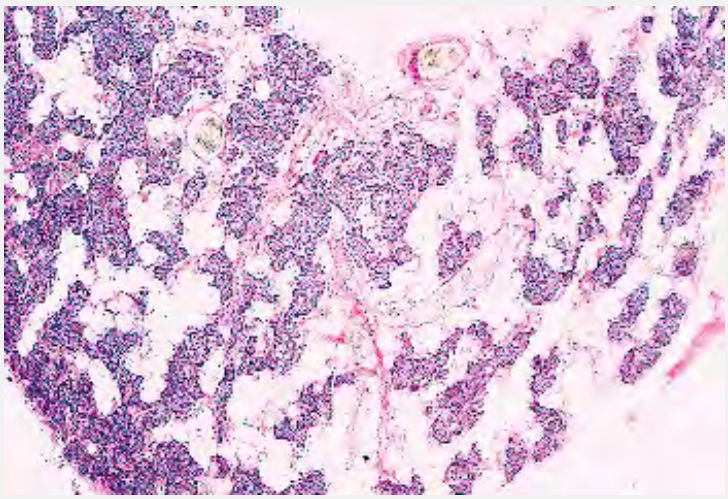

Figure 45.10 Photomicrograph of a parathyroid from a 39-year-old man. There is abundant stromal fat separating the cords of chief cells.

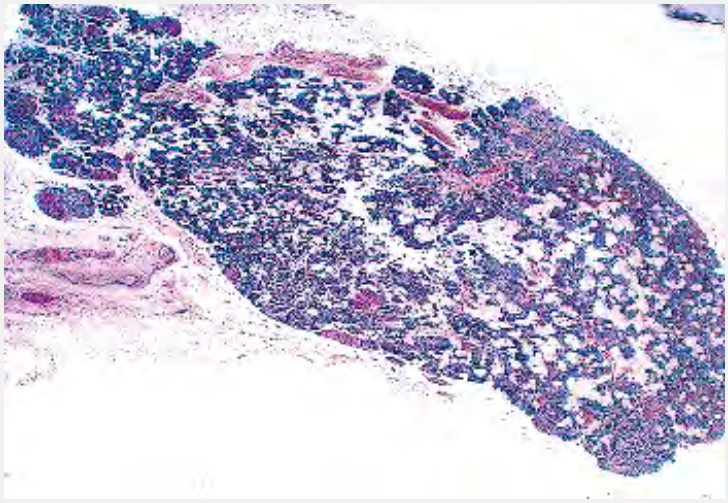

Figure 45.11 A parathyroid from a 69-year-old woman. There is a moderate amount of stromal fat, largely concentrated in the center of the gland. A few small oxyphil nodules can be seen in the parenchyma.

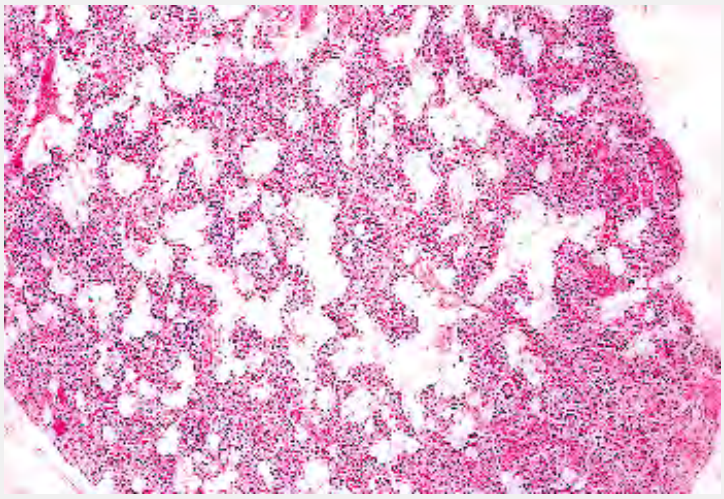

Figure 45.12 A parathyroid from a 76-year-old man. There is a moderate amount of stromal fat, largely in the center of the gland. Small oxyphil nodules are present.

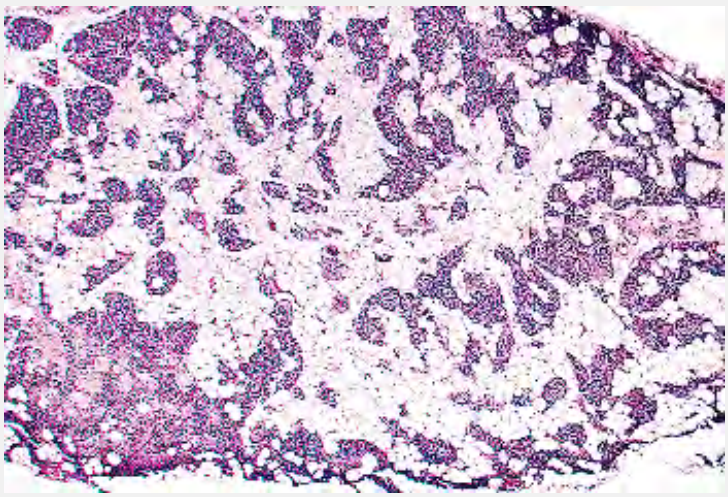

Figure 45.13 A parathyroid from a 77-year-old man with abundant stromal fat. The parenchyma is composed entirely of chief cells.

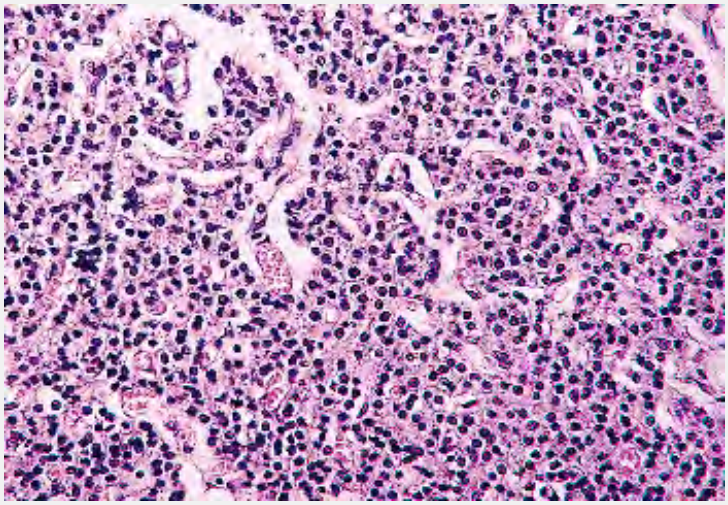

Figure 45.14 A normal parathyroid from a 70-year-old woman showing almost no stromal fat or oxyphil cells.

Each parenchymal cell is separated from the stroma by a prominent basement membrane. The parenchymal cells are arranged in irregular sheets without prominent stroma in infants and prepubertal children. In infants and young children only one type of cell is present, the chief cell. The chief cells of the newborn and infantile parathyroid gland are small and regular, measuring 6 to 8 Âµm in diameter (Figure 45.16). The chief cell membranes are poorly demarcated, and the cytoplasm is amphophilic, relatively lucent, and occasionally vacuolated. Intracellular fat in the chief cells of children is low compared with the adult gland, with only 30 to 40% of the chief cells of children containing large intracellular fat droplets on fat stains (113). The

nuclei are often molded and they overlap. The nuclei are centrally located, with uniform chromatin and small, inconspicuous nucleoli.

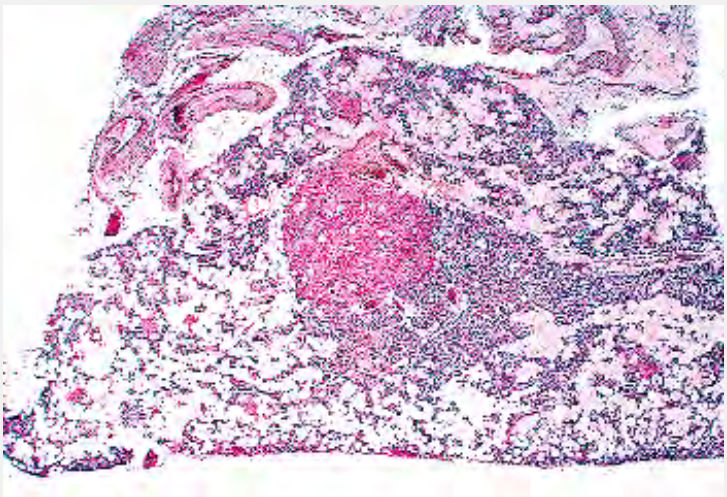

Figure 45.15 A parathyroid gland of a 77-year-old man. The

stroma is almost completely replaced by adipocytes. There is a large oxyphil cell nodule in the center of the gland.

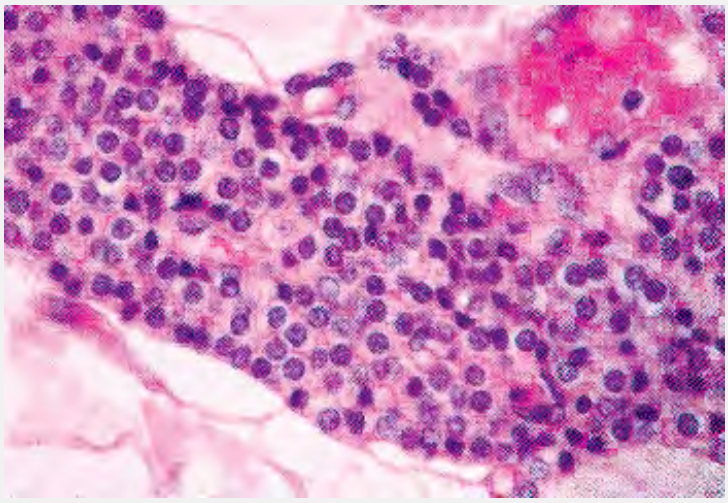

Figure 45.16 Sheets of chief cells in a newborn. The stroma has little collagen and is outside the large sheet. The cell membranes are poorly demarcated. The cytoplasm is eosinophilic.

In the adult, the parenchymal cells are arranged in solid nests, rounded or lobulated masses and trabeculae, or a combination of these (Figures 45.8,45.9,45.10,45.11,45.12,45.13,45.14,45.15,45.16,45.17). A pseudofollicular pattern also has been described in normal glands (Figure 45.18) (114,115,116). Ultrastructural evidence indicates that follicle formation in the parathyroid is the result of a proliferation of parenchymal cells, with ischemic necrosis and degeneration of those cells separated from their blood supply by other parenchymal cells.

These pseudofollicles are usually filled with cellular debris and a pink eosinophilic homogeneous material resembling the colloid seen in thyroid follicles (Figure 45.18) (114). This material contains

glycoproteins, as evidenced by the positive periodic acid-Schiff (PAS) reaction, and PTH as evidenced by immunostaining. Several investigators have further reported that it stains with Congo red and shows the apple-green birefringence characteristic of amyloid (115). A similar finding has been reported in the follicles of pathologic parathyroid glands (116,117). Cinti et al. (114) were unable to confirm either the presence of amyloid or glycoproteins in the follicles of a series of normal parathyroids removed at the time of thyroidectomy. However, electron microscopy of follicles in a pathologic parathyroid gland did demonstrate fibrils closely resembling those of amyloid in pseudofollicles (113).

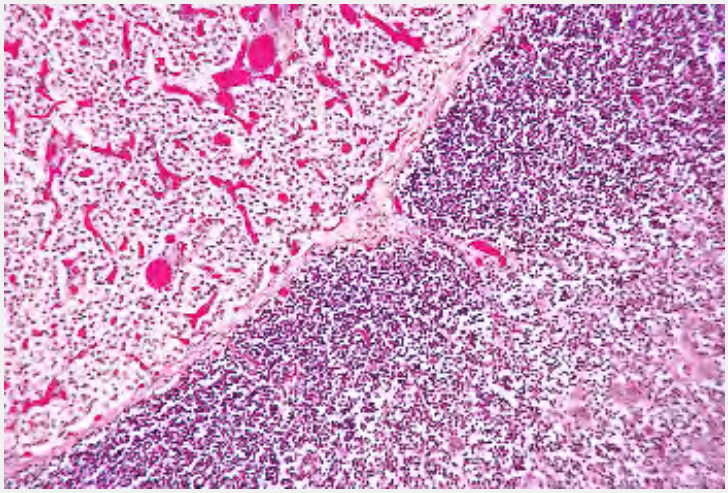

Figure 45.17 Sheets of parathyroid chief cells showing amphophilic clear cytoplasm, adjacent to the thymus. The prominent vascularity of the gland is visible.

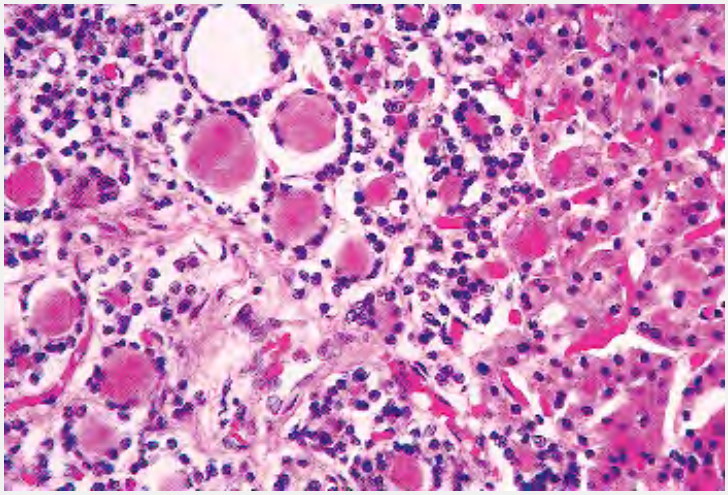

Figure 45.18 Numerous pseudofollicles in a normal parathyroid of a 58-year-old white man. Lining the pseudofollicles are chief cells. At the right of the micrograph is the edge of an oxyphil cell nodule.

There are two types of parenchymal cells recognized by light microscopy in the adult normal parathyroid gland. These are the chief cells (Figures 45.15, 45.18,45.19,45.20), in their active and inactive forms, and the oxyphil cell (Figures 45.15, 45.18,45.19,45.20) (19,118,119). In adults the chief cells are arranged in sheets, cords, trabeculae, and small

nodules. They are spherical and measure 8 to 12 Âµm in diameter. The cell borders are poorly defined. The cytoplasm is amphophilic or faintly eosinophilic, with 70 to 80% of the chief cells containing large prominent fat droplets, (Figure 45.21) (5,17), corresponding to the lipid bodies seen in the resting chief cells by electron microscopy (120). It is of interest that these lipid droplets were first recognized in human chief cells by SandstrÃ¶m (17,18), although he did not appreciate their significance. By ordinary light microscopy, the active chief cell may be difficult to identify. The inactive chief cell may be

recognized by the vacuolated clear appearance of the cytoplasm that is filled with lipid, glycogen, and lysosomes (120,121,122,123). Deposition of silver particles on the secretory granules is responsible for the argyrophil reaction seen in normal parathyroid glands using the Grimelius silver nitrate stain (120,124,125,126). The granules correspond to the location of PTH (Figure 45.22) (127,128,129,130,131) and chromogranin (Figure 45.23) (128). Differences in the parathyroid and chromogranin content of the chief cells indicate a variation in the secretory granule content and supports the presence of a secretory cycle in the parathyroid chief cell. The nuclei are round, centrally located, have a sharp nuclear outline, even chromatin, and small rare nucleoli (5,113).

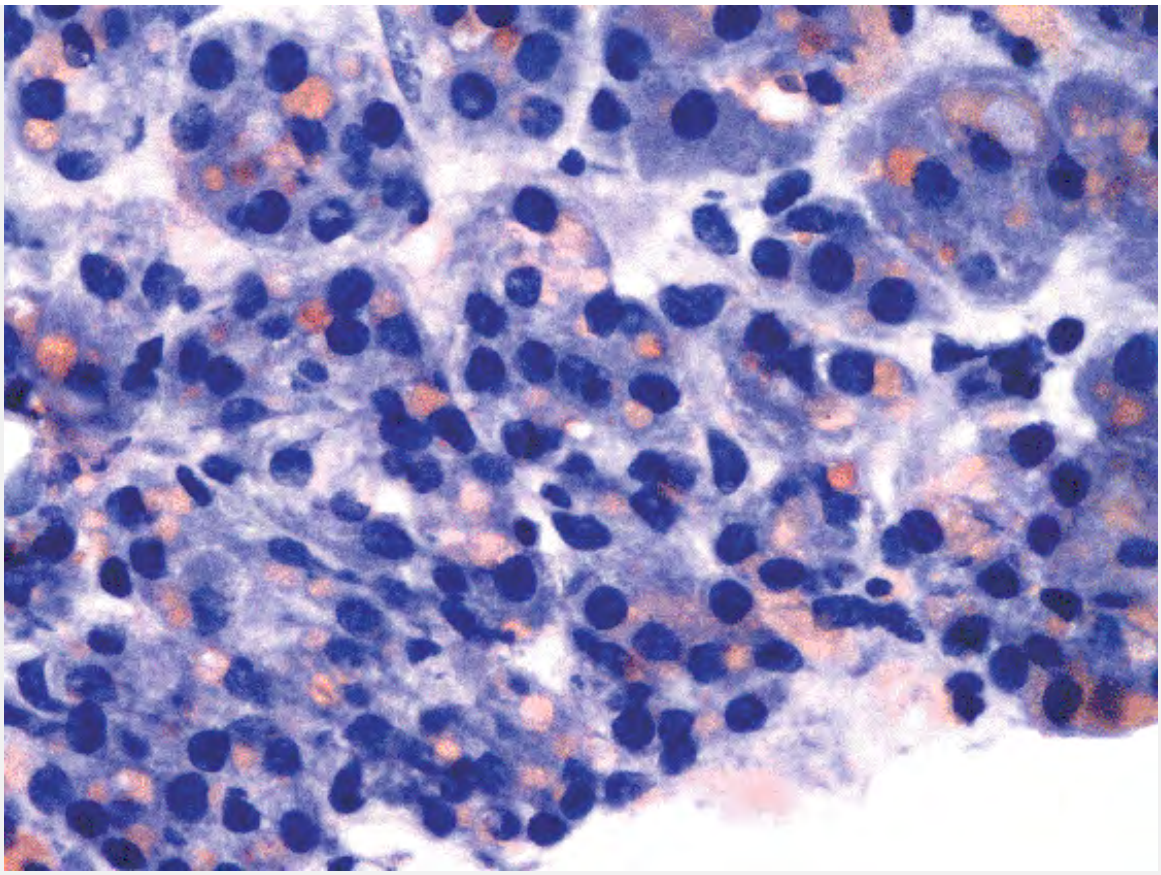

Figure 45.21 Chief cells with intracytoplasmic lipid droplets (Oil-Red-O stain, hematoxylin counterstain).

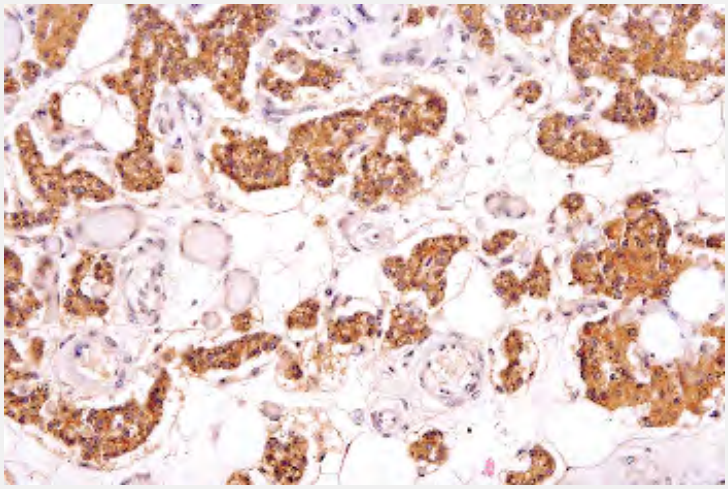

Figure 45.22 Chief cells showing abundant PTH in the parathyroid gland. Note the variation in the amount of hormone in various chief cells. (Immunoperoxidase stain for PTH, hematoxylin counterstain.)

Ultrastructural features of the chief cell correlate with its functional activity (120,121,122,129,130,131,132,133,134,135). The chief cell, considered the basic functional unit of the parathyroid gland, is responsible for the production and secretion of PTH and, in turn, in the maintenance of the homeostasis of ionized calcium (136,137,138,139). To achieve this, each individual chief cell undergoes a secretory cycle (120,121,122,129,130,131,132,133) (Figure 45.24) similar to that of the follicle of the thyroid. Each chief cell is polarized with the Golgi apparatus and granular endoplasmic reticulum farthest from the basement membraneâ€“lined perivascular surface (140).

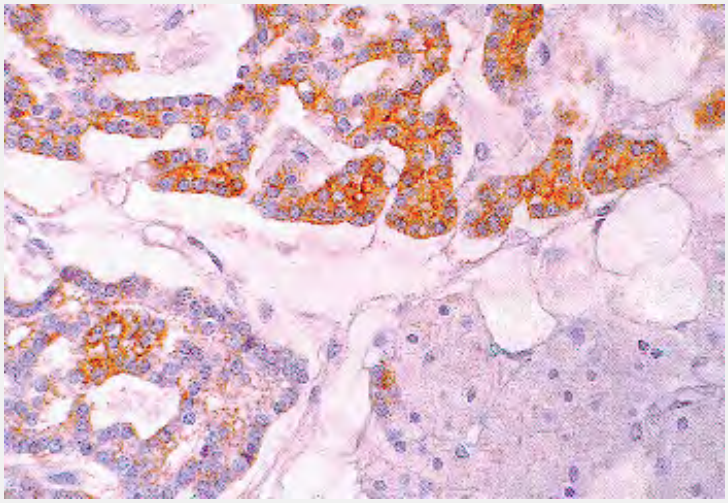

Figure 45.23 Parathyroid gland showing abundant chromogranin in the chief cells. The chief cells have different amounts of chromogranin. The oxyphil cells are free of chromogranin.

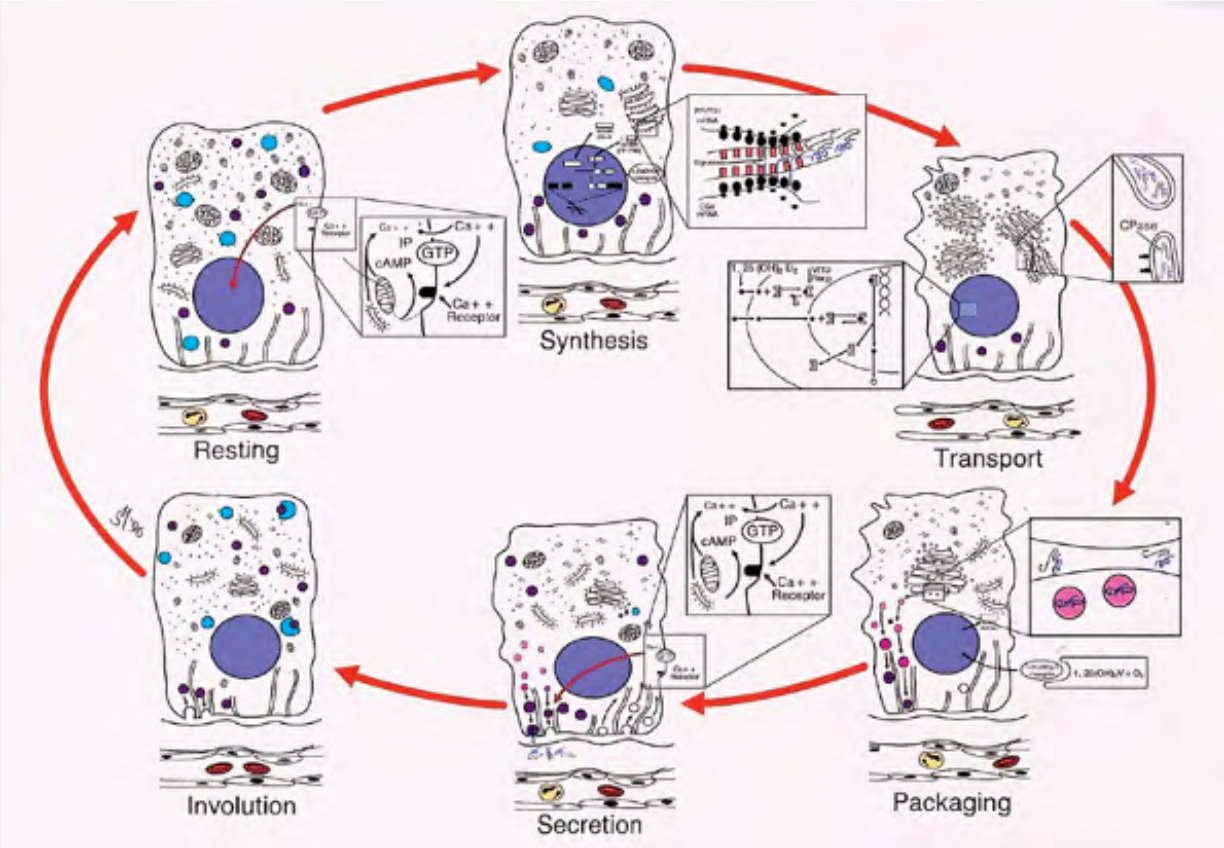

Figure 45.24 Diagram of the secretory cycle of the parathyroid chief cells (derived from electronmicroscopic studies (9). Although these comprise a continuum, typical stages have been recognized ultrastructurally. During the resting phase, the cells are rich in glycogen and lipid bodies with dispersion of the granular endoplasmic reticulum (GER) and free ribosomes. Dense-core secretory granules are relatively uncommon and scattered throughout the cytoplasm. Rare lysosomes are seen. The Golgi apparatus is small and inconspicuous, with few vesicles and vacuoles. The cell membranes are relatively straight with few interdigitations. At the end of the resting phase, presumably due to decreased cytoplasmic [Ca^{2+}] and release of vitamin D, metabolite from the upstream promotor site, the cell begins the process of PTH synthesis. As the synthetic phase begins, transcription of the gene for PTH begins with production of the

complimentary RNA for prepro-PTH and presumably accompanied by a similar transcription of chromogranin. The mRNA is produced by removal of the introns and splicing of the exons. The mRNA moves to the granular endoplasmic reticulum, which aggregates [the perinuclear body of Pappenheimer and Wilens (48)]. This is accompanied by aggregation of the free ribosomes to polysomes. The preprohormone crosses into the lumen of the GER, where the preportion of the molecule is removed by a ligase. Other alterations include depletion of the dense-core granules, lysosomes, glycogen, and lipid bodies. The cell membrane increases in tortuosity, probably due to loss of cytoplasmic volume. The synthesis and secretion of hormone is halted, presumably by the action of 1Î±,25 dihydroxyvitamin D on the upstream promotor region of PTH and the cytosolic [Ca^{2+}]. In the transport phase, the hormone, supposedly accompanied by chromogranin, is transported through the cisternae of the GER to the Golgi apparatus as the pro segment is removed by a â€œclipase.â€• The hormone is conveyed to the Golgi vesicles. Further depletion of lipid bodies, glycogen, and secretory granules occurs, and the cisternae of the GER disperse. In the packaging phase, the hormone is bundled along with chromogranin into dense-core granules and the Golgi apparatus begins its involution. Secretion occurs as the dense-core granules containing PTH and chromogranin move along the microtubules, fuse with the cell membrane, and release the hormone into the pericapillary extracellular space. Depending on the ambient [Ca^{2+}], the granules are rapidly passed along the microtubules and secreted (low [Ca^{2+}]) or left free in the cytoplasm (high [Ca^{2+}]), to be destroyed by lysosomes or to be secreted at a later time. The Golgi continues to decrease in size and complexity. The free ribosomes disaggregate. The cells begin to involute toward the resting phase with gradual loss of secretory granules and further involution of the Golgi apparatus. The cells begin to accumulate glycogen and lipid bodies and

approach the resting phase. Lysosomes containing acid phosphatase accumulate in the cells. These presumably serve to destroy excess hormone and unsecreted secretory granules. (Modified with permission from:
Roth SI. Parathyroid glands. In: Damjanov I, Linder J, eds. *Anderson's Patology.* 10th ed. St. Louis: Mosby-Year Book; 1966:1980â€“2007.
)

The resting phase, which corresponds to the inactive chief cell, is characterized by accumulation of glycogen and large lipid bodies that correspond to the lipid seen by light microscopy (see Figure 45.21). The rest of the cell organelles, the Golgi apparatus, the granular endoplasmic reticulum, and secretory granules are small and inconspicuous. This is best seen in the chronically suppressed cell in atrophic parathyroid glands (120,121,122,129,132,134,135). During this stage, lysosomes (141) as well as variable numbers of small dense-core secretory granules are present, the latter being peripherally located. Sacs of granular endoplasmic reticulum are dispersed throughout the cytoplasm, whereas free ribosomes are only partially aggregated into polysomes. The Golgi apparatus is small and inconspicuous, with few vacuoles and prosecretory granules. The cell membranes are straight with few interdigitations (104).

The synthetic phase is marked by the parallel aggregation of the cisternae of rough granular endoplasmic reticulum and is noted at the light microscopic level by the presence of the body of Pappenheimer and Wilens (120,142). Free ribosomes aggregate into polysomes. It is during this phase that prepro-PTH and chromogranin (120,134) are synthesized within the granular endoplasmic reticulum. During the next phase, the prohormone is split and transferred to the Golgi apparatus which begins to enlarge with

increases in smooth membranes, vesicles and vacuoles, and prosecretory granules of different electron densities. As the packaging phase emerges, the granular endoplasmic reticulum disperses throughout the cytoplasm, and larger dense-core secretory granules appear in the Golgi region, gradually moving to the periphery. PTH and chromogranin A are present in the aggregated granular endoplasmic reticulum and dense core granules (128,129). As the secretory granules progress along the microtubules toward the cell surface, there is an involution of the Golgi apparatus; acid phosphatase appears at the secretory face and eventually is transferred into large lysosomes (141). Separation of the secretory granules from the microtubules into the cytoplasm could account for the second compartment of PTH storage postulated by Cohn and MacGregor (136). The cell cytoplasm in the synthetic and secretory phases becomes depleted of glycogen and lipid bodies. During the last phase, there is margination of the lysosomes and secretory granules, fusion of the plasma membrane with that of the secretory granules, and emptying of the products into the extracellular space. The membranes of the secretory granules and lysosomes are probably recycled (143). Shannon and Roth (141) and Hashizume et al. (144) demonstrated that the stored parathyroid secretory granules fuse with lysosomes which provide a mechanism for intracellular degradation of PTH. The chief cell returns to the resting phase with a resultant accumulation of glycogen and complex lipid bodies, which are the best indicators of the resting or functionally suppressed cell. In chronically suppressed normal glands adjacent to a hyperfunctioning adenoma, 90 to 95% of the chief cells are inactive. In comparison, the normal adult gland has 70 to 80% of the chief cells in the resting phase, and the normal prepubertal gland has 30 to 40% in the resting phase (113,121).

Correlative morphologic studies in normal, adenomatous, and hyperplastic glands have shown that the intracellular content of fat in the chief cells is inversely related to its endocrine activity and is a better indicator of hormonal function than is the stromal fat. An

increased cytoplasmic lipid content is a feature of a functionally suppressed chief cell (120,121,145,146,147,148,149,150), whereas hormonally active cells of adenoma and hyperplasia are largely in the active stages of hormone synthesis and secretion and thus are fat depleted. Based on this fact, evaluation of intracellular fat content by Oil-Red-O stain (Figure 45.21) has been demonstrated to be useful in differentiating between normal and adenomatous or hyperplastic parathyroid glands (141,142,143,144,145,146,147,148,149,150). Care must be taken in interpreting these fat stains because some areas of adenomas and hyperplasias may contain intracellular fat (151,152,153,154).

Cell culture studies (155,156) using a sequential hemolytic plaque assay confirm the cyclical secretion of both PTH and chromogranin A by individual parathyroid cells. Roth and Raisz (134) demonstrated that the ambient ionized [Ca^{2+}] controls the length of the resting phase of the chief cell cycle. Proliferation of parathyroid chief cells is also controlled by the ambient ionized [Ca^{2+}] (157). Molecular studies (158) have shown that the mechanism of this control may be via depression of cyclins D1 and D2.

The second cell type in the adult gland is the oxyphil cell (see Figures 45.9, 45.12, 45.15, 45.17, 45.19, and 45.25). These are felt to be derived from the chief cells (99,159,160,161,162), although the stimulus for the development of oxyphil cells has not yet been identified. Before puberty, only extremely rare oxyphil cells are present in the glands. Beginning at puberty and increasing throughout life, increasing numbers of these cells appear (159). They are distributed among the chief cells as individual cells, sheets, and small or large nodules (5,113), indicating that there is both a continual transformation (see Figures 45.19, 45.20, and 45.24) from the chief cells and clonal proliferation of the oxyphil cells (160). Rarely, these nodules enlarge enough to be visible grossly. When this happens, it is not possible to differentiate these presumably nonfunctioning oxyphil nodules from functioning oxyphil adenomas (5). The normal oxyphil cells contain only minimal PTH or

chromogranin (see Figure 45.23).

Oxyphil cells in multiple organs, including abnormal parathyroid glands, have been demonstrated to contain decreased cytochrome oxidase (163). Studies on oncocytic salivary gland tumors (164) manifested decreased concentrations of mitochondrial enzymes when measured against the amount of mitochondrial protein. This is in contrast to histochemical studies showing marked increases in mitochondrial

enzymes (165,166,167). These studies, along with the fact that oxyphil cells increase with age, suggest that there is a mitochondropathy, which may lead to the proliferation of the mitochondria within the cells. PTH-related peptide has been described in oxyphil cells (168), although its function is not clear.

The oxyphil cell measures 12 to 20 Âµm in diameter and has a clearly demarcated cell membrane, a pyknotic nucleus, and abundant eosinophilic granular cytoplasm (Figure 45.25), rich in mitochondria and resembling the HÃ¼rthle cells of the thyroid or the oncocytes of other endocrine organs (159,160,161,162). Ultrastructurally, their cytoplasm is completely filled with mitochondria, often with a bizarre shape and size, as well as occasional lysosomes and lipofuscin granules (120). Their function is unknown; however, the oxyphil cells in normal glands do not seem to contain the organelles responsible for PTH synthesis and secretion [i.e., granular endoplasmic reticulum, Golgi apparatuses, and secretory granules (119,120)], as indicated by electron microscopy and the absence of PTH and chromogranin (see Figure 45.23). However, cases of functioning oxyphil cell adenomas (5,6,169) and chief cell hyperplasias (121) have been reported. Protein secretory and synthetic organelles and dense core granules have been demonstrated in these tumor cells.

Transitional oxyphil cells may be recognized by light microscopy by the decreased density of their cytoplasmic eosinophilia. By electron microscopy, these cells have lesser numbers of mitochondria and

some of the organelles associated with PTH synthesis and secretion, such as granular endoplasmic reticulum, Golgi apparatuses, and dense-core secretory granules. Both forms of oxyphil cells contain sparse amounts of lipid droplets (150,151).

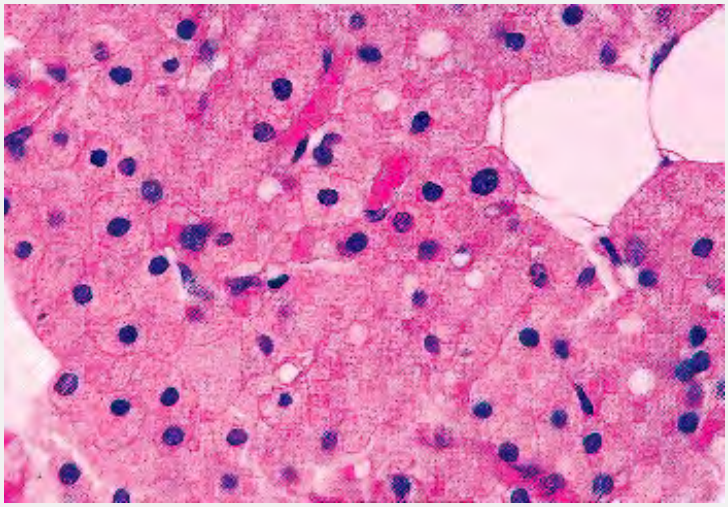

Figure 45.25 Oxyphil cells of the parathyroid in an 80-year-old woman. The centrally located, variably sized, pyknotic nuclei are seen within the granular eosinophilic cytoplasm. The cell membranes and the vascular channels are easily visible.

Cytology of previously localized tumors has been proposed as useful in the preoperative identification of parathyroid neoplasms (170,171,172,173). Intraoperative imprints of tumors and normal glands may allow differentiation of adenomas and hyperplasia (174,175,176). Touch preps or smears from normal glands (Figure 45.26) show small nests or flat sheets of chief cells, with attached stromal fat, as well as naked nuclei in the background. Microfollicles may be present. The nuclei are round to oval and slightly pleomorphic with granular chromatin. The chief cells have pale vacuolated cytoplasm, some with intracytoplasmic lipid droplets (Figure 45.26). Oxyphil cells, with abundant cytoplasm and small,

centrally located nuclei, may be

identified as well. In contrast, the cytology of parathyroid adenomas shows large dense clusters of crowded cells with increased pleomorphism and decreased intracytoplasmic lipid. (177).

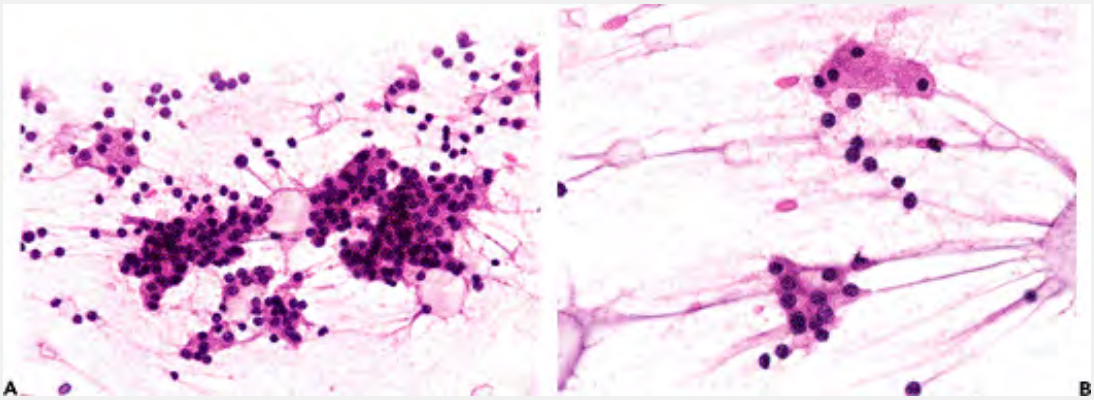

Figure 45.26 A. Parathyroid gland smear preparation obtained at autopsy, showing sheets and nests of parenchymal chief cell with attached stromal fat and naked nuclei in the background. B. Intracytoplasmic lipid droplets can be seen as well (Hematoxylin and eosin).

The use of pure histologic criteria in the estimation of the functional or hormonal activity of the gland and in the differentiation between normal, hyperplastic, and adenomatous glands is difficult. The gland size and weight, the shape, and the relative proportion of stromal adipocytes and chief cells are all important criteria in making these distinctions. Account must be taken of the number of oxyphil cells because in normal glands, but not adenomas or primary hyperplastic glands, oxyphil cells are nonfunctional. We have found that the appraisal of these elements, along with the patient's clinical history, and evaluation of cellular cytology and intracellular fat content of the

chief cells, all must be carefully considered in arriving at a proper pathologic diagnosis.

Footnotes

[1] Though hyperplasia is commonly used to describe the pathology of primary hyperplasia involving all four glands, studies of patients with multiple endocrine neoplasia and familial disease (2) demonstrate that these are in fact neoplastic diseases.

[2] Result of a hetologous deletion of a portion of the long arm of chromosome 22(del22q11.2), containing *Tbx1.*

Ricardo V. Lloyd

Introduction

The paired adrenal glands are a composite of two endocrine organsâ€”one steroid producing, the other catecholamine producingâ€”that are located in the retroperitoneum, superomedial to the kidneys. The two organs have a different embryonic origin, histology, and function.

Anatomy

The main portions of the adrenal gland are easily recognized on the fresh or formalin-fixed cut surface (Figure 46.1). Externally, a relatively thick yellow layer is applied to a narrow dark brown band that abuts on a solid, pearly gray interior. The former two zones correspond histologically to the zona fasciculata and zona reticularis of the cortex, and the latter to the medulla of the organ.

The anatomic location of the human adrenal glands, which sandwiches them between several organs, is responsible for their particular shape: pyramidal on the right and crescent shaped on the left. The depression and ridge (crest) on the posterior surfaces (Figure 46.2) result from their close relationship to the kidneys.

When a kidney is congenitally absent, the corresponding adrenal is round and the characteristic longitudinal ridge on the posterior surface is missing (1).

Evolution

The anatomic relationship of the adrenal cortex to the medulla that exists in mammals is not found in lower animals. In the shark, for example, the cortex and medulla are topographically completely separate; in amphibians, the two structures are in close contact; in birds, they are

intermingled. Only in mammals does the intimate proximity seen among the human adrenal cortex and medulla occur. In a prototypic mammal (e.g., the rat), the medulla forms a central core that is uniformly surrounded by the cortex. The distribution of the two zones in the human adrenal is different. In the human adrenal (Figure 46.3), most of the medulla is in the head of the gland (medial), some occurs in the body, and there is usually none in the tail (lateral) (3). Two bands of cortex applied one to the other form the alae of the glands.

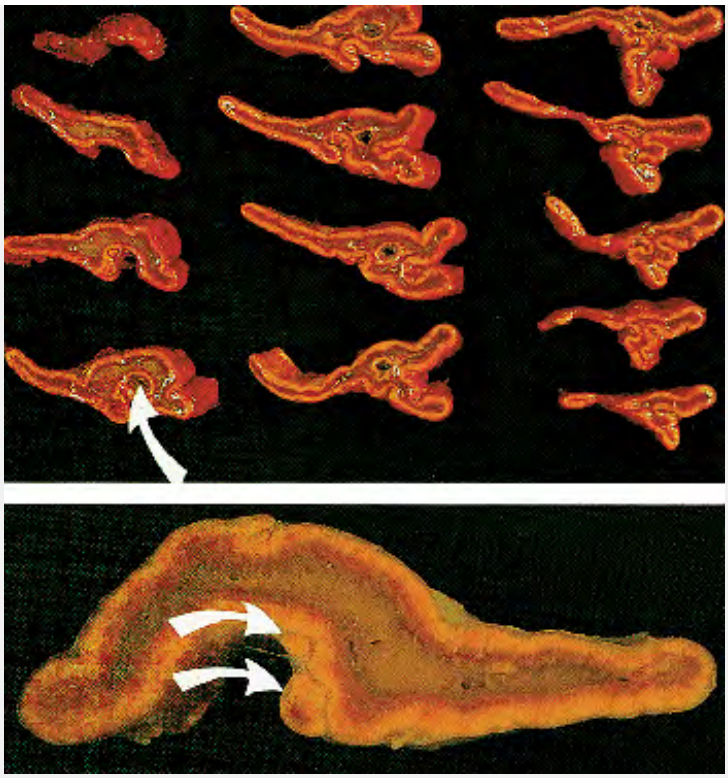

Figure 46.1 Normal adrenal gland. Top: Fresh gland sliced from head (*upper left*) through body (*center*) to tail (*lower right*). The yellow cortex and pearly gray medulla are visible in the head (*left*). Yellow zona fasciculata surrounds dark brown zona reticularis in the tail (*right*), where medulla is absent. The gland can be identified as the left adrenal because on this side the adrenal vein runs in a well-developed groove on the surface of the gland at the junction of the head and body (*arrow*). Invaginated cortex surrounds the central vein in the interior of the body. Bottom: Slice of formalin-fixed adrenal gland showing, from exterior inward, cortical zona fasciculata (yellow), zona reticularis (brown), and medulla (gray). The cortex is about 1 mm in thickness. Dilated tributaries of the central vein are seen in the medulla. The adrenal vein has been removed from its groove. Nodules of accessory cortex are present (*arrows*).

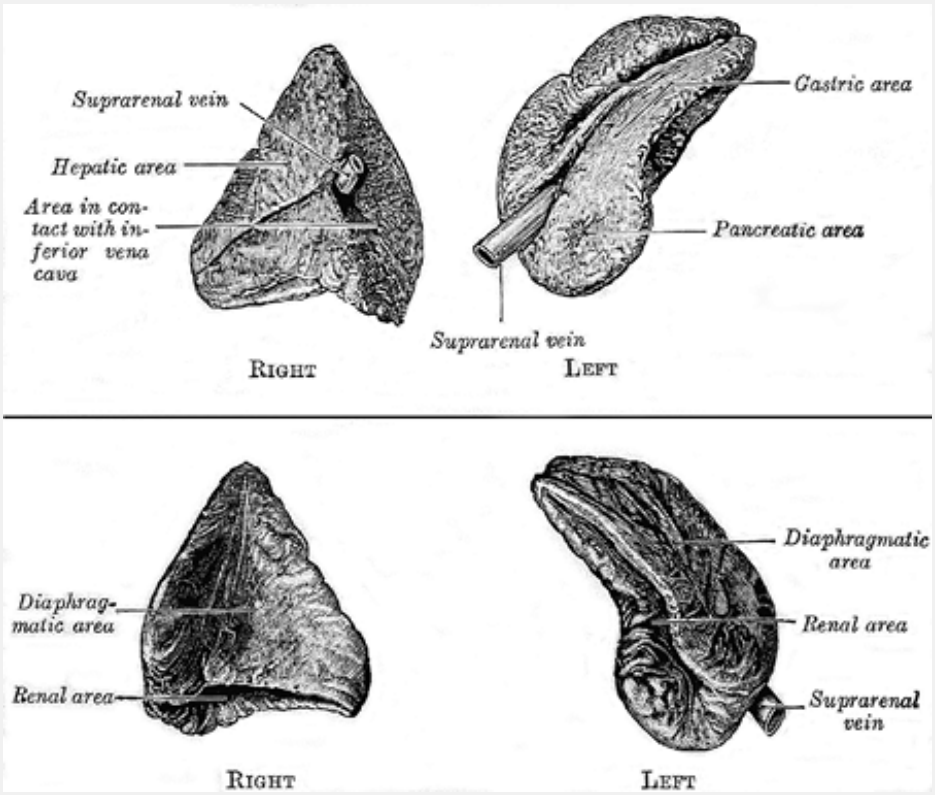

Figure 46.2 External appearance of anterior (*above*) and posterior aspects (*below*) of right and left adrenal glands. The right gland is pyramidal, and the left is crescent shaped. The right adrenal vein is short. The left vein is longer and lies in a groove on the anterior surface of the gland. (Reprinted with permission from:
Goss CM, ed. *Gray's Anatomy of the Human Body*. 29th ed. Philadelphia: Lea & Febiger; 1973.
)

Development

Cortex

The adrenal cortex is of mesodermal origin. Its primordia appear at the 9-mm embryo stage (6th week of gestation) as bilateral cellular aggregations (Figure 46.4) at the mesenteric root, medial to the developing gonad and anterior to the kidney (mesonephros) (4,5). These primordia are composed of two groups of mesenchymal cells: one destined to be the precursor of the transitory provisional or fetal cortex, the other to become the adrenal capsule and its supporting connective tissue framework (5). By the 7th week of gestation, the primordia have become more defined, have separated from the coelomic lining, and include polyhedral cells with eosinophilic, lipid-poor cytoplasm. These cells increase in size and proliferate rapidly, forming a series of parallel columns and cords of cells that ultimately compose the bulk of the provisional cortex. External to this dominant mass, a thin subcapsular

rim of smaller cells (the precursor of the permanent or adult cortex) appears (Figure 46.5). These cells are arranged in nests and arches that cap the columns of deeper cells. They have hyperchromatic, closely packed, overlapping nuclei. The nuclei are larger, more vesicular, and less hyperchromatic in the cords. Continuous, spottily distributed degeneration of the cells is found in the cords, and dead cells (apoptosis) are continuously replaced by the proliferation of cells in the narrow subcapsular band. Growth of the developing cortex is therefore centripedal (from outside inward).

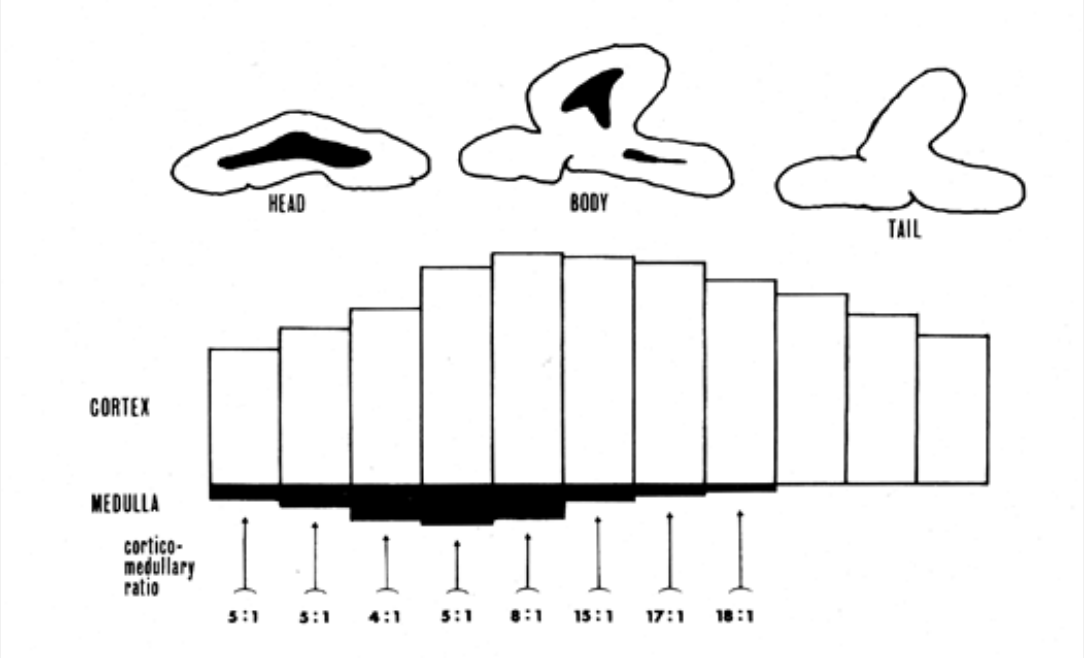

Figure 46.3 Diagrammatic illustration of the distribution of medulla (black) in the head, body, and tail of the adrenal gland (*above*) and corresponding corticomedullary ratios (*below*). (Reprinted with permission from: Symington T. *Functional Pathology of the Human Adrenal Gland.* Baltimore: Williams & Wilkins; 1969.)

At the end of gestation, the provisional cortex accounts for the bulk of the gland (Figure 46.6). Within hours of birth, it becomes acutely congested and starts to degenerate. At the end of 7 to 10 days, the provisional cortex is largely disorganized and necrotic. The narrow peripheral band of cell clusters survives and becomes the source of the permanent cortex.

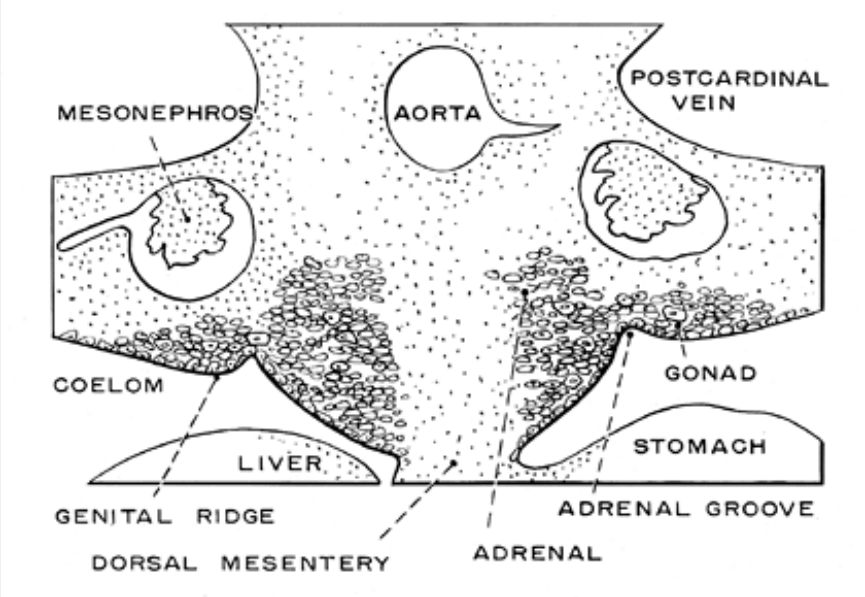

Figure 46.4 Diagrammatic representation of a human embryo at 6 weeks' gestation showing the anatomic relationship of developing adrenal gland to coelomic cavity, gonad, and kidney (mesonephros). (Reprinted with permission from: Dahl EV, Bahn RC. Aberrant adrenal cortical tissue near the testis in human infants. *Am J Pathol* 1962;40:587â€“598.)

Medulla

The adrenal medulla is of neuroectodermal origin (5). Precursor cells originate in the neural crest and migrate from primitive spinal ganglia (sixth thoracic to first lumbar) to form the primitive sympathetic nervous system situated dorsal to the aorta. Sympathogonia cells (from the sympathetic anlagen) migrate farther into nerves that sprout from the sympathetic chain, then move alongside large blood vessels that penetrate into the (as yet) unencapsulated fetal adrenal cortex, primarily at its caudal pole

(head). [This very likely explains the nonuniform distribution of medulla in the adult adrenal mentioned previously.] The neural cells enter the adrenal primordium as fingerlike processes and pass among the fetal cortical cells. In this manner, sympathogonia and a plexus of nerves are initially scattered among fetal cortical cells (Figure 46.7). Two sets of progeny of the sympathogonia evolve: the majority, small cells with little cytoplasm and

a darkly staining nucleus (neuroblasts); the minority, larger cells with a vesicular nucleus and basophilic cytoplasm (pheochromoblasts). At birth, the medulla comprises a central, very thin core of these cells with offshoots stretching a short distance into the peripheral degenerating provisional cortex. The medullary cells are arranged in irregularly sized clumps containing both cell types, the larger cells now predominating. The postnatal collapse of the provisional cortex and its stroma removes the framework that supported the medullary offshoots and their associated nerve plexus in the cortex (3). With this loss of scaffolding, these structures coalesce around the central veins.

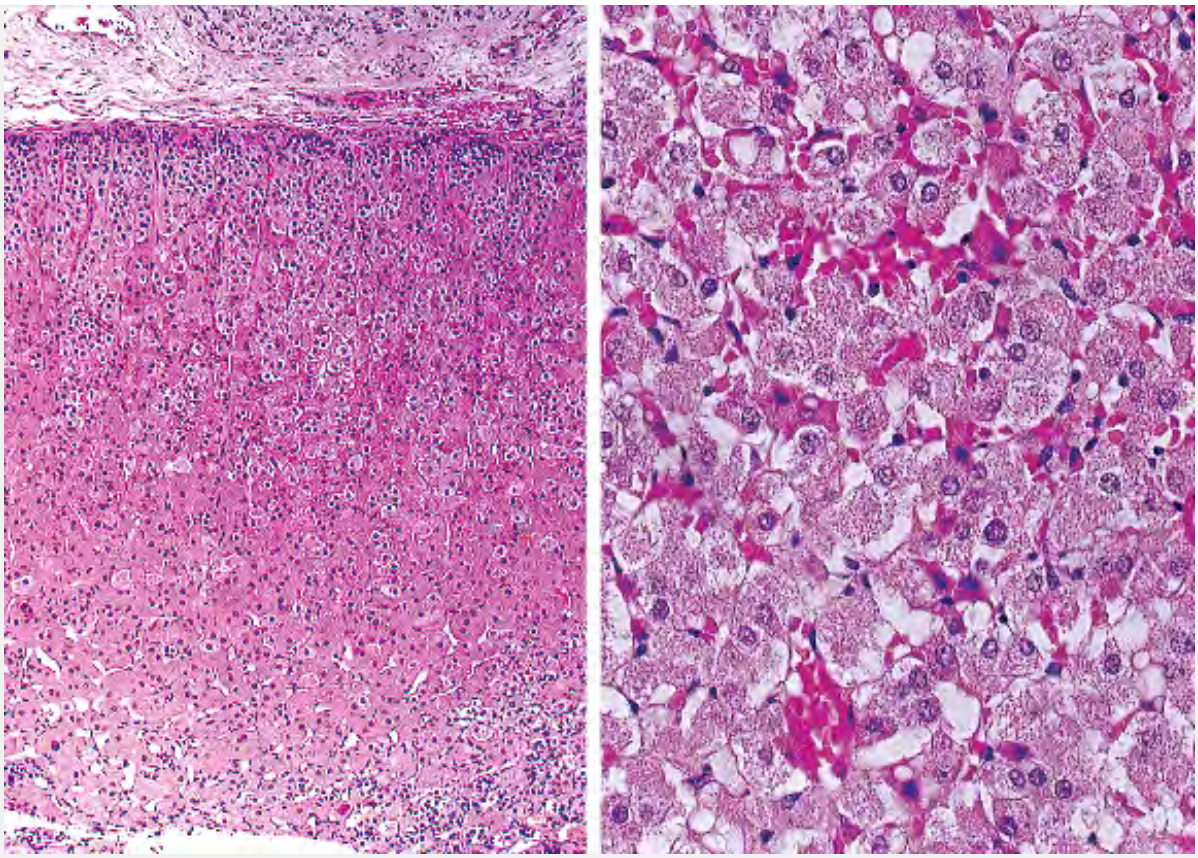

Figure 46.5 Provisional (fetal) cortex (29 weeks' gestation, stillborn infant). A. Cortex is dominated by large cells with eosinophilic cytoplasm in vague columns and solid sheet with prominent capillaries. Just beneath the tenuous capsule, there is a rim of smaller cells, the source of the permanent cortex. A sympathetic ganglion and a small nerve are present in the periadrenal connective tissue. B. Large, liverlike cells with cytoplasm that is voluminous, eosinophilic, and granular. Nuclei are vesicular with a single small nucleolus. Vascularity is prominent.

Figure 46.6 Adrenal cortex at birth (35 weeks' gestation; infant died at 2 days). The central, degenerating, eosinophilic provisional cortex is surrounded by the developing, darkly staining outer rim of permanent cortex.

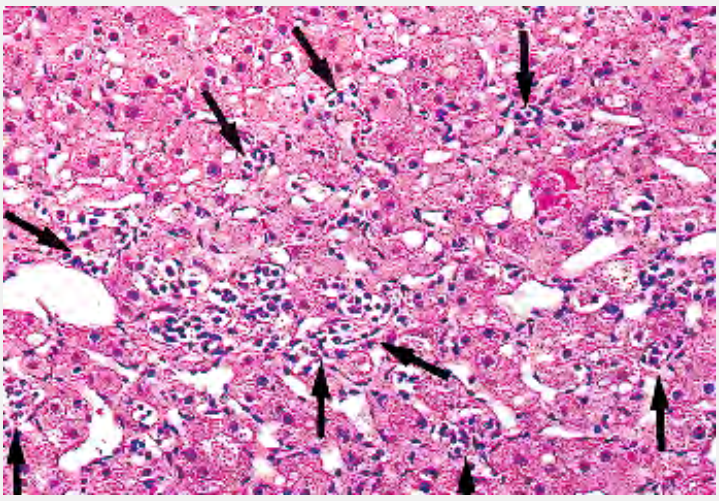

Figure 46.7 Developing adrenal medulla (29 weeks' gestation, stillborn infant). Clusters of small medullary cells with deeply

staining nuclei (*arrows*) irregularly distributed in very vascular provisional cortex. When the latter degenerates, the clusters of medullary cells survive and, lacking the support of the cortical cells, aggregate together.

Gland Weight and Cortical Thickness

Although not a structural feature of the adrenal, the weight of the glands is important because assessment of the adrenal normalcy takes this feature into account. Information on truly normal adrenal weight is difficult to obtain because the organ (specifically the cortex) responds rapidly to stress by an increase in mass. Therefore, accurate normal adrenal weight can be determined only from selected autopsy material (e.g., healthy individuals who die suddenly). The combined adrenal weight in these circumstances is about 8â€“9 g (1). Exceptionally, a gland weighs as little as 2 g or as much as 6 g. Sex differences are not apparent. Formalin fixation has little effect on the gland weight.

Relative to body weight, the adrenals are actually largest at the 4th month of gestation (2). In unselected autopsy cases, the combined average weight of the glands at birth is about 20 g. By the end of the 1st week of life, this mass has decreased (as a result of involution of the provisional cortex) to about 12 g, and a further small decrease occurs during the 2nd week, such that each gland comes to weigh approximately 5 g. Total gland weight then remains constant for 2 years, then gradually rises to the adult postmortem weight of about 13 g between 15 and 20 years of age (3).

The thickness of the normal adult adrenal cortex is approximately 1 mm and ranges from about 0.7 to 1.3 mm. For accuracy, the thickness should be determined microscopically with an ocular micrometer; it is impractical to detect small alterations in the thickness using a metric scale.

Adrenal Glands for Histologic Study

Ideal Material

Ideally, for the reasons already mentioned, adrenal glands used for study of normal histology of the organ should be obtained from healthy patients. Results obtained from the study of glands of patients with primary adrenal disease or disorders that might affect the adrenal histology secondarily should be used with caution. Nevertheless, because the two portions of the adrenal gland, cortex and medulla, are separate functional units that apparently do not affect each other, we think that it is not unreasonable (until shown to be otherwise) to study, for example, the histology of the adrenal medulla (thinking of it as being normal) in a gland surgically removed for a clinically and biochemically nonfunctioning small adrenocortical adenoma. Similar considerations apply to the cortex.

For study of cytologic detail, material should be fresh and not autolysed and therefore obtained at surgery or shortly after death. The zona reticularis of the cortex quickly begins to show the effects of anoxia (degeneration). However, glands that are less than optimally preserved for study of the cell details are satisfactory for determination of general microanatomy of the organ. In practice, fresh (and to a variable extent â€œnormalâ€•) adrenal is most often available at the time of radical nephrectomy, in the course of which a gland is removed with the kidney. However, many such glands are torn during the surgical procedure, limiting to some extent their use for study of normal histology. Their usefulness is also limited in that they are representative only of the gland appearance in a particular age range (middle-aged or older patients). In practice, it is difficult to get the complete range of normal adrenal specimens (fetal to aged) that would be ideal for study of normal histology.

Actual Material

The actual tissue used for the histologic description that follows included adrenals from all the foregoing categories. Autopsy material was obtained from individuals (mostly male) who died suddenly (homicide, suicide, or traumatic injury). For some cases there was minimal or no medical history available, and the autopsy protocol and other autopsy slides could not be reviewed. Thus, the state of health of these patients and the condition of other organs could not be determined. A number of normal glands were available from patients undergoing nephrectomy. Also, opportunity was taken to study apparently normal extratumoral medulla and cortex in cases of adrenalectomy for certain primary adrenal neoplasms that were small or relatively small (adrenocortical adenomas producing aldosterone, nonfunctioning adrenocortical adenomas, and pheochromocytoma).

Histology

Blood Vessels

The blood supply of the adrenal gland has been studied mostly from the anatomic point of view, often by observing

the distribution of injected material in the vasculature. The tone of the subcapsular vascular plexus controls circulation through the organ. The histologic appearance of the vessels distal to the plexus suggests that the intravascular pressure in the organ is low.

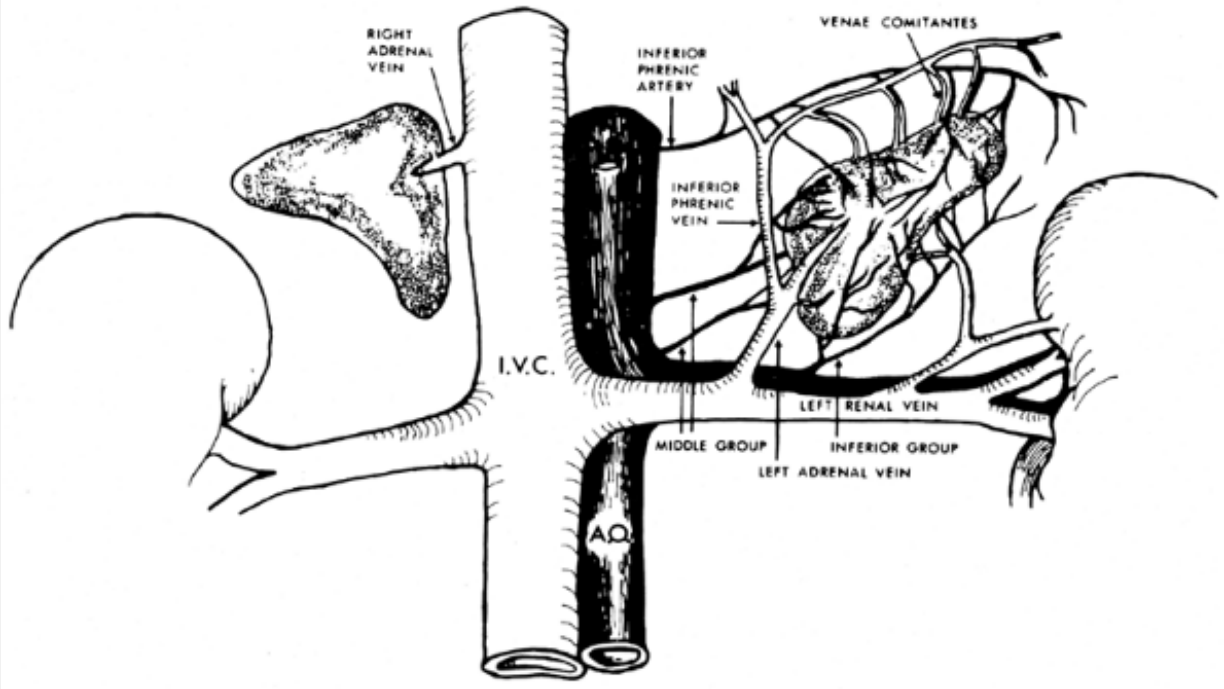

Figure 46.8 Diagrammatic representation of the arterial supply (black) and venous drainage (light and hatched) of the left adrenal gland. (Reprinted with permission from: Symington T. *Functional Pathology of the Human Adrenal Gland.* Baltimore: Williams & Wilkins; 1969.
)

Arteries

Three separate groups of arteriesâ€”superior, middle, and inferiorâ€”arising from the inferior phrenic artery, the aorta, and the renal artery, supply each adrenal gland (Figure 46.8). The main vessels divide into 50 to 60 small feeder vessels that penetrate the anterior and posterior surfaces of the glands and form a plexus beneath the capsule of the gland. The former are commonly encountered close to the capsule of the gland; in older patients, they frequently exhibit atherosclerotic changes. The subcapsular plexus,

important in regulation of the circulation in the gland, as has just been indicated, is not conspicuous in routine histologic preparations.

Intraglandular Vasculature

Capillary loops from the subcapsular plexus surround the cells of the zona glomerulosa (see â€œZona Glomerulosaâ€•), then extend toward the interior of the organ between the columns of cells of the zona fasciculata, and ultimately open into wide interconnecting channels in the zona reticularis to form a second vascular plexus. This ends abruptly in a vascular dam at the corticomedullary junction that finally drains into the sinusoids of the medulla by relatively fewer channels. The marked vascular congestion commonly seen at the corticomedullary junction of adrenal glands obtained at autopsy may be a reflection of this vascular barrier. Although the medulla receives some arterial blood supply, most of its vascular supply has already nourished the cortex.

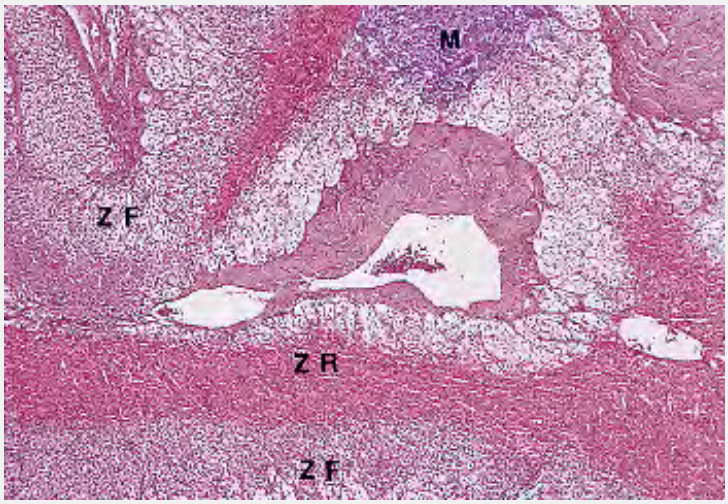

Figure 46.9 Central adrenal vein. Low-power view of the vein surrounded by an invaginated cuff of cortical cells with clear cytoplasm (zona fasciculata type). Distribution of smooth muscle in the vein wall is uneven. The zona fasciculata (ZF) and zona

reticularis (ZR) of the cortex are evident, and there is a small amount of basophilic medulla (M).

The venous drainage from the organs occurs via a single vein that emerges from the anterior surface of each gland (Figure 46.2). Inside the organs, the central adrenal vein (which ultimately becomes the adrenal vein as it leaves the organ) and its tributaries have a unique muscle coat, 2 to 6 longitudinally running muscle bundles, varying in size and eccentrically situated around the vein lumen (Figure 46.9). The bundles are heavily laden with elastic fibers that extend into tributaries of the larger central veins and in some instances outline clusters and trabeculae of medullary cells.

The eccentricity of the muscle bundles results in a vein wall that varies greatly in thickness and focally is devoid of muscle. In the zones where the muscle bundles are deficient (and these may be extensive), medullary cells (and sometimes cortical cells) are separated from the bloodstream by intima and a minimal amount of subintimal connective tissue only. This peculiar anatomic structure permits medullary cells or cortical cells to occasionally form polypoid endothelium-covered projections into the lumen of the central vein (Figure 46.10). (This ready access of pheochromocytes to the venous lumen explains the occasional finding of an intravenous tumor plug of pheochromocytoma.) A thick cuff of invaginated cortical cells surrounds the intramedullary central vein and its larger tributaries (Figure 46.10). (Development of a neoplasm in this â€œdisplacedâ€• cortex probably explains the occasional cortical neoplasm that appears to have developed in the medulla of the organ. As explained later, there is another possible source for a cortical neoplasm in this locationâ€”from cortical cells that occur among cells of the medulla.)

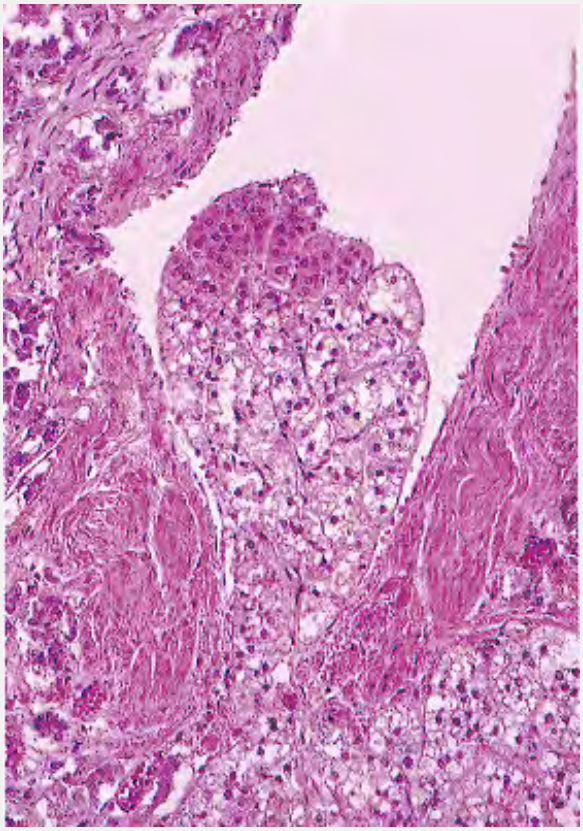

Figure 46.10 Central adrenal vein. Intraluminal protrusion of endothelium-covered adrenocortical cells between the discontinuous muscle bundles of a tributary of the central adrenal vein.

Veins

The left adrenal vein, 2 to 4 cm in length, initially lies in a groove on the anterior surface of the gland and terminates in the left renal vein (Figures 46.2 and 46.8). The right adrenal vein is short (1â€“5 mm) and drains into the inferior vena cava (Figures 46.2 and 46.8). Histologically, the extra-adrenal and immediately intra-adrenal portions of the veins have a muscular coat composed of large, similarly sized, evenly disposed smooth muscle bundles, arranged

side by sideâ€”a structure found in other veins of this size.

Nerves and Ganglia

The innervation of the adrenal gland, specifically of the medulla, emanates from the lower thoracic segments of the spinal cord and passes through the greater splanchnic nerve and the upper lumbar sympathetic ganglia via the celiac plexus. This nerve supply forms a plexus of medullated and nonmedullated nerves on the capsule of the gland, primarily on its posterior aspect. Thus, the largely preganglionic nerve fibers pass into the medulla following either the course of emerging or penetrating vessels or connective tissue trabeculae. Occasionally, a large nerve penetrates directly into the medulla. The number of nerves visible in the medulla varies greatly from case to case; some feature a perineurium, whereas others do not; frequently, they have associated ganglion cells (Figure 46.11). Ganglion cells are also commonly seen singly or in clusters among the pheochromocytes (Figure 46.12). The cells of the cortex do not have a nerve supply.

Lymphatics

Injection studies have demonstrated that there is a rich plexus of lymphatic channels in the capsule of the gland (3). Lymphatics are distributed to the adventitia of the central vein and its main tributaries. There is no lymphatic supply to the cortex. The lymphatics drain into aortic lymph nodes.

Capsule

The capsule of the adrenal gland is composed of hypocellular fibrous tissue in the form of coarse, hyalinized collagen bundles and elastic fibers (Figure 46.13). Usually, the capsule is thin, but it varies considerably in thickness from gland to gland and even within the same gland (Figure 46.14). It is tough and hard to cut but tears

easily and does

not support the unfixed gland, which is limp and readily bends. The soft consistency of the fresh glands makes them difficult to section; cooling them for 15 minutes in a refrigerator facilitates this operation.

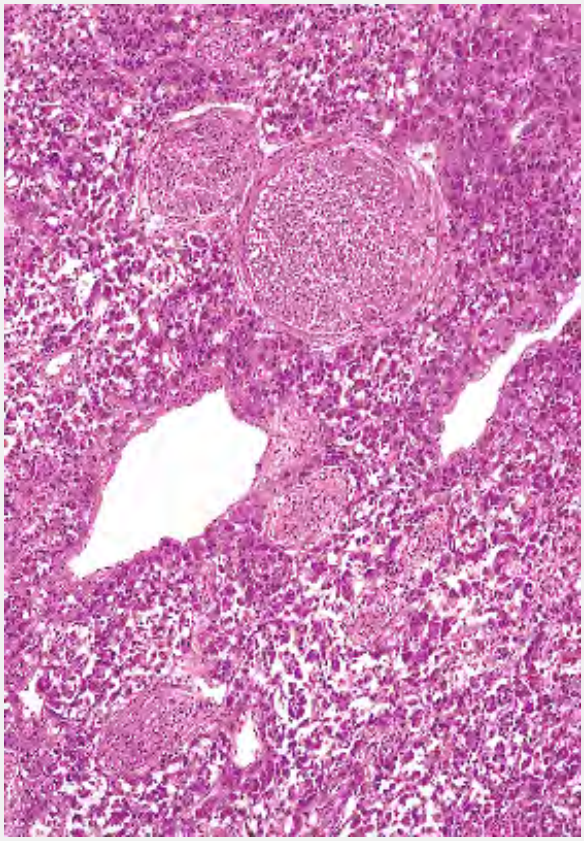

Figure 46.11 Adrenal medulla. Unusual concentration of nerves, some with perineurium and others without.

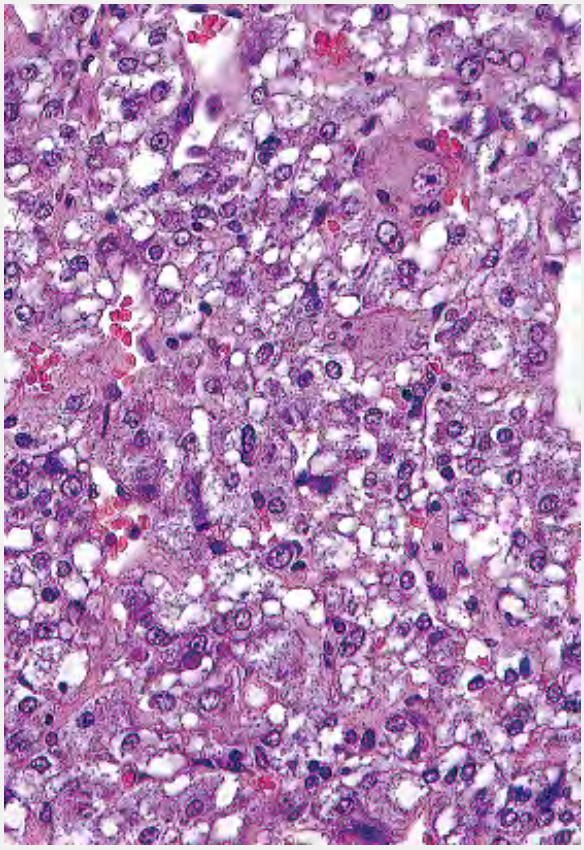

Figure 46.12 Adrenal medulla. Sheet of medullary cells with cytoplasm that is nonhomogeneous, variably basophilic, granular, and vacuolated, resulting in a mottled appearance. A ganglion cell is present among the pheochromocytes.

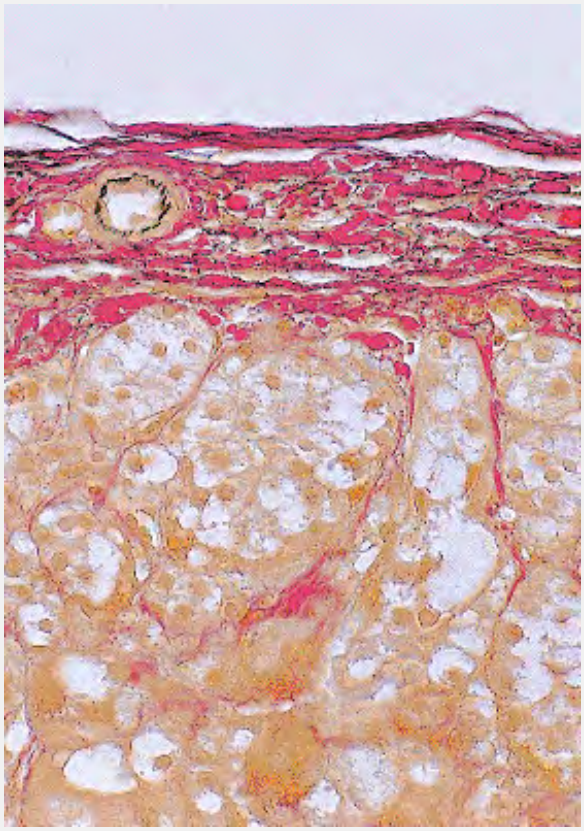

Figure 46.13 Adrenal capsule. Elasticâ€“van Gieson stain shows collagen bundles (red) and intermingled elastic fibers (black). A small artery is present in the capsule.

Figure 46.14 Adrenal capsule. Four-fold variation in the thickness of the capsule, which at its maximum thickness measures 0.3 mm.

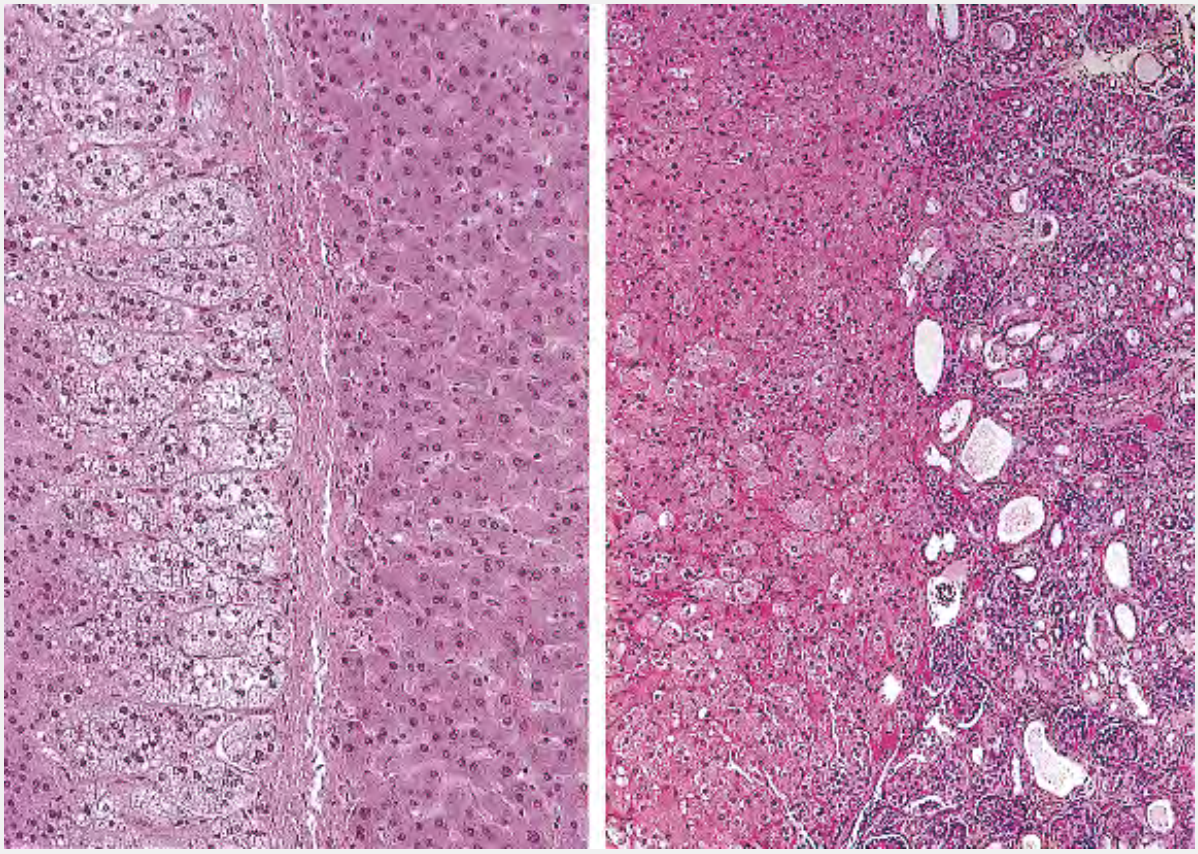

Figure 46.15 Adrenal capsule. A. Common capsule of adrenal (*left*) and liver (*right*). Note that a zona glomerulosa is not evident in the adrenal cortex. B. Absence of an adrenal and kidney capsule results in direct contact of adrenal cortex (provisional) and renal parenchyma.

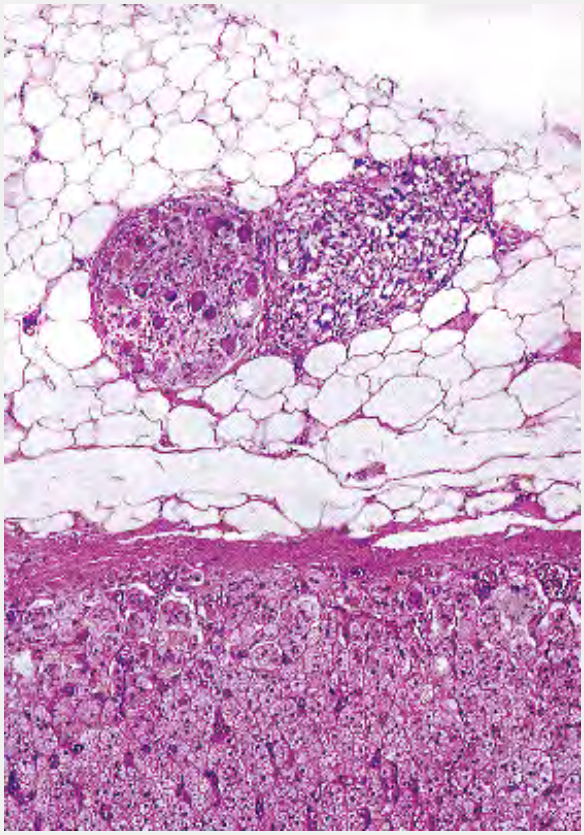

Figure 46.16 Normal adrenal gland. Juxtaposed sympathetic ganglion (*above left*) and paraganglion (*above right*) in periadrenal adipose tissue. The adrenal cortex features cells with clear cytoplasm (zona fasciculata). Zona glomerulosa is not evident.

Because of the propinquity of development of adrenals and kidneys and the liver (on the right side), there is occasional fusion or sharing of a common capsule among the adrenal and kidney and the adrenal and liver (Figure 46.15). The common capsule may be deficient focally, and then parenchymal cells of two organs come into direct contact. The adrenal capsule is surrounded by adult-type fat (brown fat in the fetus and newborn) that features small arteries, veins, nerves, accessory cortex, excrescences of cortex, sympathetic

ganglia, and an occasional paraganglion (Figure 46.16).

The capsule is penetrated by blood vessels supplying and draining the gland, the nerves to the medulla, and lymphatic channels. In random sections of the glands, only the site of exit of the adrenal vein is regularly encountered (because of its relatively large size); occasionally, the site of penetration of a large nerve is seen; the entry sites of the small arteries into the glands are also sometimes seen. Commonly found are narrow (occasionally wide) defects in the capsule through which the cortex protrudes into the periadrenal fat to form small nodules of cells that are sometimes delimited by a distended and attenuated adrenal capsule, sometimes not (Figure 46.17).

These excrescences are composed predominantly of epithelial cells with normal zonation patterns among the cells. The protrusions may contain a connective tissue component, and sometimes there is an equal mixture of cords of epithelial cells and fibrous tissue. Single rows and groups of cortical cells, small and oval or large and round, are commonly found here and there in capsular â€œpocketsâ€• (Figure 46.18). Larger oval aggregates cause a slight depression in, and thinning of, the underlying cortex, so that the total width of the two portions of cortexâ€”that in the capsular pocket and that normally situatedâ€”is about normal (Figure 46.18).

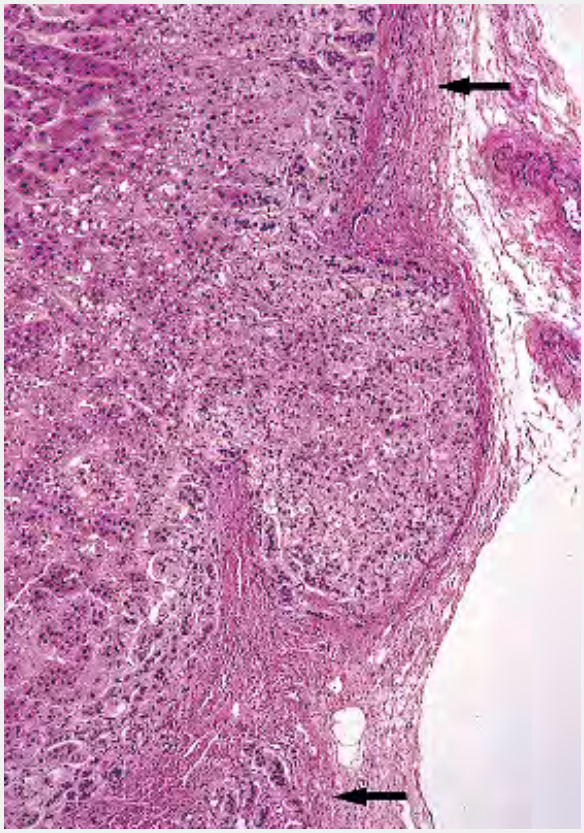

Figure 46.17 Normal adrenal gland. Protrusion of cortical cells surrounded by attenuated capsule through a â€œwideâ€• defect in the adrenal capsule. A few cortical cells in rows and small aggregates are present in the capsule (*arrows*). A suggestive zona glomerulosa is present deep to the adrenal capsule (*top*).

Sometimes seen attached to the capsule are wedge-shaped foci of small, plump spindle cells with hyperchromatic nuclei. These protrude into the cortex to varying depths and may be present bilaterally (Figure 46.19). The cells are arranged in interlacing bundles and whorls. Largely because of their light microscopic resemblance to ovarian cortical stroma, these aggregates have been termed â€œovarian thecal metaplasiaâ€•; an alternative interpretation is that they represent areas of adrenocortical blastema that for

unknown reasons have failed to mature (6,7,8). These foci undergo fibrosis, hyalinization, and sometimes calcification. Nests of cortical cells are occasionally found in the spindle cell proliferation, presumably entrapped.

Exceptionally, the proliferations penetrate into the medulla as increasingly narrow tongues of tissue. Ovarian thecal metaplasia is said to occur in postmenopausal women, occasionally in premenopausal women, and exceptionally in old men. We have not seen it in any of the normal adrenal glands we have examined despite a good search. However, we have encountered it fairly commonly in the extratumoral cortex associated with a range of functioning adrenocortical adenomas and in adrenals removed for other pathology, cortical and medullary, always in perimenopausal or postmenopausal females. The â€œlesionsâ€• are generally incidental microscopic findings that were not recognized grossly.

Cortex

Traditionally, the cortex has been divided into three areas based on light microscopy findings from the capsule inwardâ€”the zona glomerulosa, the zona fasciculata, and the zona reticularisâ€”forming the typical zonation pattern of the adrenal cortex (Figure 46.20). The functional significance of this morphologic separation is questionable, but the zona glomerulosa is the site of aldosterone production and is responsive to angiotensin and potassium, and the zona fasciculata and zona reticularis synthesize glucocorticoids and sex hormones. Cells of all zones respond to adrenocorticotropic hormone (ACTH). Recent studies using monoclonal antibodies have shown some differential staining of the normal human cortical parenchyma (9). Division figures are rare in the normal adult cortex; in fact, the zone(s) of normal proliferation for replacement of effete cells is not known, although it is believed to be near the periphery of the cortex. [Under the influence of increased circulating levels of ACTH (Cushing's disease), mitotic figures may be seen in the zona

fasciculata and zona reticularis, indicating that cells in the deeper areas of the cortex are also capable of proliferating.]

A number of modern techniques for studying cell proliferation and programmed cell death (apoptosis), specifically, KI-67 immunostaining and 3â€²-OH nick end-labeling method, respectively, have been applied to study of the human adrenal cortex (10). Cell proliferation as indicated by KI-67 immunoreactivity occurred principally in the zona fasciculata. Cortical cells positive for nick-end labeling (apoptotic) were uniformly present in the zona reticularis and in the zona glomerulosa in one third of cases. The findings suggest that cortical cells may disperse in two directions, centripetally and centrifugally, from the zona fasciculata to the zona reticularis and from the zona fasciculata to the zona glomerulosa, in some cases. Biochemically, apoptosis features chromatin cleavage. Morphologically, there is shrinkage of cytoplasm, condensation, and fragmentation of nuclei and membrane blebbing. Adrenocortical cells undergoing apoptosis are believed to be phagocytosed by histiocytes and cells lining the sinusoids.

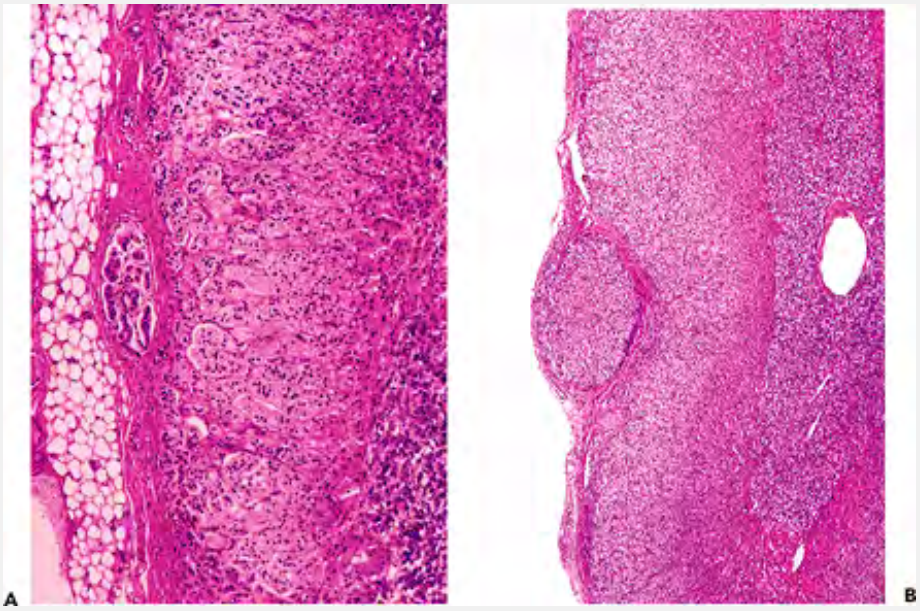

Figure 46.18 Normal adrenal gland. A. Aggregate of cells with features of zona glomerulosa type in â€œpocketâ€• in capsule. B. Cortex featuring zona fasciculata (clear cells) and zona reticularis (compact cells) abuts medulla. A larger aggregate of cortical cells with clear (peripheral) and compact cytoplasm (central) is present in a pocket in the capsule. The cortex deep to the pocket is slightly attenuated. A zona glomerulosa is not clearly visible.

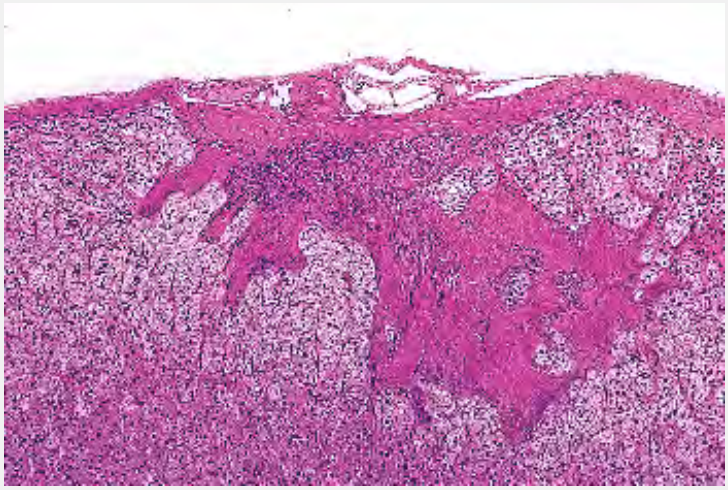

Figure 46.19 Ovarian thecal metaplasia (63-year-old woman with a 2-cm aldosterone-producing adrenocortical adenoma). A group of packed spindle cells is attached to the adrenal capsule. Nests of cortical cells are trapped by hyalinized fibrous tissue. A poorly defined zona glomerulosa is present).

Nucleolar organizer regions, loops of ribosomal DNA that appear to be an indicator of cellular and nuclear activity, have been studied to a limited degree in the human adrenal cortex, using a silver technique and formalin-fixed, paraffin-embedded tissue (11).

Zona Glomerulosa

The zona glomerulosa is the narrow, inconstant band of cortex situated immediately beneath the capsule and superficial to the zona fasciculata (Figure 46.21). Sometimes it can be identified throughout a section or over a large portion of one as a distinct rim beneath the capsule; more often it cannot. Where it is deficient, the zona fasciculata extends to the capsule (Figure 46.22). The zone is often easier to identify

in autopsy preparations. In routine hematoxylin and eosin preparations, the band may merge with and be separated with difficulty from the outer cells of the zona fasciculata.

Figure 46.20 Normal adrenal gland. A thick capsule surrounds the adrenal cortex (outer clear zona fasciculata and inner eosinophilic zona reticularis) that encloses the basophilic adrenal medulla. An area of medulla in the ala (*arrow*) is not in continuity with the main mass of medulla. The adrenal vein is surrounded by a cuff of invaginated cortex.

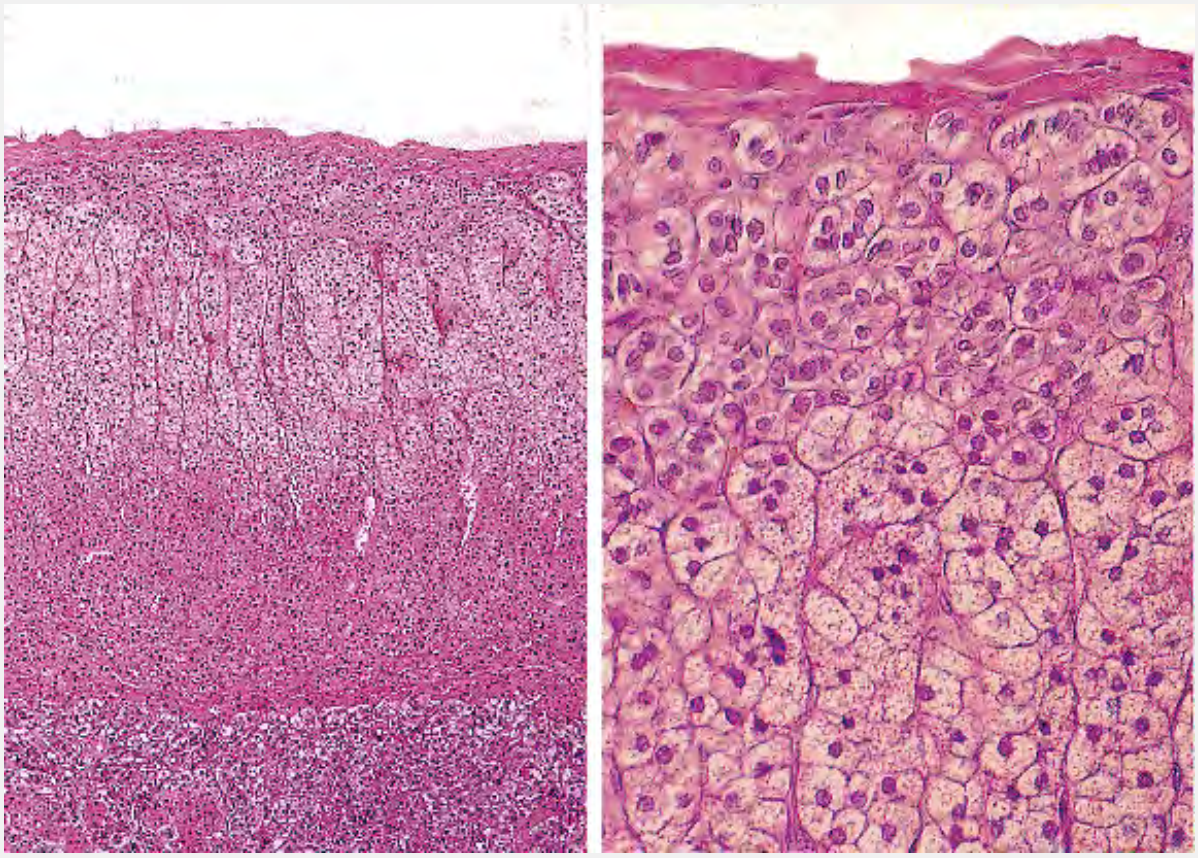

Figure 46.21 Normal adrenal gland. A. The normal pattern of zonation of the cortex is seen (clusters of cells with stainable cytoplasm in the zona glomerulosa, columns of cells with clear cytoplasm in the zona fasciculata, and cells with acidophilic cytoplasm in the zona reticularis). There is a sharp interface between the cortex (zona reticularis) and medulla (clusters of cells with basophilic cytoplasm). B. Zona glomerulosa composed of packed clusters and short trabeculae of cells beneath the adrenal capsule and superficial to the columns of vacuolated cells of the zona fasciculata. The zona glomerulosa nuclei tend to be oval; those of the zona fasciculata are round.

The zona glomerulosa cells are well outlined and aggregated into small clusters that are supported by a minimal amount of

fibrovascular stroma (Figure 46.21). The clusters occasionally merge into short trabeculae, straight, bent, or hairpin shape. The cells that tend to be columnar also occur in short cords or one-cell rows set parallel to the capsule. The cytoplasm is faintly acidophilic or amphophilic and minimally to distinctly vacuolated. The round nuclei sometimes are indistinguishable from those of the other zones of the cortex, but often they appear slightly smaller and more deeply staining. Commonly, they are ellipsoidal and elongated and display a longitudinal groove, a nuclear configuration not seen in the deeper areas of the cortex (Figure 46.21). The nuclear to cytoplasmic ratio is high.

Zona Fasciculata

The zona fasciculata is a broad band, more than half the thickness of the cortex, that lies between the zona glomerulosa (superficial) and the zona reticularis (deep) (Figures 46.20, 46.21, and 46.23). The transition between the zones is not sharp. The zona fasciculata cells are large, have distinct cell membranes, are arranged in two-cell wide cords (with the cord axes perpendicular to capsule) and are bounded laterally by parallel-running capillaries. The nuclei are more vesicular and less chromatic than those of the zona glomerulosa, feature a single small nucleolus, and are central in the cells. Especially in the outer two thirds of the zone, the cells are filled with lipid (cholesterol, fatty acids, and neutral fat), much of which is birefringent (Figure 46.24). Because this lipid is dissolved with the usual technical procedures, the fasciculata cells have a spongy, vacuolated, clear appearance and are often referred to as clear cells. When frozen, and sections are stained with a vital dye or stained for fat, the large amount of intracellular lipid can be appreciated (Figure 46.24). The yellow color of the zone seen grossly is due to this high lipid content.

Zona Reticularis

The zona reticularis lies deep to the zona fasciculata, and in the head and body of the gland abuts on the medulla (Figures 46.9, 46.20, 46.21, and 46.23). In the tail of the gland,

where there is no medulla, the zona reticularis is in contact with zona reticularis forming a lateral raphe. It constitutes approximately one quarter of the thickness of the cortex. Zona reticularis cells are arranged in a spongelike meshwork of gently buckled anastomosing one-cell wide rows of cells that are separated by dilated capillaries. The well-outlined cells are smaller than those of the zona fasciculata and have cytoplasm that is granular, acidophilic, and relatively lipid sparse. The cytoplasm is sometimes referred to as â€œcompactâ€• and the reticularis cells as â€œcompact cells.â€• The deepest cells adjacent to the medulla usually contain yellow lipochrome pigment (lipofuscin), diffusely distributed as coarse granules in the cytoplasm or localized in a single body (Figure 46.25). The yellow pigmentation of the cytoplasm extends outward into the reticularis for a variable distance. The solid granular eosinophilic cytoplasm and the lipochrome pigment combine to produce the dark brown coloration of the zone seen on cut surface of a fresh or formalin-fixed gland.

Figure 46.22 Normal adrenal cortex with discontinuity of zona glomerulosa. Zona glomerulosa (*upper half*) composed of clusters of cells with amphophilic cytoplasm forms a distinct band beneath the capsule and is sharply demarcated from the deeper zona fasciculata with its clustered cells having clear cytoplasm. Where the zona glomerulosa is absent (*lower half*), the zona fasciculata extends to the capsule.

Accessory (Heterotopic) Adrenal

The adrenocortical primordium initially is unencapsulated and develops, as has been mentioned, close to the emerging gonad. Therefore, it is not surprising that (a) some cells of the unencapsulated adrenocortical primordium may become associated

with and migrate alongside the gonad (testis or ovary) to be found postnatally distant from the adrenal in the path of gonad descent and (b) cortical cells not sequestered by adrenal capsule formation are subsequently found in the retroperitoneal fat close to the adrenal glands. In practice, accessory adrenocortical tissue is most often encountered around the adrenal glands themselves (Figure 46.26); it also occurs in the inguinal region and around the ovary, fallopian tube, epididymis, and rete testis. Microscopically, accessory cortex shows normal zonation and responds to ACTH. Rarely, medulla is also present (Figure 46.26).

Adrenocortical Nodules

Adrenocortical nodules, roughly spherical, uncapsulated areas of hypertropic and hyperplastic cortical cells, are not regarded as true neoplasms. They range in size from microscopic to grossly obvious lesions (12). Before the fourth decade of life, they are rare; thereafter, they are encountered with increasing frequency. Although

regarded by some as an aging phenomenon, they are not invariably found in older individuals. Usually, multiple nodules commonly consist of large, lipid-laden clear cells; some nodules are composed of clear and compact cells; a minority feature reticularis-type cells only (Figure 46.27). The smallest nodules may be found at any level of the cortex, but usually they occur in the zona fasciculata. Initially, they appear to be the result of hypertrophy of contiguous cells in three or more adjacent cords. The smallest ill-defined nodules thus have the cord structure of the parent tissue. As they enlarge further due to cell proliferation, this organized appearance is lost, and larger nodules are patternless. Large nodules cause compression and distortion of the surrounding cortex.

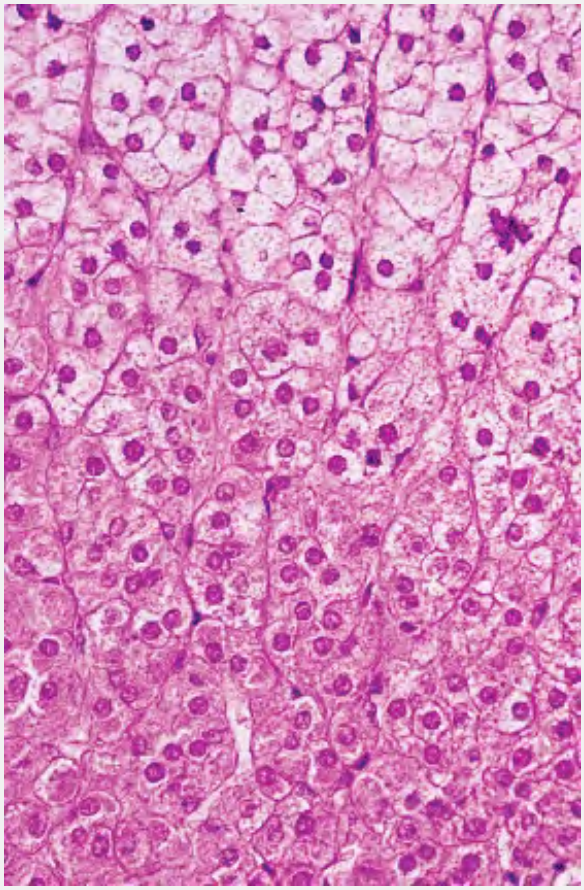

Figure 46.23 Normal adrenal cortex. Zona fasciculata (*upper*) features two-cell wide columns of cells with clear cytoplasm, and zona reticularis (*lower*) consists of cells having acidophilic granular cytoplasm that do not form a distinct pattern. Nuclei are vesicular, and nucleoli are small.

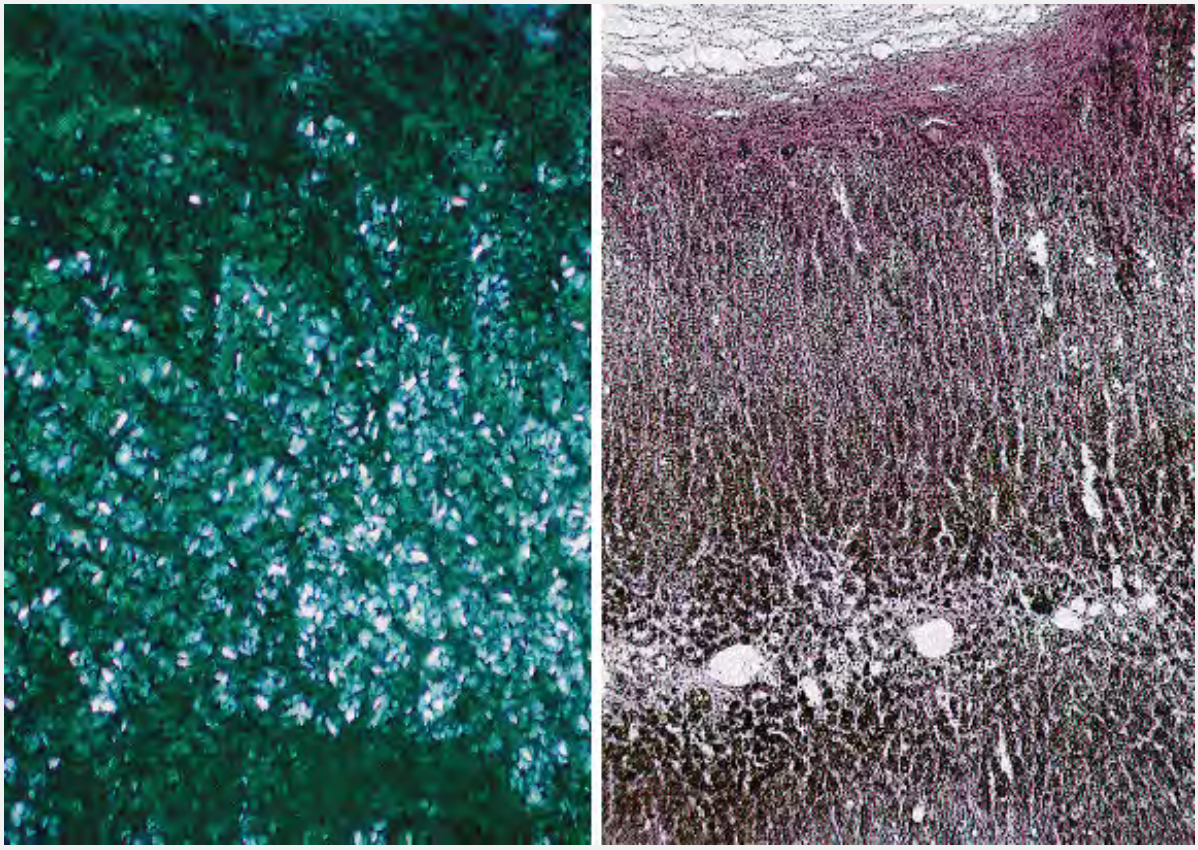

Figure 46.24 Normal adrenal cortex. A. Partial polarization shows high lipid content of zona fasciculata and low content of zona glomerulosa (*above*) and zona reticularis (*below*). B. Fresh frozen section of adrenal cortex stained with polychrome methylene blue. One complete band of cortex (*above*) and portion of another (*below*) is seen; the junction point between the two is located by the dilated sinusoidal tributaries of the central adrenal vein. Zona fasciculata cells are packed with lipid globules. There are fewer globules in the zona glomerulosa (beneath the adrenal capsule) and in the zona reticularis (on either side of the sinusoidal vessels).

Medulla

The medulla is situated in the interior of the organ in the head and body of the gland, deep to the zona reticularis (Figures 46.9 and 46.20). Its area and weight are one tenth those of the cortex (1,3). The medulla rarely measures more than 2 mm in thickness. Because of the different staining of cells of the two tissuesâ€”acidophilia in zona reticularis and basophilia in the medullaâ€”the interface between cortex and medulla is readily visible on low-power microscopic examination. The junction is sharp, with no or minimal intervening connective tissue, leaving cortical and medullary cells in direct contact (Figures 46.20 and 46.25).

The medulla extends to a variable extent into the crest of the gland (the ridge on the posterior surface) and into one or both of the alae (Figure 46.20). Areas of the medulla in the alae are not necessarily in direct continuity with the main mass of the medulla around the central veins. The medulla sometimes extends into the tail of the gland. The finding of medulla in this location therefore does not automatically equate with pathologic abnormalityâ€”specifically, medullary hyperplasia. Rarely, a narrow tongue of medulla accompanied by a vessel or nerve or unaccompanied extends through the cortex to contact the capsule of the gland.

The medulla, for practical purposes, is composed of a single cell population, the pheochromocytes (medullary or chromaffin cells) (Figure 46.28). Among the dominant population are scattered small groups of cortical cells and clusters and individual ganglion cells (Figure 46.29). Not

uncommonly, the ganglion cells feature cytoplasmic, round, lightly acidophilic, hyalin bodies, with concentrically arranged fibrillar appearance, up to 30 Âµm in diameter (Figure 46.30). Sometimes these bodies appear to be external to the ganglion cells and to indent them; in immunostain preparations (vimentin and S-100) they are separated from the cells by a small amount of intercellular substance. It is unusual to observe these bodies in ganglion cells

outside the adrenal medulla. Their nature has not been investigated. The pheochromocytes are arranged in tight clusters and short trabeculae, supported by delicate fibrovascular stroma (Figures 46.28 and 46.31). Sustentacular cells at the periphery of the clusters and trabeculae are not seen in routine histologic preparations (13), but are readily demonstrated by immunostaining for S-100 protein (Figure 46.32).

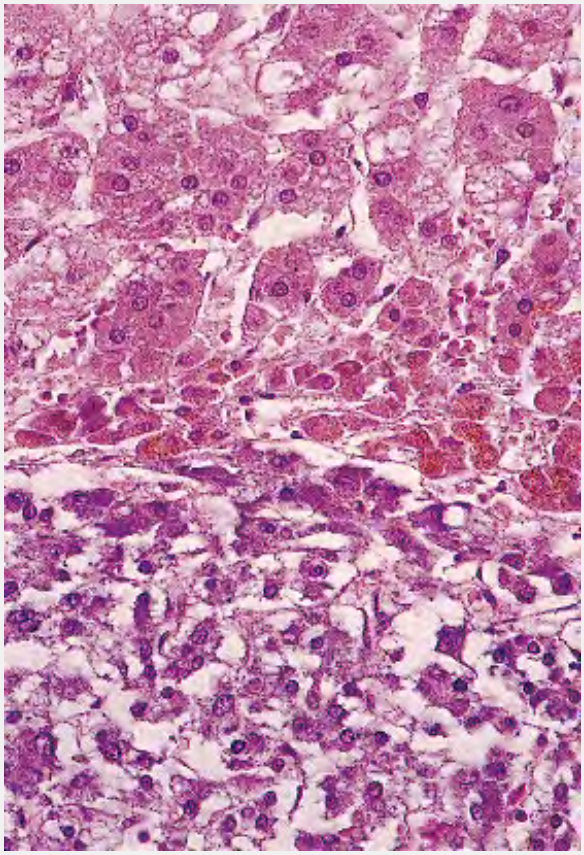

Figure 46.25 Corticomedullary junction. The zona reticularis of the cortex (*upper*) is sharply demarcated from the medulla (*lower*). The deepest cells of the zona reticularis contain granular yellowish pigment (*lipofuscin*).

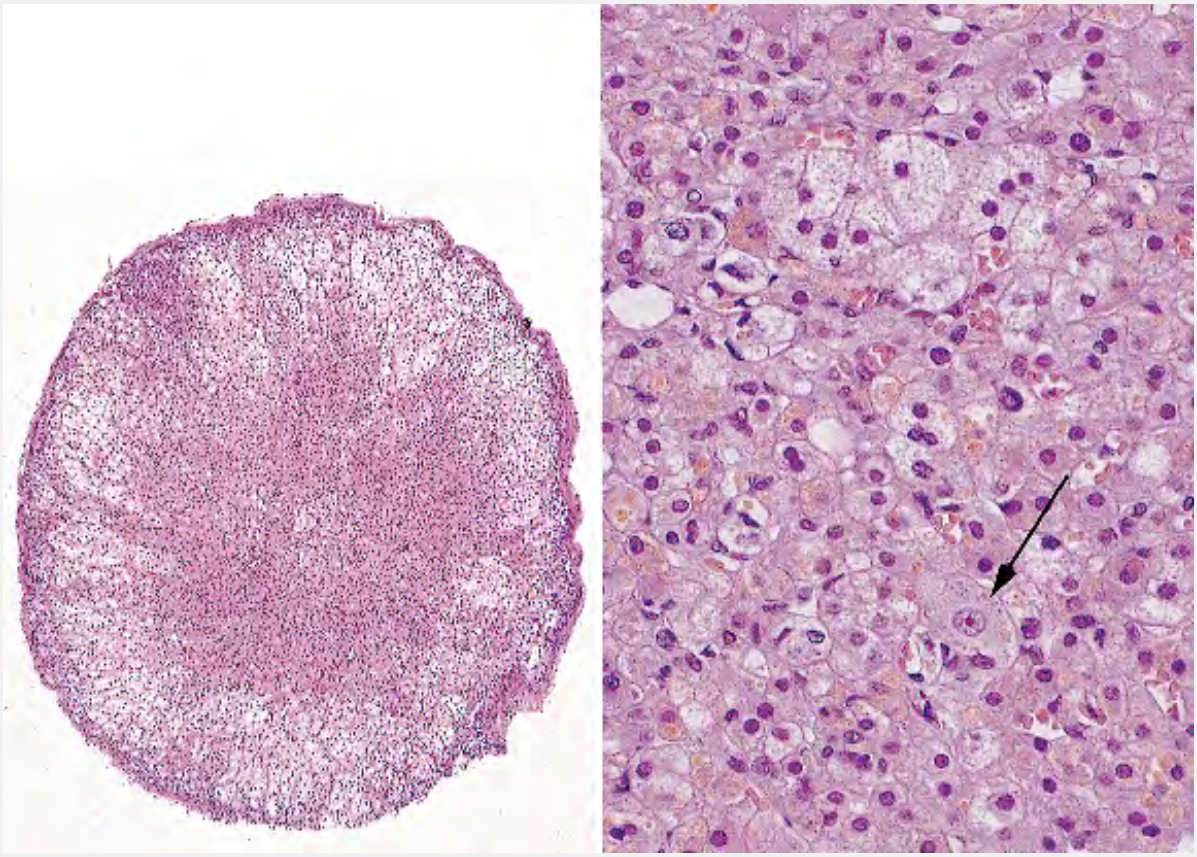

Figure 46.26 Accessory adrenal cortex in retroperitoneal fat. A. Normal zonation is suggested by the narrow rim of cells with clear cytoplasm that surrounds the main mass of cells with light eosinophilic cytoplasm. B. Ganglion cell (*arrow*) indicating presence of medulla among cortical â€œclearâ€• and â€œcompactâ€• cells. The latter contain lipofuscin.

The pheochromocytes are moderately large cells, polygonal to columnar, and slightly to considerably larger than cortical cells. Poorly outlined, their complete cell borders are visible only occasionally. Although the cytoplasm of most medullary cells is basophilic, finely granular and occasionally vacuolated, sometimes it is amphophilic or slightly acidophilic. Rarely is it partly basophilic and partly acidophilic. The resulting variability and unevenness of

medullary cytoplasmic staining and cytoplasmic vacuolization often impart an overall mottled light and dark appearance at intermediate

magnification. A rare normal cell has one or more periodic acid-Schiff positive cytoplasmic colloid droplets (Figure 46.33). The majority of the medullary cells are roughly similar in size, but occasionally standard-sized cells merge with groups of cells that are much smaller or much larger (Figure 46.31).

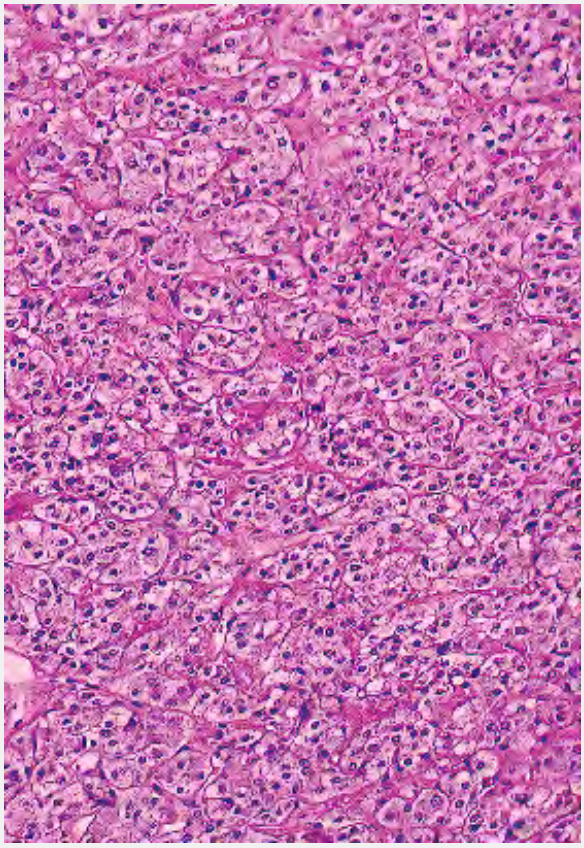

Figure 46.28 Normal adrenal medulla. Clusters of poorly outlined cells with basophilic cytoplasm are separated by a vascularized supporting stroma. There is some variation in nuclear size and shape.

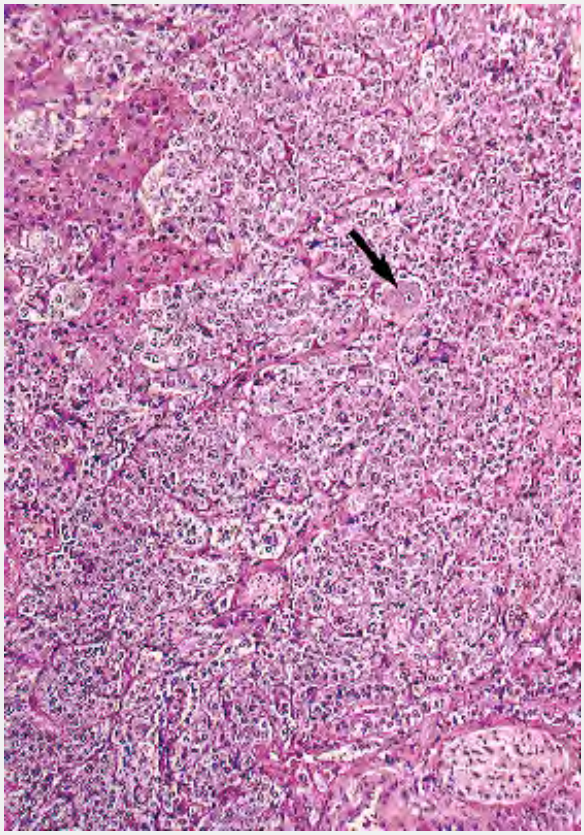

Figure 46.29 Normal adrenal medulla. Pheochromocytes are arranged in poorly delineated clusters. An irregularly shaped group of cortical cells (*upper left*) and an isolated ganglion cell (*arrow*) are present.

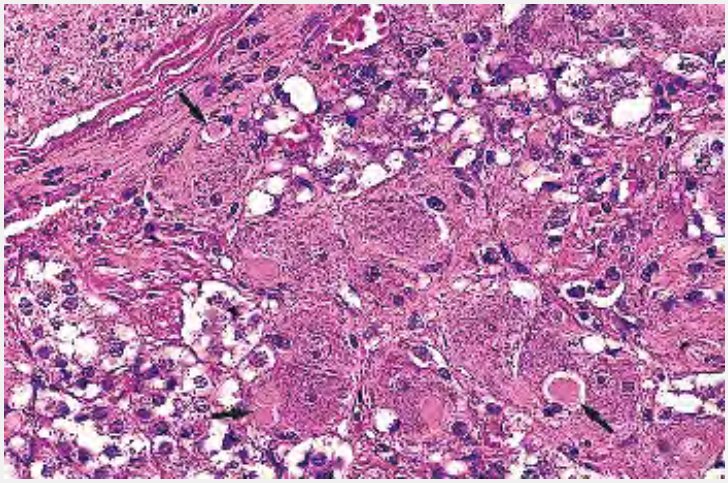

Figure 46.30 Normal adrenal medulla. A group of ganglion cells demarcated by pheochromocytes (*upper right and lower left*) and a nerve (*upper left*). A number of the ganglion cells feature cytoplasmic acidophilic bodies, some outlined by a rim of retracted cytoplasm (*arrows*). There are two such bodies in one cell.

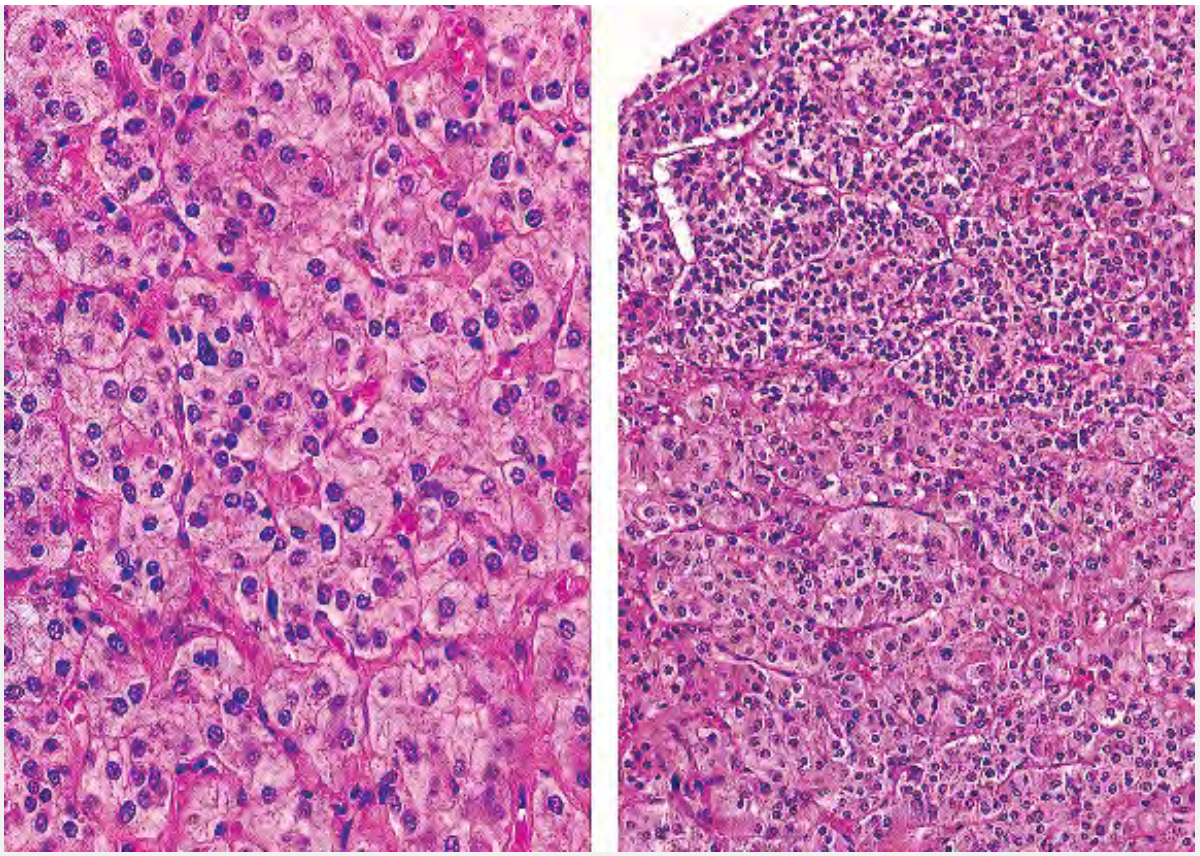

Figure 46.31 Normal adrenal medulla. A. Pheochromocytes arranged in vague clusters. Cell outlines are visible here and there. Nuclear variation in size and shape is typical. The nuclear chromatin is coarsely clumped and often marginated at the nuclear membrane. B. Variation in cell size, nuclear size, and cell pattern.

The nuclei of medullary cells characteristically have slight but definite variability of size, shape, and location in the cell. Most pheochromocyte nuclei are slightly larger than those of cortical cells, but nuclei that are larger and smaller than the usual ones are common. The usual nucleus has a finely or coarsely clumped chromatin pattern with a relatively clear nuclear background (Figure 46.31). The chromatin tends to be peripherally disposed and

separated into irregular clumps. Larger nuclei often have a prominent eosinophilic nucleolus; smaller nuclei are deeply staining. A rare cell has two or more nuclei.

The nuclei exhibit slight but definite polymorphism. Most are spheroidal, but many are ellipsoidal, and some have other shapes. Large, intensely hyperchromatic and sometimes pleomorphic nuclei are common, usually single and located close to the corticomedullary junction (Figure 46.34). The positions of the nuclei in the cells are not fixed; most are central, but some tend to be eccentric, located away from the vascular pole (Figure 46.35).

The medullary cells have several distinctive histochemical reactions related to their content of secretory granules. The granules contain catecholamines, dihydroxy derivatives of tyrosine, that are converted to colored polymers by oxidizing agents such as potassium dichromate, ferric chloride, ammoniacal silver nitrate, and osmium tetroxide. The oxidized and polymerized derivatives are termed

adrenochromes. This staining has been called the chromaffin reaction.

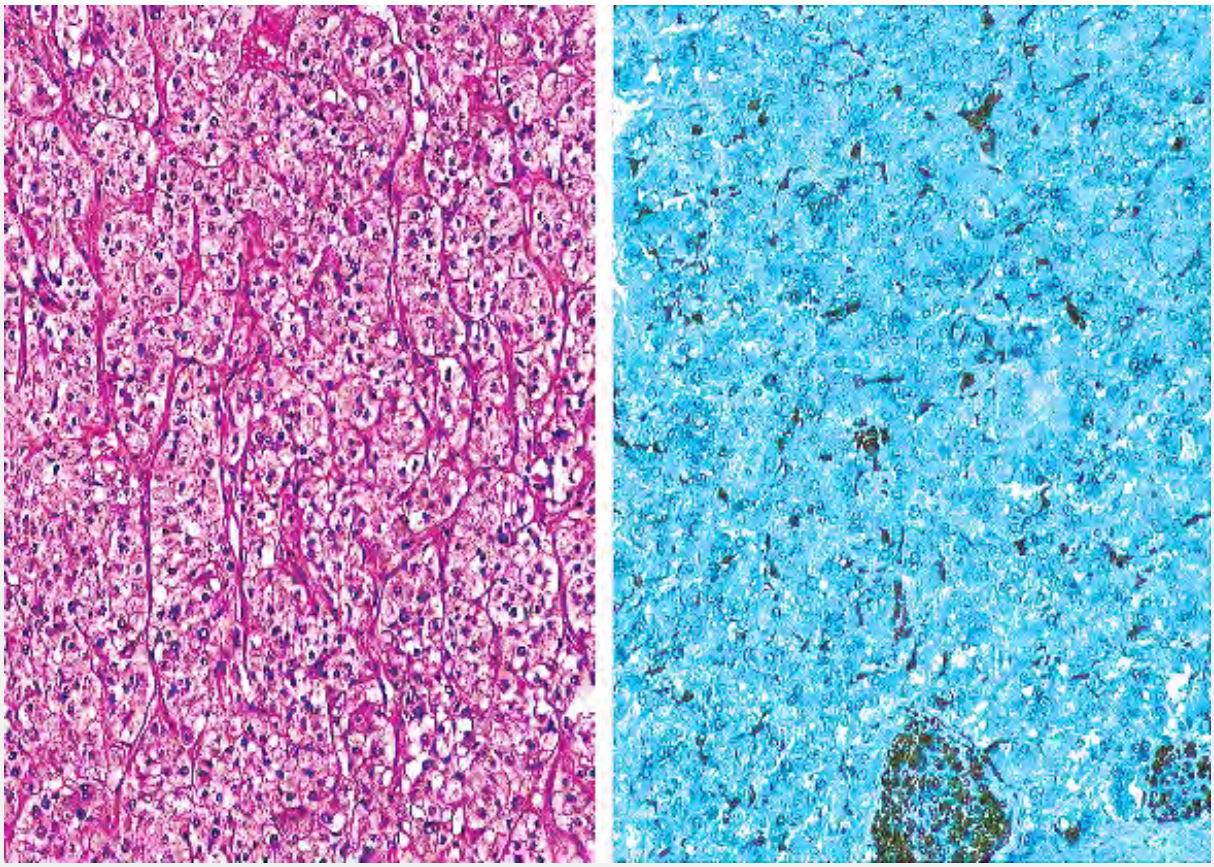

Figure 46.32 Normal adrenal medulla. A. Pheochromocytes arranged in trabecular pattern outlined by a delicate vascular supporting stroma. B. Sustentacular cells identified by S-100 immunostain that also highlights two nerves.

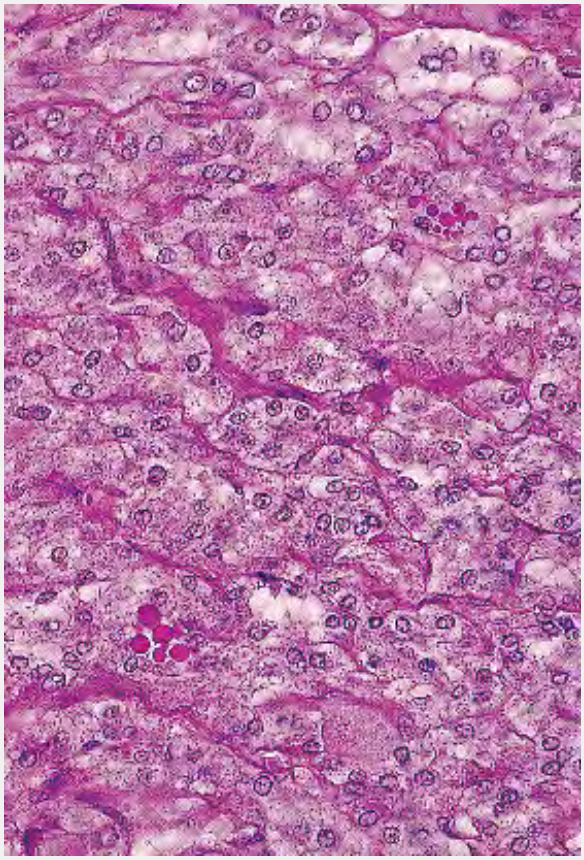

Figure 46.33 Normal adrenal medulla. Cytoplasmic globules, a rare finding in normal pheochromocytes, stained with periodic acid-Schiff. Condensation of the nuclear chromatin at the nuclear membrane is well demonstrated.

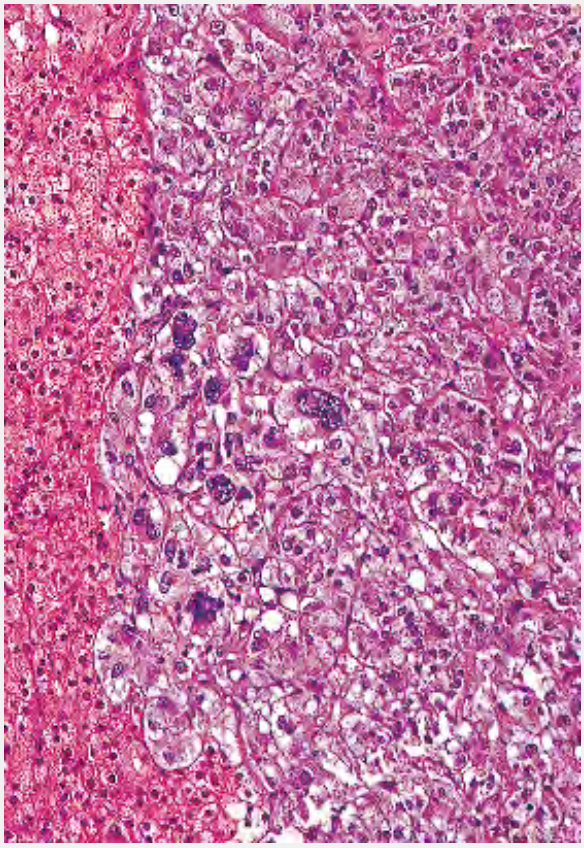

Figure 46.34 Normal adrenal medulla. Pheochromocyte nuclear atypia at the corticomedullary junction. The number of atypical pheochromocyte nuclei crowded together here is unusual; ordinarily, the atypical nuclei are seen one to a medium-power field. The pheochromocytes have basophilic granular cytoplasm. The zona reticularis (*left*) features cells with granular eosinophilic cytoplasm and lipofuscin.

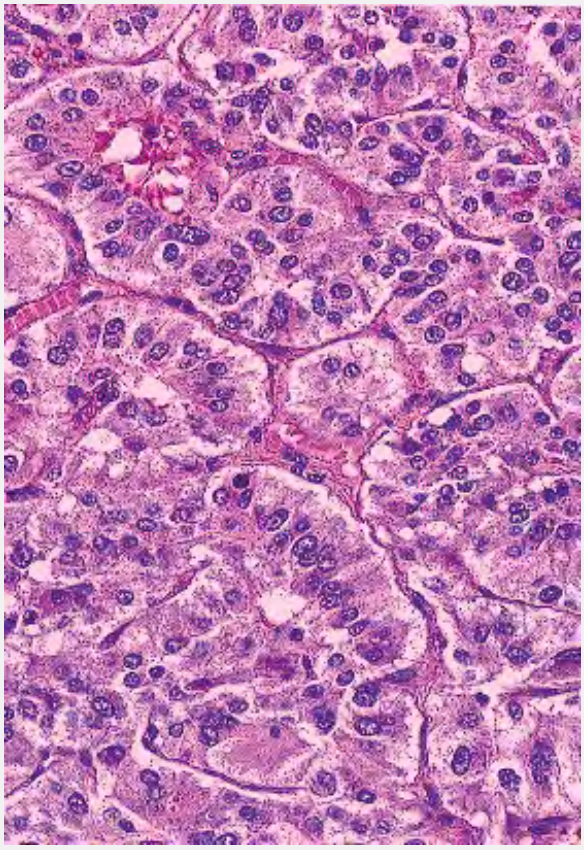

Figure 46.35 Normal adrenal medulla. Uncommon pattern in which pheochromocytes are columnar in shape with nuclei that are located away from the vascular pole. The variations in size and shape of the nuclei are typical. Cytoplasmic staining is uneven and ranges from almost clear to basophilic and granular.

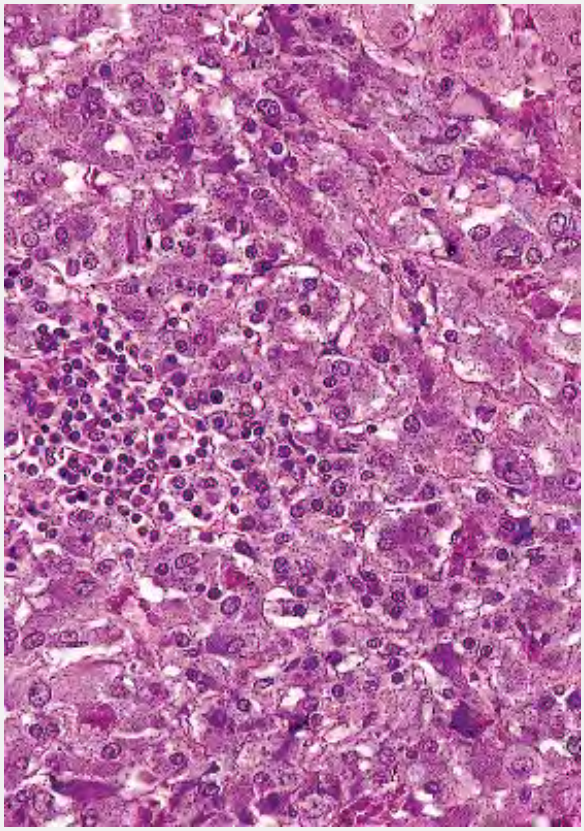

Figure 46.36 Normal adrenal medulla. Aggregates of lymphocytes and plasma cells are often encountered.

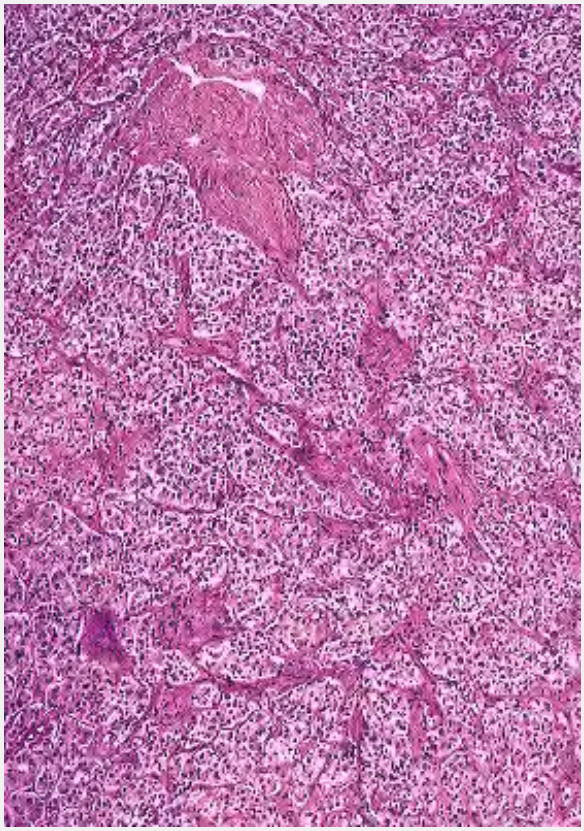

Figure 46.37 Normal adrenal medulla. Bundles and strands of smooth muscle are derived from the smooth muscle of central vein.

Ganglion cells are scattered randomly among the pheochromocytes or in groups, often associated with a nerve (Figure 46.29). Their number varies greatly from medulla to medulla; accordingly, they are found easily or not. Cortical cells also are a regular component of the medulla, found in irregularly shaped groups, sometimes in continuity with the zona reticularis, but more often not (Figure 46.29).

Single or multiple small-to-large accumulations of round cells, plasma cells, and lymphocytes (positive for leukocyte common antigen), often paravascularly located, are common in the normal medulla (Figure 46.36). They have no known significance. The

delicate vascular stroma of the medulla is not conspicuous. Sometimes it is augmented focally by prolongations of the musculature of the central veins that separate groups of medullary cells (Figure 46.37).

Immunohistochemistry

Cortex

Cells of the normal adrenal cortex are reported to be immunoreactive against a cytokeratin cocktail and AE1 (14). In our experience, small groups of cells and isolated cells of the three zones have strong reactivity to low- and medium-molecular-weight keratin antibodies (CAM 5.2 and AE1, and MAK 6, respectively). Reactivity is greatest in the zona

glomerulosa and external zona fasciculata, with some strongly reactive cells in the deep zona reticularis. The character of the staining is variable, membranous, punctate cytoplasmic, diffuse cytoplasmic, and perinuclear, in decreasing order of frequency. There is weak staining to the keratin antibodies, often diffuse, in the zona reticularis. The zona glomerulosa is vimentin positive (Figure 46.38). Cells of the outer zona fasciculata and the zona reticularis are positive for melan A and inhibin Î±, respectively (Figure 46.39). Cells of the three zones are variably synaptophysin positive. Cortical cells do not stain with epithelial membrane antigen, chromogranin, or S-100 antibodies.

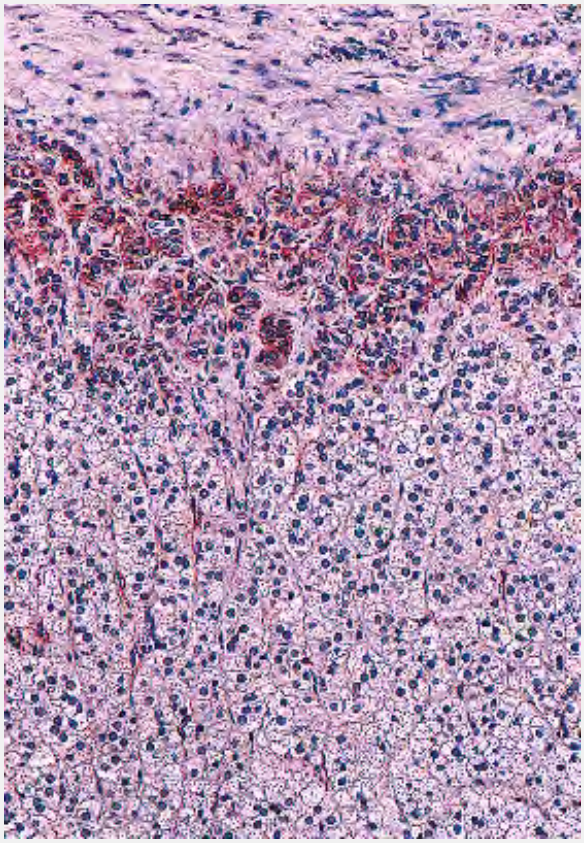

Figure 46.38 Normal adrenal cortex. Zona glomerulosa stains positively for vimentin.

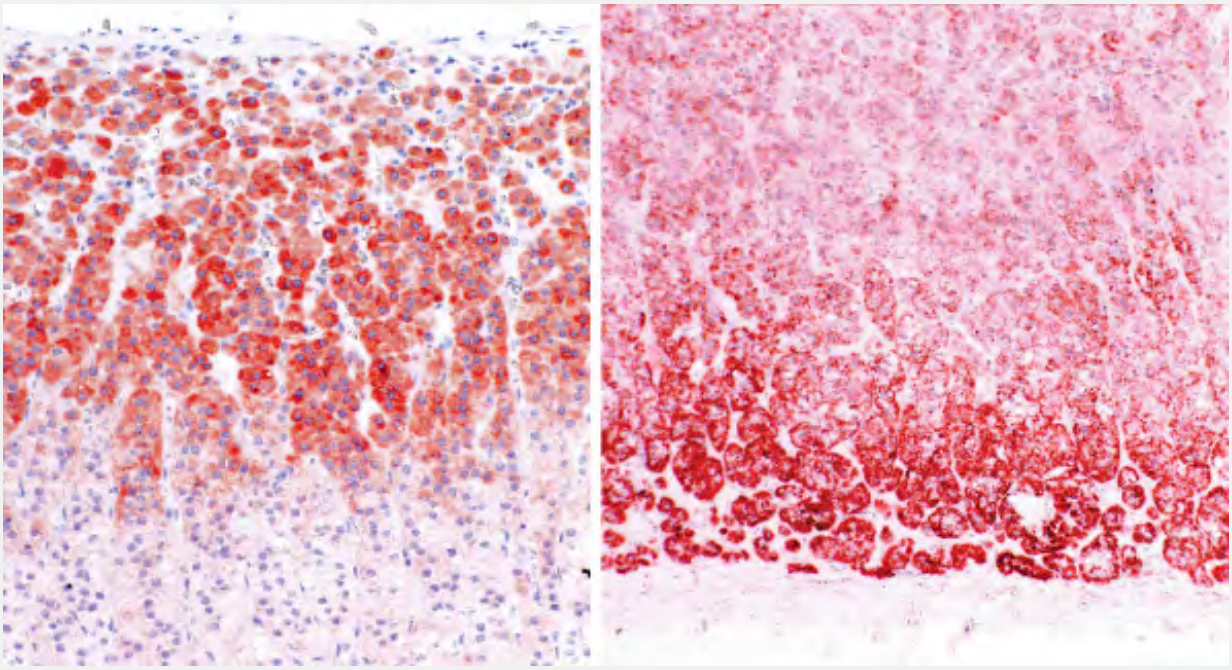

Figure 46.39 A. Melan A stains the outer zona fasciculata most strongly. B. Inhibin Î± stains the region of the zona reticularis strongly and the remainder of the cortex weakly.

Medulla

Pheochromocytes stain with antibodies to chromogranin and synaptophysin. The sustentacular cells that mantle the clusters and trabeculae of pheochromocytes are S-100 protein positive (Figure 46.40), as are nerves in the medulla. Some pheochromocytes stain with S-100 antibodies.

Ultrastructure

Cortex

There are ultrastructural features shared by the three layers of the

cortex relating to their common functionâ€”synthesis of steroid hormones. The cells feature voluminous endoplasmic reticulum, stacks of rough endoplasmic reticulum, a well-developed Golgi apparatus, lysosomes, and many mitochondria. The distribution and internal structure of some of the organelles (e.g., the mitochondria) vary from zone to zone. Using the electron microscope, the sometimes distinct transition seen between the zones is not apparent; rather, a gradual alteration from one organelle distribution and type to another being observed. Mitochondria in the zona glomerulosa are round, oval, or elongate, with lamellar infolded cristae, resulting in a ladderlike internal structure, similar to that found in many other

tissues (Figure 46.41). In the zona fasciculata, these organelles are large, spherical, and feature tubular cristae (Figure 46.41). Lipid droplets are large and numerous. The mitochondria in the zona reticularis (Figure 46.41) tend to be more elongated and exhibit tubular and vesicular cristae that are a feature of steroid-producing cells. Lipofuscin granules, membrane-bound organelles with a moderately dense matrix that contains dense granules and clear lipid globules are prominent. Glycogen is present.

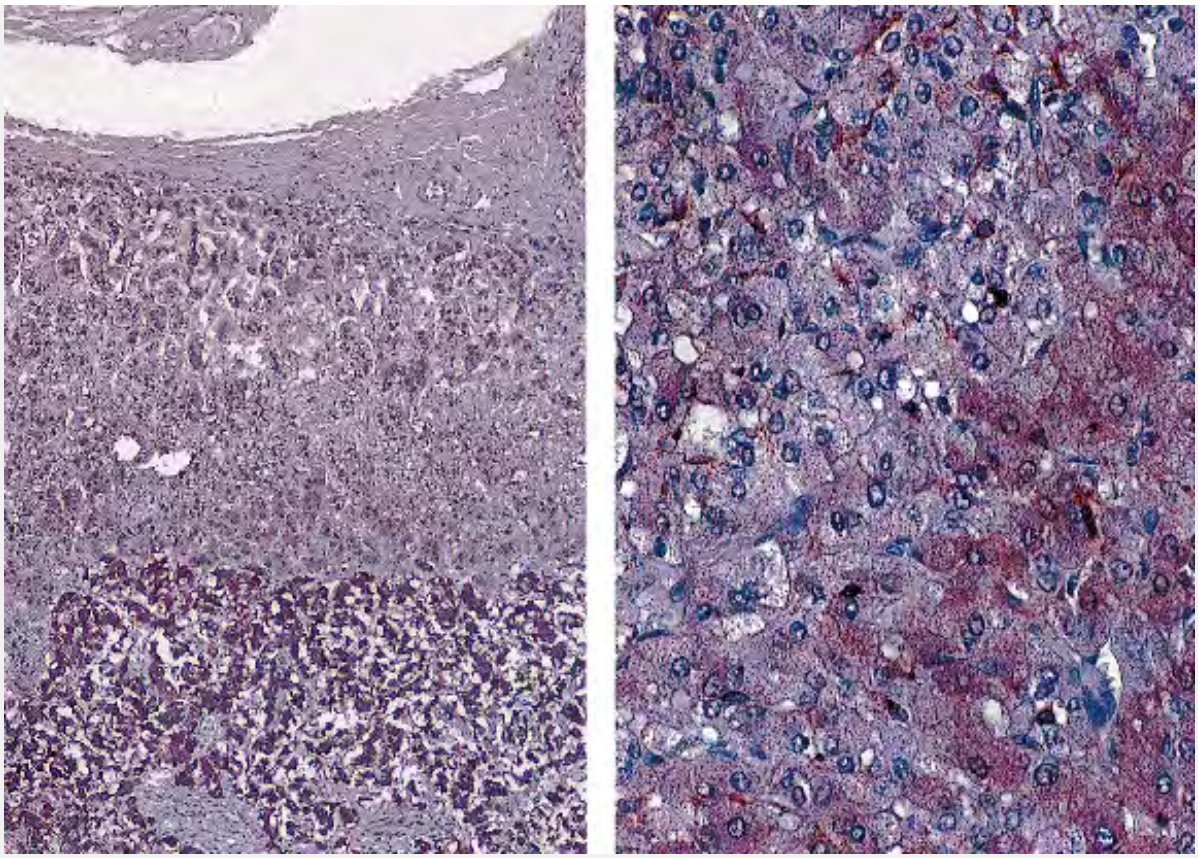

Figure 46.40 Normal adrenal medulla. A. Medulla (*below*) stains with chromogranin antibodies; cortex is unstained. B. Sustentacular cells and about one half of the pheochromocytes are stained by S-100 protein antiserum.

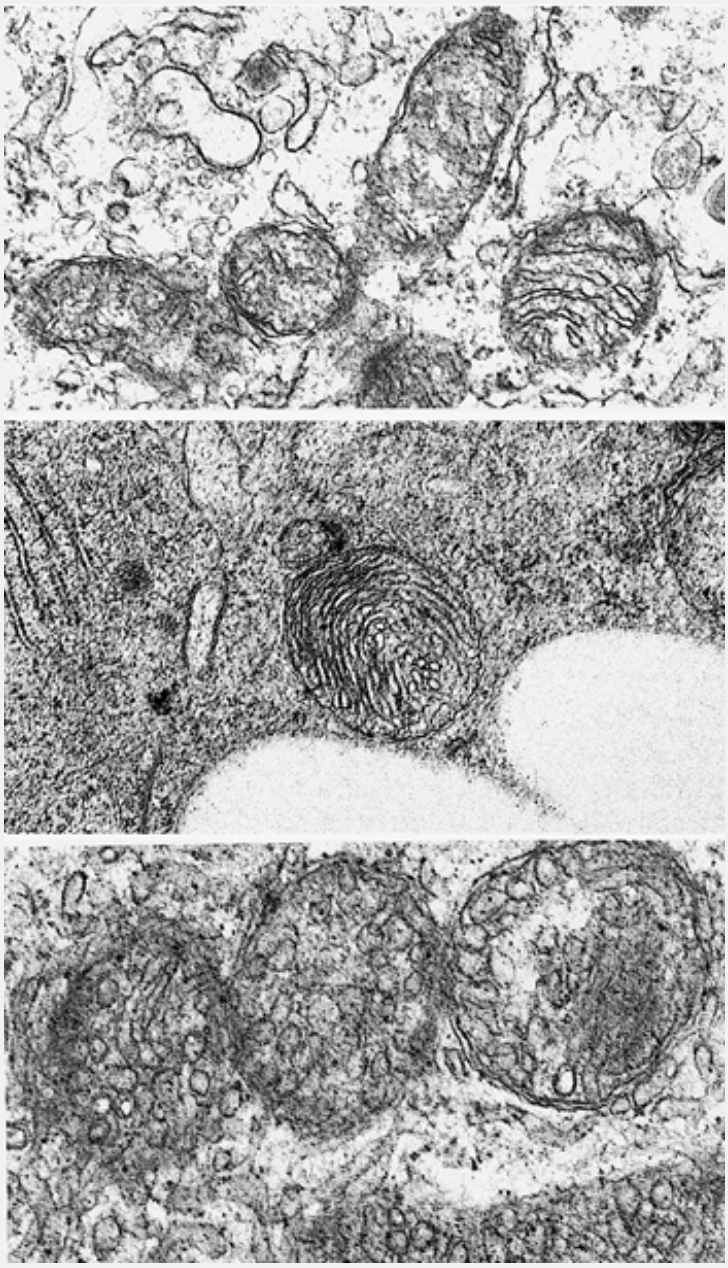

Figure 46.41 Normal adrenal cortex. A. Electron micrograph of mitochondria in the zona glomerulosa have lamellar pattern. B. Mitochondria in the zona fasciculata have a tubular and vesicular pattern. C. Mitochondria in the zona reticularis are elongated and have a vesicular appearance. Bar =1 Âµm.

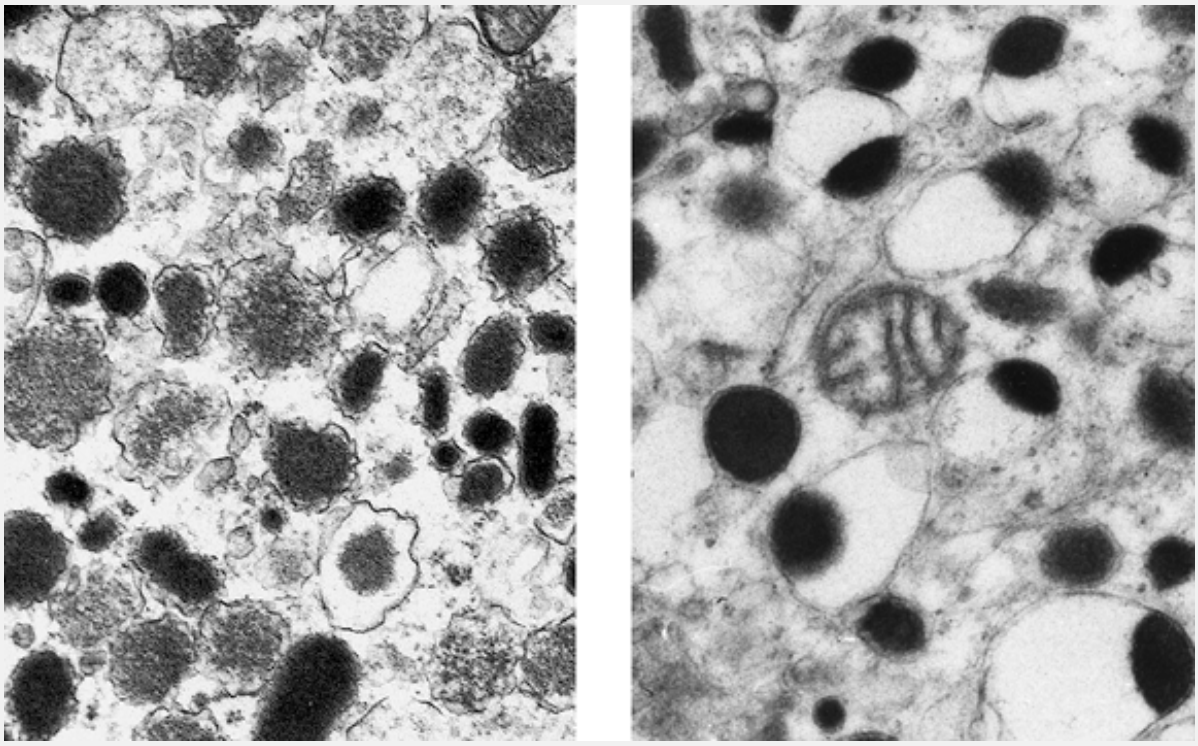

Figure 46.42 Normal adrenal medulla. Electron micrographs of medullary secretory granules. A. Epinephrine granules with a variably electron-dense content that fills the majority of the sacs. B. Content of norepinephrine granules is electron dense and often eccentrically located. Bar = 1 Âµm.

Medulla

Catecholamine-secreting cells dominate the medulla. Two cell types, epinephrine and norepinephrine, distinguished by granule type are present. In tissue fixed in glutaraldehyde, cells that contain epinephrine feature granules (Figure 46.42) measuring about 190 Âµm in diameter, with a finely granular texture that is moderately dense but not opaque, and fills the enclosing membrane. Norepinephrine-secreting cells have granules (Figure 46.42) that are

electron opaque, often located eccentrically within a dilated sac, and measure about 250 Âµm in diameter.

The Neuroendocrine System

Ronald A. DeLellis

Yogeshwar Dayal

Introduction

The results of numerous studies over the past 50 years have established that there are many striking similarities between neurons and neuroendocrine cells. Both cell types have polarized membrane orientations, two separately regulated secretory pathways, neurotransmitter synthesizing enzymes and neural cell adhesion molecules (1). Detailed biochemical and molecular studies have shown a commonality of biosynthetic products that may act as classical hormones, neurotransmitters, and paracrine or autocrine factors. Accordingly, concepts of the endocrine system have been expanded to include not only the traditional endocrine glands but also the peptidergic neurons and the system of neuroendocrine cells that is dispersed throughout many tissues of the body. Although neuroendocrine cells are discussed in the context of other tissues and organs in other chapters of this volume, this chapter will provide a more general overview of this fascinating cell type.

Historical Perspectives and Nomenclature

Current concepts of the neuroendocrine system evolved directly from a series of seminal observations that were

initiated more than a century ago. Heidenhain, in 1870, demonstrated a population of chromaffin cells in the gastrointestinal tract and suggested that they might have an endocrine function (2). Pierre Masson (3) later showed that the intestinal chromaffin cells were also argentaffin positive, and subsequent studies by Hamperl (4) using argyrophilic staining techniques led to the identification of a second population of putative endocrine cells within the intestine and a variety of extraintestinal sites. Feyrter, in 1938, suggested that the clear cells (helle Zelle) of the gastrointestinal tract formed a diffuse epithelial endocrine system (â€œdiffuse epitheliale endokrine organeâ€•) and that some of these cells might have a paracrine or local hormonal action (5 ,6). Similar groups of clear cells were illustrated by FrÃ¶lich within the bronchial tree, and Feyrter also considered them to be a part of the diffuse epithelial endocrine system (7). Ultimately, the argentaffin, argyrophil, and clear cells were recognized as components of a diffusely distributed system of endocrine cells (8).

The modern view of the neuroendocrine cell and neurosecretory neuron stemmed directly from the observations that oxytocin and antidiuretic hormone were synthesized by hypothalamic neurons and were stored within neuronal processes in the posterior pituitary before their release into the circulation (9). Furthermore, the discovery that hormone-releasing and -inhibiting factors were synthesized by hypothalamic neurons, transported via axonal transport to the median eminence, and secreted into the pituitary portal system for interactions with specific adenohypophyseal cell types, established without doubt that

neurons could function as endocrine cells (9) (Figure 47.1). These cells essentially could serve as neuroendocrine transducers by converting electrical input directly into chemical or hormonal signals (10).

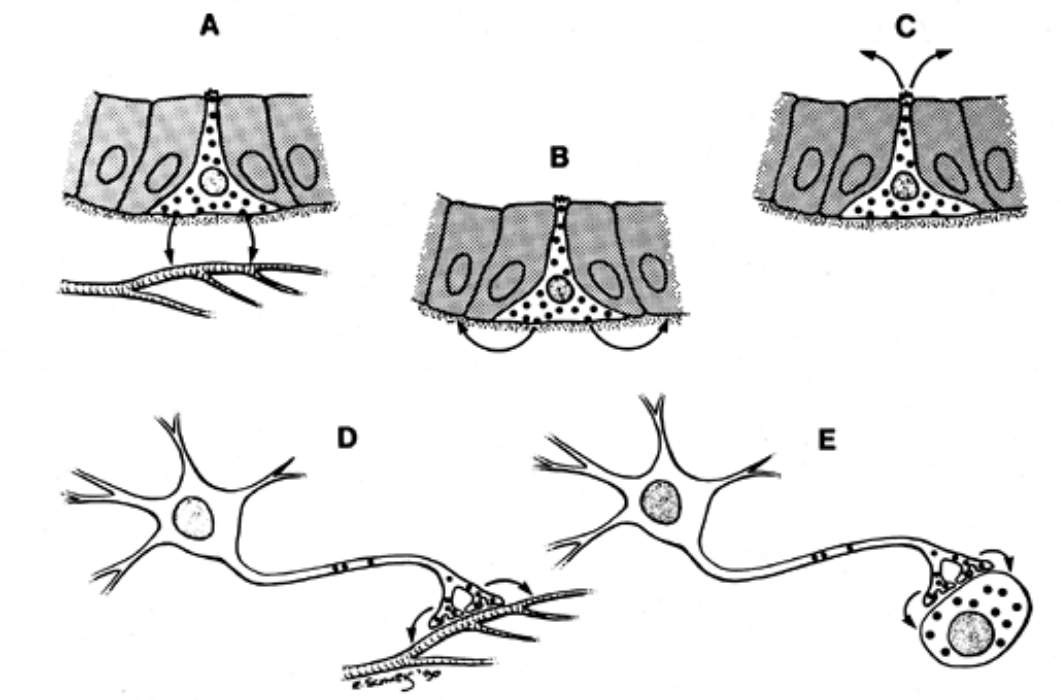

Figure 47.1 Secretory activities of neuroendocrine cells and neurons. A. Neuroendocrine cells may secrete their products through the basement membranes into adjacent capillaries for interactions with target tissues at distant sites (endocrine function). B . Neuroendocrine cells may secrete their products locally to influence the activities of adjacent epithelial cells (paracrine function). C . Neuroendocrine cells may secrete their products within a glandular lumen (luminal secretion). D . Neurons may secrete their products into the circulation for interactions with target tissues at distant sites (neuroendocrine function). E . Neurons also may secrete products that serve as neurotransmitters or neuromodulators. (Adapted with permission from:

secretion. *Science* 1979;205:1393â€“1395.
)

The discovery that the argyrophil/argentaffin cells and the cells of Feyrter's diffuse epithelial endocrine system did, indeed, have an endocrine function originated from studies conducted in the early to mid-1960s on the source of the hormone calcitonin (11 ,12). The thyroid glands of many species were known to contain parafollicular cells, which appeared clear in hematoxylin and eosinâ€“stained sections and which showed varying degrees of argyrophilia or argentaffinity (13 ,14). With immunofluorescence techniques, the parafollicular cells were ultimately shown to be the source of calcitonin, for which they were subsequently renamed C cells (15 ,16). These studies also led to the discovery that certain endocrine cells shared a series of remarkable functional and morphologic similarities with neurons (15).

In addition to the presence of calcitonin, C cells had the ability to synthesize and store catecholamines or indolylethylamines after uptake and decarboxylation of precursors of these substances (15). The latter property led to the introduction of the descriptive acronym APUD (amine precursor uptake and decarboxylation) (13). The APUD mechanism was subsequently identified in certain cells of the anterior pituitary and pancreatic islets. Cholinesterase, nonspecific esterases, Î±-glycerophosphate dehydrogenase, and certain endogenous amines were also noted variably across diverse animal species and among different endocrine cell types (14) (Table 47.1).

In comparing the APUD cells of the thyroid, pancreas, and pituitary to cells of known neural ancestry, Pearse suggested that â€œthe amine storing mechanism and presence of cholinesterase together point towards a common ancestral cell of neural origin, perhaps coming from the neural crestâ€• (15). The list of APUD cells was

then expanded to include almost all the peptide- and amine-producing cells throughout the body, including the adrenal medulla, extra-adrenal paraganglia, and parathyroid glands.

As the numbers of candidate APUD cells increased (17), it was recognized that the synthesis of regulatory peptides was a more consistent functional parameter than was synthesis of amines, and amine synthesis was ultimately dropped from the definition of these cells. In view of the many similarities between APUD cells and neurons, the essentially synonymous term, â€œparaneuronâ€• was introduced by Fujita and Kobayashi (18). Paraneurons, according to Fujita (19), were endocrine and sensory cells that shared structural, functional, and metabolic features with neurons and that produced substances identical with or related to neurohormones and neurotransmitters. The paraneurons also possessed neurosecretory-like granules and synapse-like vesicles, and they recognized stimuli on specific receptors and released their products via the secretory portion of the cell. Many investigators also began to apply the term â€œneuroendocrine cellâ€• to these cells (17).

Fluorogenic amine content
Amine precursor (5-hydroxytryptophan and DOPA) uptake
Aromatic amino acid decarboxylase
Nonspecific esterase or cholinesterase
Alpha glycerophosphate dehydrogenase
Cytosolic proteins
Neuron specific enolase, protein gene product 9.5 (PGP 9.5), histaminase, some enzymes involved in amine synthesis
Secretory Granule/Membrane Proteins
Chromogranins/secretogranins, prohormone convertases, peptidylglycine alpha amidating monooxygenase and related enzymes, some enzymes involved in amine synthesis, cytochrome b561.
Synaptic vesicle, docking and plasma membrane proteins

Vesicle membrane protein

Synaptophysin, synaptic vesicle protein 2, vesicular monoamine transporters, vesicle associated membrane protein (VAMP)/synaptobrevin, Rab3a, synaptotagmin

Plasma membrane

SNAP-25 (synaptosomal protein of 25kDa), syntaxin

Other markers

CD56 (NCAM), CD57, transcription factors (TTF-1, CDX2, pit-1, adrenal 4 site/steroidogenic factor), somatostatin receptors (sst2)

[a] The first six markers in this listing were described by Pearse in the original formulation of the APUD concept; however, endogenous amine content and the capacity for amine precursor uptake and decarboxylation are present only in some members of the dispersed neuroendocrine cell system.

Table 47.1 Markers [a] of Neuroendocrine Cells

Embryology

Embryologic data using the chickâ€“quail chimera system have now refuted the neural crest origin of most neuroendocrine cells (20 ,21). Currently, the only neuroendocrine cells of proven neural crest origin are those of the adrenal medulla, extra-adrenal paraganglia, cells of the myenteric plexus and sympathetic ganglia, and the thyroid C cells (20 ,21); however, several studies have questioned the neural crest origin of C cells (22). The peptide- and amine-producing cells of the bronchopulmonary tract and gastroenteropancreatic axis have now been shown to be of endodermal origin.

Studies of normal, chimeric, and transgenic mice have suggested that all gut epithelial cells, including endocrine cells, originate from a single multipotential stem cell present within the base of the intestinal crypts, whereas pancreatic endocrine cells appear to originate from the ductal epithelium. However, those factors

responsible for the modulation of ductal epithelium into islets of Langerhans remain largely unknown (23).

Although the neural crest origin of most neuroendocrine cells is no longer tenable, the list of neuroendocrine markers has continued to expand (Table 47.1). In its current context, the term â€œneuroendocrineâ€• does not imply an embryologic origin from the neuroectoderm but rather implies a shared phenotype characterized by the simultaneous expression of multiple genes encoding a wide variety of neuronal and endocrine traits (24 ,25).

Molecular Aspects of Neuroendocrine Cell Development

Although the precise mechanisms for the acquisition of the neuroendocrine phenotype have not been conclusively identified, recent studies suggest an important role for both

positively and negatively acting transcription factors. An important class of regulatory proteins includes those with common DNA binding and dimerization domains, the basic helix-loop-helix (b-HLH) region. The genes encoding these proteins are analogous to the achaeteâ€“scute complex, which has been identified during neuronal differentiation in *Drosophila* (26). The homologous mammalial genes have been named mammalian achaeteâ€“scute homologs (MASH) while the homologous human genes have been termed HASH. In Drosophila, one group of b-HLH factors encoded by genes such as MASH-1 activates neural differentiation whereas another group of b-HLH factors encoded by Hes1 represses neuronal differentiation. Repressive b-HLH factors such as Hes1 (hairy enhancer of split) appear to be regulated by the Notch pathway (27 ,28). Known targets of Hes1 mediated silencing include MASH1/HASH1 in the nervous system and lung. Neuroendocrine differentiation in the gastrointestinal tract and pancreas, which are under the control of b-HLH factors, are also

inhibited by Hes1.

MASH1 (HASH1 in humans) plays a critical role in the development of the nervous system and neuroendocrine cells of the lung, adrenal medulla, and thyroid (C cells) (29). In the developing mouse lung, MASH1 staining coincides with the appearance of synaptophysin and calcitonin gene related peptide in the neuroendocrine cells. Pulmonary neuroendocrine cells are absent from MASH1 knockout mice while Hes1 knockout mice demonstrate the precocious appearance of neuroendocrine cells, which also are hyperplastic. The results of this study indicate that MASH1 is critical for neuroendocrine differentiation while Hes1 inhibits neuroendocrine differentiation by inactivation of MASH1. Notch receptors, which can activate Hes1, are expressed in nonneuroendocrine cells and are also regulated by Hes1. These observations suggest that Notch receptors can play important roles in differentiation towards nonneuroendocrine cells. In addition to the Notch/Notch ligand pathways, other pathways such as Sonic hedgehog may also play important roles in the differentiation of airway epithelial cells.

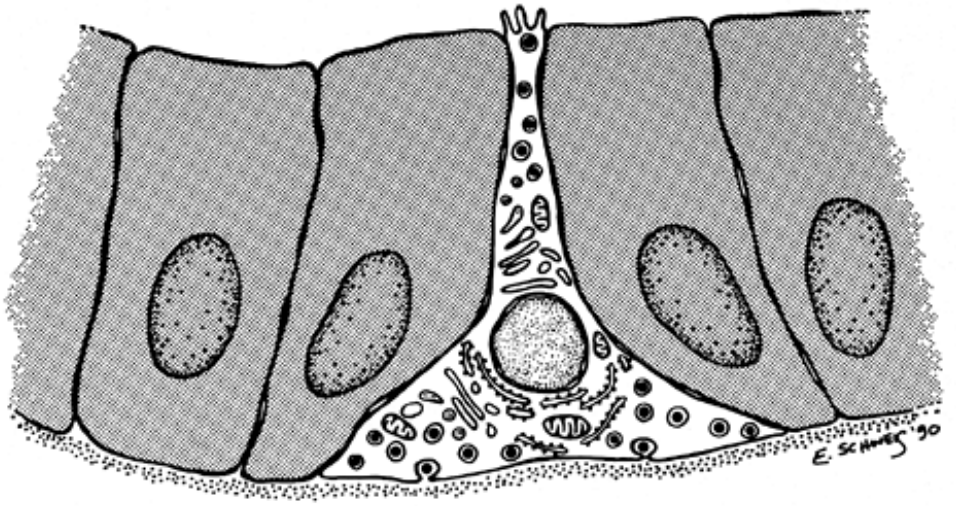

Figure 47.2 Diagram of typical open-type neuroendocrine cell. Secretory granules are concentrated at the basal pole of the cell. Stimulation of such a cell leads to the release of hormonal product

by the process of exocytosis. The basal lamina is indicated by the stippled area. Secretory granules are also present in the apical extension of the cell.

Light Microscopy and Histochemistry

Neuroendocrine cells are difficult to recognize in routinely prepared hematoxylin and eosinâ€“stained sections, where they may appear as oval, pyramidal, or flask-shaped, often with clear cytoplasm (Figures 47.2 and 47.3). In some instances, the cytoplasm may contain fine eosinophilic granules that are often difficult to resolve with usual microscopic preparations. Some neuroendocrine cell types, such as those of the intra- and extra-adrenal paraganglia and gastrointestinal tract, develop a characteristic brown to yellow coloration after primary fixation in potassium dichromate or chromic acid. This pigment results from oxidation of cellular stores of catecholamines (intra- and extra-adrenal paraganglia) or serotonin (gastrointestinal tract and other sites). In the gastrointestinal tract, the chromaffin-positive cells have also been referred to as â€œenterochromaffin cellsâ€• (EC).

Some neuroendocrine cells exhibit a characteristic yellowâ€“green fluorescence after fixation in formaldehyde and other aldehyde fixatives (30) (Figure 47.4). In some instances, the cells may become fluorescent only after administration of L-dihydroxyphenylalanine (DOPA) or 5-hydroxytryptophan. Formaldehyde forms highly fluorescent tetrahydroisoquinoline condensation products with catecholamines and Î²-carboline derivatives with tryptamines such as serotonin. Occasionally, strong fluorescence may be observed after formalin fixation and paraffin embedding. In other instances, freeze-dried tissues or fresh-frozen sections must be used for the demonstration of cellular stores of amines (30).

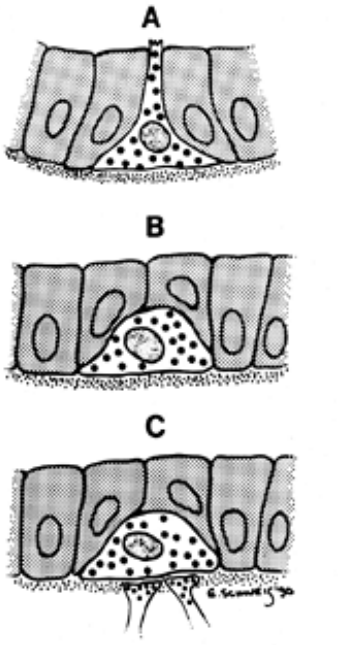

Figure 47.3 Comparison of â€œopenâ€• (A) and â€œclosedâ€• (B and C) neuroendocrine cells. A . Open cells may be found within the gastrointestinal tract and other sites. B . Closed cells are also widely distributed. The thyroid C cells are typically of the closed type. C . The Merkel cells of the skin are innervated closed-type neuroendocrine cells.

Some neuroendocrine cells, including those of the gastrointestinal tract, have the ability to reduce ammoniacal silver to the metallic state (3 ,4). Such cells are termed â€œargentaffin cellsâ€• (Figure 47.5). In many other neuroendocrine cells, silver positivity is evident only after the addition of an exogenous reducing agent to the staining solution, and such cells are said to be argyrophilic. The chromaffin and argentaffin reactions of neuroendocrine cells in the gastrointestinal tract are due primarily to the presence of serotonin. While argentaffin cells are also argyrophilic, only a subset of argyrophil cells is argentaffin positive (31). The chemical basis of the argyrophil reactions (Grimelius, Churukian-Schenk, Sevier-Munger) is unknown,

although it is apparent that reduced silver salts have an affinity for a nonamine constituent of neuroendocrine secretory granules (32).

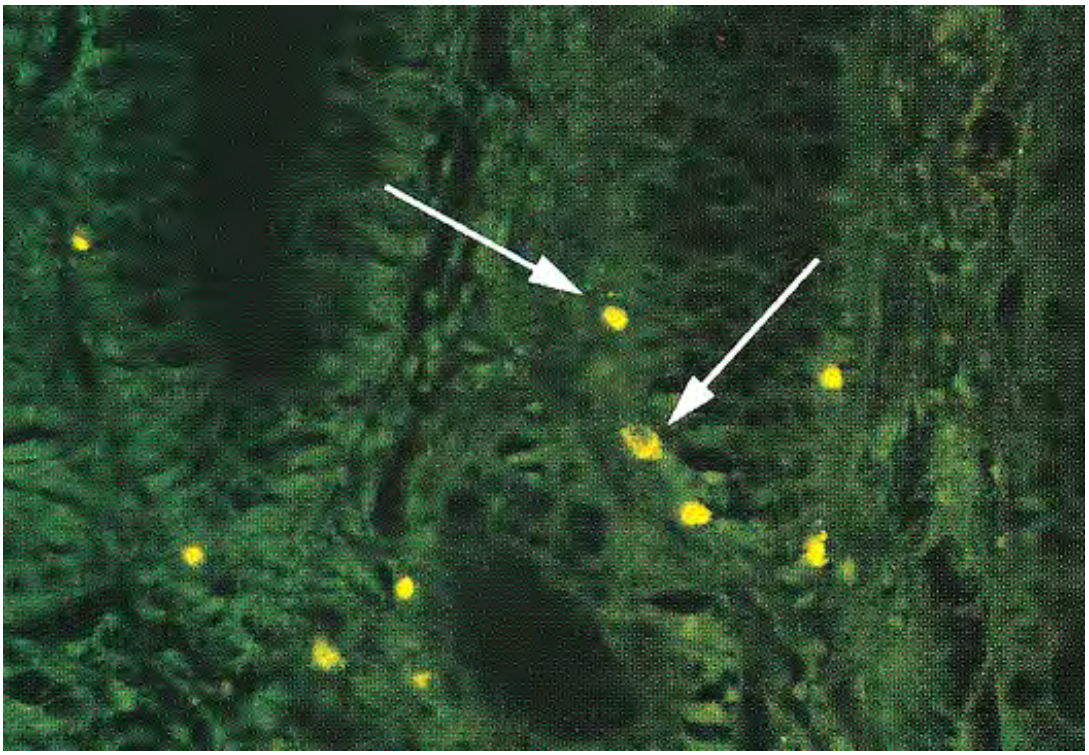

Figure 47.4 Formalin-fixed rectal mucosa photographed in ultraviolet light. The strongly fluorescent cells (*arrows*) correspond to the serotonin-containing enterochromaffin-type cells.

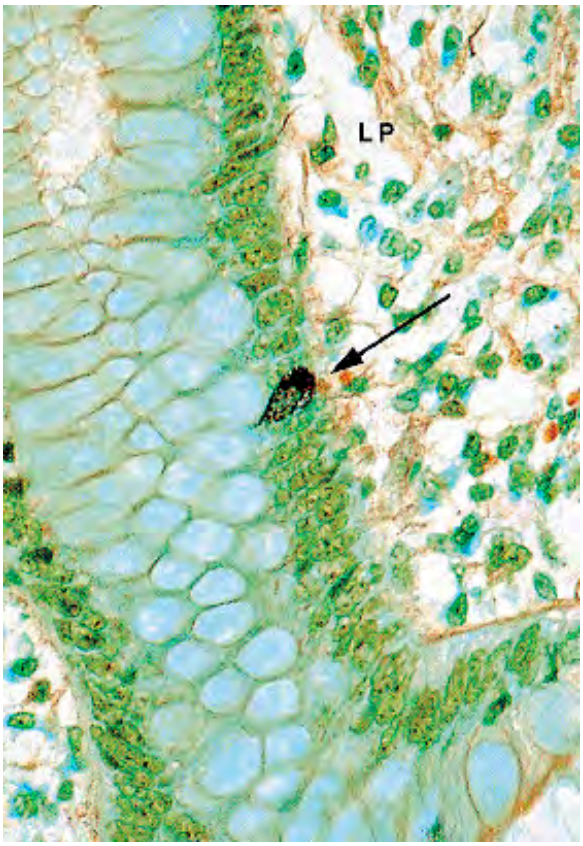

Figure 47.5 Colonic mucosa stained for argentaffin cells with the Masson-Fontana technique and methyl green counterstain. The argentaffin cell (*arrow*) illustrated in this field is characterized by the presence of black cytoplasmic granules. LP, lamina propria.

The argyrophil staining techniques have been used extensively for the identification of neuroendocrine cells; however, it should be recognized that these stains are nonspecific. Cellular products such as lipofuscin, glycogen, and certain proteins including Î±-lactalbumin may be argyrophilic (33). Alternatively, some neuroendocrine cells are argyrophilic only with certain silver staining sequences (Table 47.2).

Most neuroendocrine cells stain metachromatically with toluidine blue and coriophosphine O after acid hydrolysis of tissue sections (34). This property has been referred to as masked metachromasia. Acid hydrolysis not only removes DNA and RNA

from the cells but also converts side chain carboxamido groups to carboxyls, which are free to react with the dyes. Both chromogranin proteins and peptide hormones are most likely responsible for the property of masked metachromasia in neuroendocrine cells (34). Lead hematoxylin also has been used for the demonstration of neuroendocrine cells (34).

Table 47.2 Functional and Morphological Characteristics of Gut Endocrine Cells [a]

Cell Type	Hormone(s)	Granule Size (nm)	Morphology/Histochemistry

Neuroendocrine cells tend to be dispersed among other cell types as single cells or as aggregates of three to four cells (Figure 47.3). The basal aspects of the cells are closely applied to the subjacent epithelial basement membrane. Processes often extend from the cytoplasm to surround adjacent epithelial cells, and such neuroendocrine cells are referred to as â€œparacrine cellsâ€• (35 ,36) (Figures 47.6 and 47.7). The products of paracrine cells are thought to be released locally where they influence the activities of adjacent endocrine and nonendocrine cells (35). The apex of the neuroendocrine cell may extend directly to the glandular lumen (open-type cell) or may be covered by the cytoplasm of adjacent epithelial cells (Figures 47.3 and 47.8). The latter cells are referred to as closed neuroendocrine cells (37 ,38 ,39) (Figure 47.3). The products of open endocrine cells may be secreted directly into the lumen of a hollow viscus. In addition, such apical processes may subserve a receptor function. Although the majority

of neuroendocrine cells are not directly innervated, some cells, such as those of the skin and bronchial tree, may be innervated (Figure 47.3).

In the gastrointestinal tract, scattered neuroendocrine cells are also found within the lamina propria (40) without attachment to the overlying epithelium. Such endocrine cells are typically surrounded by Schwann cells and unmyelinated nerve fibers to form an enterochromaffin cell (EC)â€“nerve fiber complex. The ECâ€“nerve complexes are especially prominent in appendices with chronic inflammation and neural hyperplasia (40). Stromal endocrine cells also have been identified in the prostate gland (41).

Phylogenetic and ontogenetic studies have suggested that neurons are the earliest component of the neuroendocrine system because they are present in the most primitive organisms (coelenterates) (42). The next evolutionary step is the appearance of open-type neuroendocrine cells in the gut, which are present in the most highly developed invertebrates. Such cells become extensively diversified in vertebrates. The presence of gastroenteropancreatic neuroendocrine glands of classic solid type (e.g., islets of Langerhans), on the other hand, is a feature that is restricted to true vertebrates (42).

Figure 47.6 Gastric antrum stained for somatostatin using the peroxidaseâ€“antiperoxidase technique with diaminobenzidine as the chromogen (no counterstain). A process that extends from the cell body is closely applied to the basal regions of adjacent cells (*arrow*). The somatostatin-positive cells at the lower position of this microscopic field appear to be without processes; however,

the processes may be out of the plane of this section.

Ultrastructure

The most characteristic ultrastructural feature of neuroendocrine cells is the presence of membrane-bound secretory granules or vesicles, which may vary from 50 to 500 nm in diameter (Figures 47.9 and 47.10). Because of their relatively large size, these structures have also been referred to as large dense core vesicles (LDCV) or large dense core granules (LDCG) (1). Immunoelectron microscopic studies have shown that these granules represent storage sites of peptide and amine hormones. Granules storing different types of hormones are characterized by differences in size, density of contents, and substructure (43) (Table 47.2). Although most neuroendocrine secretory granules are round, others, such as those of the gastrointestinal EC and EC-like cells, are pleomorphic with elongated, reniform, round, oval, or pear-shaped forms. Secretory granules tend to be concentrated at the basal aspects of the cells in relatively close proximity to the basement membrane. Secretory granules are also prominent in cytoplasmic processes and in the apical extensions of the â€œopenâ€• cells. In addition to secretory granules, many neuroendocrine cells also contain small synaptic-type vesicles (SSVs), which have been referred to as small synaptic vesicle analogs (1). The SSVs are responsible for the release of amino acid neurotransmitters (gamma amino butyric acid, glutamate, glycine) and various biogenic amines in a regulated fashion stimulated by increases in calcium, cAMP and cGMP (1).

Apoptosis

Apoptosis plays a critical role in the physiology of many endocrine tissues. For example, deprivation of growth factors, including

thyrotropin, epidermal growth factor, and serum from cultures of thyrocytes, leads to DNA fragmentation and morphologic changes of apoptosis (44). Sasano et al. have studied the process of apoptosis in human adrenal cortex using the 3â€²-OH nick end-labeling or TdT-mediated deoxyuridine triphosphate-biotin nick end-labeling (TUNEL) method (45 ,46 ,47 ,48). With this approach, apoptotic cells were present both in the reticularis and glomerulosa, whereas proliferative cells were present primarily in the outer fasciculata. Studies of estrogen-induced prolactin cell hyperplasia in the rat have shown that withdrawal of estrogen results in increased numbers of apoptotic cells (49). This effect is enhanced by the administration of bromocriptine after estrogen withdrawal.

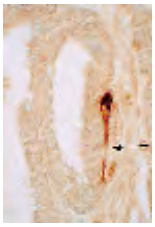

Figure 47.7 Gastric antrum stained for somatostatin using the peroxidaseâ€“antiperoxidase technique with diaminobenzidine as the chromogen (no counterstain). The process of this somatostatin-positive cell extends along the basal portion of the gland. A portion of the process is out of the plane of section (*arrow*).

Figure 47.8 Colonic mucosa stained for serotonin with the peroxidaseâ€“antiperoxidase technique with diaminobenzidine as

the chromogen and methyl green as the counterstain. A cross section of a gland contains three open-type endocrine cells whose apical processes extend into the lumen.

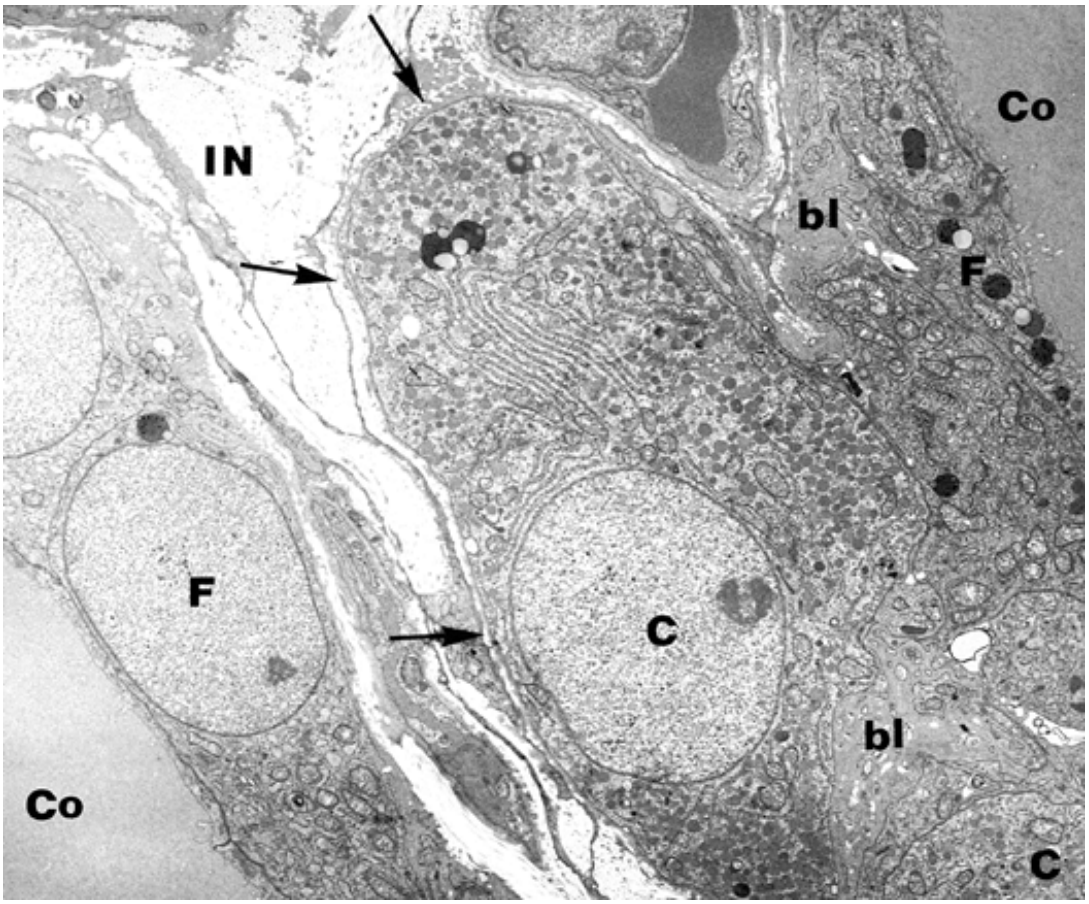

Figure 47.9 Electron micrograph of C cell from a patient with mild C-cell hyperplasia associated with the type II MEN syndrome. The C cell is present at the base of the follicle, where it is in direct contact with the basal cytoplasm of the overlying follicular cell. The basal lamina (bl) is focally thickened at the junction of the C cell and overlying follicular cells. The C cell is separated from the interstitium by the follicular basal lamina (*arrows*). C, C cell; Co, colloid; F, follicular cell; IN, interstitium (original magnification Ã—14,000).

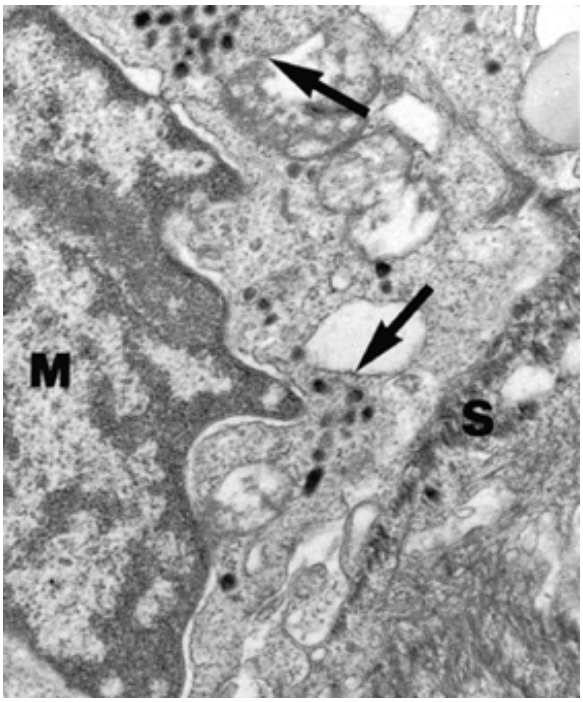

Figure 47.10 Electron micrograph of Merkel cell. Clusters of secretory granules (*arrows*) are present within the Merkel (M) cells. S, squamous cell (original magnification Ã—27,000).

Although there are few published studies of apoptosis in neuroendocrine cells of the gut and other sites, this process is initiated in neurons when the concentrations of target-derived neurotropic factors are reduced. Garcia and coworkers have demonstrated that overexpression of the bcl-2 protooncogene in cultured sympathetic neurons prevents apoptosis, which is normally induced by deprivation of nerve growth factor (50). It is likely that changes in neuroendocrine cell populations influenced by variations in tropic signals in the gastrointestinal system, pancreas, and other sites may be mediated by apoptosis. However, other mechanisms also may be operative. For example, Kaneto et al. have demonstrated that both exogenous nitrous oxide and nitrous oxide generated endogenously by interleukin (IL)-1 leads to apoptosis of isolated rat pancreatic islet cells. The action of

streptozotocin appears to be mediated by a similar mechanism (51). These findings suggest that nitrous oxideâ€“induced internucleosomal DNA cleavage is an important initial step in the destruction and dysfunction of pancreatic Î² cells induced by inflammatory stimuli or by the action of streptozotocin.

Markers of Neuroendocrine Cells

Neuroendocrine cells can be classified into those of neural (neurons, paraganglioma cells) and epithelial types. The former contain neurofilaments as their major intermediate filament type while the latter contain cytokeratins with or without neurofilaments. Both cell groups can be identified on the basis of their contents of specific hormones and neurotransmitter substances (52 ,53 ,54), as discussed in other chapters in this volume and by the presence of a variety nonhormonal products. The nonhormonal constituents of neuroendocrine cells include a wide array of cytosolic, secretory granule and vesicle membrane, and plasma membrane constituents. These products can be identified effectively via immunohistochemistry with polyclonal antisera or monoclonal antibodies. This approach is of particular importance when evaluating tissues for the presence of neuroendocrine cells when the specific hormonal product is unknown.

Cytosolic Constituents

A variety of different enzymes can be demonstrated by immunohistochemistry in neuroendocrine cells. Although some of the enzymes are present in most neuroendocrine cells, others have a more restricted distribution. Neuron-specific enolase has been considered as a generic marker both for neurons and neuroendocrine cells (55). The enolases are products of three independent gene loci, which have been designated Î±, Î², and Î³ (56 ,57 ,58). Nonneuronal enolase (Î±Î±) is present in fetal

tissues, glial cells, and many nonendocrine tissues. Beta (Î²Î²)-enolase is present in muscle tissue, whereas hybrid enolases (Î±Î³, Î±Î²) have been identified in megakaryocytes and a variety of other cell types. Neuron-specific enolase (Î³Î³) replaces nonneuronal enolase during the migration and differentiation of neurons, and it has been suggested that the appearance of neuron-specific enolase reflects the formation of synapses and the acquisition of electrical excitability. Although the sensitivity of neuron-specific enolase for the detection of neuroendocrine cells is high, its specificity is low.

Seshi et al. have demonstrated a high degree of specificity with monoclonal antibodies to neuron-specific enolase (59). Some of the monoclonal antibodies react predominantly with nerve fibers, whereas others react with the perikaryon exclusively or with the perikaryon and associated nerve fibers. In contrast to the polyclonal antisera that stain a variety of nonneuronal structures, the monoclonal antibodies stain neuronal cells in a more selective fashion. Some monoclonal antibodies also react with normal adrenal medullary cells and with subsets of pancreatic islet cells.

The protein gene product 9.5 (PGP 9.5) is a soluble protein with a molecular weight of 27,000 Daltons (60). PGP 9.5 is a ubiquitin carboxyterminal hydrolase that plays a role in the catalytic degradation of abnormal denatured proteins (61). Immunohistochemical studies have demonstrated that it is present in neurons and nerve fibers at all levels of the central and peripheral nervous system. It is also present in a variety of neuroendocrine cells, except for those in the normal gastrointestinal tract (60). The patterns of staining for PGP 9.5 and neuron specific enolases are generally similar in that positive cells show diffuse cytoplasmic reactivity that is unrelated to the type of hormone produced or to the degree of cellular differentiation. Additional enzymes that have a dominant cytolosolic distribution include histaminase (62) and some of the enzymes involved in catecholamine biosynthesis (54).

Secretory Granule Constituents

The chromogranins/secretogranins (Cg/Sg) represent a widely distributed family of soluble proteins that represent the predominant constituent by weight of neurosecretory granules (Table 47.1 and Figure 47.11) (63 ,64 ,65). Three major chromogranin proteins have been identified and categorized and have been designated chromogranin A, chromogranin B, and secretogranin III. Additional members of the granin family include secretogranins III, IV, and V. The chromogranins are calcium binding proteins that play important roles in the packaging and/or processing of regulatory peptides. These proteins contain multiple dibasic residues that are sites for endogenous proteolytic processing to smaller peptides (66 ,67). For example, chromogranin A contains 439 amino acids that represent potential cleavage sites by proteases such as the hormone proconvertases.

Resultant peptides include chromostatin, pancreastatin, parastatin, and vasostatin. Functional roles for these smaller peptides include intracellular binding functions, inhibitory effects on the secretion of other hormones and antibacterial/antifungal effects. Both pancreastatin and chromostatin are present in most neuroendocrine cells, adrenal medulla and anterior pituitary (68 ,69), while derivatives of chromogranin B (GAWK protein) have been localized to neuroendocrine cells in the pituitary, gastrointestinal tract, pancreas, and adrenal medulla (70).

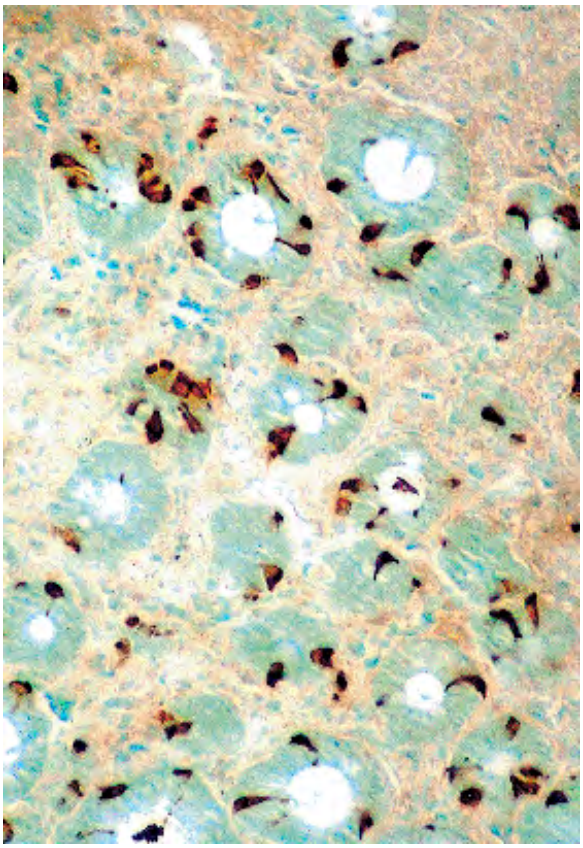

Figure 47.11 Colonic mucosa stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and methyl green as the counterstain. This cross section is at the level of the lower third of the mucosa and shows many opened and closed neuroendocrine cells.

The Cg/Sg are widely distributed throughout the entire system of neuroendocrine cells and have distinctive patterns of tissue and cellular distribution (71). Although many neuroendocrine cells contain CgA, CgB, and SgII, others contain only one or two of these proteins. For example, thyroid C cells contain CgA and SgII but lack CgB. Parathyroid chief cells, on the other hand, are positive for CgA but lack SgII. The distribution of this family of proteins is reviewed in detail by Huttner et al. (71). The chromogranins are cosecreted with other granule contents, but their replenishment is differentially regulated.

A variety of endopeptidases and carboxypeptidases are required for the formation of biologically active peptides from precursor molecules and are present in the trans-Golgi region and secretory granules of neuroendocrine cells. They include the prohormone convertases, PC1/PC3 and PC2, and carboxypeptidases H & E (72 ,73). The proconvertases are widely distributed in neuroendocrine cells while other types of endocrine cells (thyroid follicular cells, parathyroid chief cells, adrenal cortical cells, and testis) are negative. Neuroendocrine cells with a neural phenotype (adrenal medullary cells) contain a predominance of PC2 while epithelial neuroendocrine cells contain a predominance of PC1/PC3. With the exception of parathyroid cells, the presence of PC2 and PC3 correlates with the presence of chromogranin and secretogranins. PC2 and PC1/PC3 are present in normal pituitaries and adenomas, with ACTH producing adenomas containing a predominance of PC1/PC3 and other adenomas expressing a predominance of PC2.

Peptidylglycine Î±-amidating monooxygenase (PAM), peptidyl-glycine Î±-hydroxylating monooxygenase (PHM), and peptidylamidaglycolate lyase (PAL) are present in neuroendocrine secretory granules (74 ,75). These enzymes are responsible for the Î± amidation of the C-terminal regions of peptide hormones, a function which is critical for the biological function of peptides. These enzymes are not restricted in their distribution to neuroendocrine cells. For example, they have also been found in the lung in cells of the airway epithelium and glands, vascular endothelium, some chondrocytes of bronchial cartilage, alveolar macrophages, and smooth muscle cells.

Cytochrome b561 (Chromomembrin B), a neurosecretory granule membrane constituent, is responsible for the transport of electrons into the secretory granule matrix in order to maintain a supply of reduced ascorbic acid, which serves as an electron donor for dopamine Î²-hydroxylase and for amidases that modify C-terminal portions of certain neuropeptides (76). Antibodies to cytochrome

b561 may be useful for the identification of neuroendocrine cells that are engaged in specific functions related to catecholamine synthesis or peptide amidation (77).

Synaptic Vesicle and Docking Constituents

Synaptophysin (molecular weight 38,000) was one of the earliest markers developed to visualize small synaptic vesicle analogs in neurons and neuroendocrine cells (78 ,79 ,80). This protein is widely distributed in nerve terminals in the central and peripheral nervous system and is also present in neuroendocrine cells that are specialized for the regulated secretion of peptide hormones. Synaptophysin is the most abundant integral membrane protein of neuronal vesicles. It is localized in a punctate pattern in synaptic regions of neurons and has a diffuse cytoplasmic distribution in neuroendocrine cells. Ultrastructurally, synaptophysin is present predominantly in smooth-surface synaptic-type vesicles. Although synaptophysin was originally thought to

be specific for neuroendocrine cells, it is also expressed in other cell types, including the adrenal cortex (81 ,82).

Synaptic vesicle protein 2, (SV2), an integral membrane protein, is present in the central and peripheral nervous system and in a wide variety of neuroendocrine cell types (83). This glycoprotein occurs in 3 well-characterized isoforms, which have been designated SV2A, SV2B and SV2C. Immunoreactivity for SV2 is present in neuroendocrine cells in the gastrointestinal tract, pancreas, anterior pituitary, thyroid (C cells), parathyroid, and adrenal medulla. Chief cells of the gastric oxyntic mucosa are also positive for SV2. Interestingly, gastrointestinal stromal tumors have been reported to be positive for SV2 (84). Comparison of SV2, synaptophysin, and chromogranin A immunoreactivities have shown more SV2 and synaptophysin than chromogranin A positive

cells in the gastric antrum and pancreas. More SV2 than synaptophysin positive cells were seen in other regions of the gastrointestinal tract and other endocrine organs. Generally, more chromogranin A than SV2 immunoreactive cells were present in the duodenum, colon, and parathyroid.

The vesicular monoamine transporters (VMAT1 and VMAT2) are integral membrane proteins that mediate the transport of amines into vesicles of neurons and neuroendocrine cells (85 ,86). These two isoforms show broad selectivity for different amines and are distributed differently in various cell types. VMAT1 is expressed in gastrointestinal enterochromaffin (EC) tumors and in the corresponding normal EC cells and the small intensely fluorescent cells of the sympathetic ganglia. VMAT2, on the other hand, is present in histamine producing ECL cells and in central and peripheral neurons. VMAT1 and VMAT2 are both expressed by adrenal medullary cells.

The process of regulated secretion in neurons and neuroendocrine cells is highly complex (1 ,87 ,88). According to the SNARE (SNAP-receptor) hypothesis, the selective docking of a transport vesicle with the appropriate target membrane occurs via the formation of a complex between a vesicle membrane protein (v-SNARE) and the corresponding target membrane protein (t-SNARE) (89). The resulting SNARE complex ultimately leads to membrane fusion. Three families of SNARE proteins are currently recognized. They include the VAMP (vesicle associated membrane protein)/ synaptobrevin family of v-SNAREs and two families of t-SNAREs, the syntaxin family and the SNAP-25 family. In the initial phases of exocytosis, N-ethylmaleimide-sensitive factor (NSF) and soluble NSF attachment protein (Î±-SNAP) act on synaptobrevin, syntaxin, and SNAP-25. This leads to dissociation of the SNARE complexes, activation of the SNARE proteins and removal of the negative regulators of exocytosis. Subsequently, the vesicle protein Rab3 promotes reversible vesicle attachment (tethering) to the presynaptic membrane. Tethering permits the formation of the

SNARE complex, which consists of synaptobrevin, syntaxin, and SNAP-25. This series of events brings the vesicle into a docked position, immediately adjacent to the plasma membrane and calcium channels. Docking is an irreversible step in which there is some degree of membrane fusion. At some time during docking, synaptotagmin is recruited to the SNARE complex (89).

Many of the proteins involved in the process of regulated secretion can be visualized in immunohistochemical formats and have been utilized as neuroendocrine cell markers. While some of these proteins are localized within the plasma membranes [SNAP-25 (synaptosomal protein of 25kDa) and syntaxin], others (synaptobrevin, synaptophysin, Rab3a, and synaptotagmin) are present in the synaptic vesicle membranes. The soluble proteins involved in this process include N-ethylmaleimide-sensitive fusion protein (NSF) and soluble NSF attachment proteins (SNAPs).

The vesicle associated membrane proteins (VAMP) play important roles in docking and/or fusion of secretory vesicles with their target membranes. VAMP, which is also known as synaptobrevin, occurs in 3 isoforms, which are designated VAMP-1, VAMP-2, and VAMP-3 (cellubrevin). VAMP-2 and VAMP-3 are expressed in pancreatic islets (90) and are involved in calcium mediated insulin secretion. VAMP-1 is present primarily in pancreatic acinar cells (91).

The synaptotagmins (p65) include a large family of calcium binding proteins that are constituents of the membranes of synaptic vesicles. In the normal pancreatic islets, synaptotagmins are colocalized with insulin in Î² cells and are involved with calcium induced insulin secretion (92).

Rab proteins are low-molecular-weight GTP binding proteins. The Rab3 isoforms are involved in the exocytosis of synaptic vesicles and secretory granules in the CNS and anterior pituitary. In normal human pituitary, Rab3 isoforms are present primarily within the cytoplasm of growth hormone producing cells with rare

expression in other cell types. Among pituitary adenomas, Rab3 is most commonly expressed in growth hormone producing adenomas but also occurs in adenomas of other types (93).

SNAP-25 has been studied most extensively in the pituitary gland. This protein is localized predominantly to the plasma membranes of both normal and neoplastic adenohypophyseal cells (94 ,95). Similar patterns of localization have been documented in the adrenal and pancreatic islets (96 ,97).

The presence of certain lymphoreticular antigens in some neuroendocrine cells suggests that these proteins may serve similar functions in endocrine and lymphoid tissues (98 ,99 ,100). These functions potentially include some aspects of cell-to-cell recognition and release of secretory products (e.g., hormones and lymphokines) in response to common microenvironmental signals (98). CD57 (leu 7;HNK-1) recognizes epitopes in natural killer lymphocytes, myelin-associated glycoprotein (MAG), neuronal cell adhesion molecules, and a granule matrix constituent of chromaffin cells (99 ,100). The largest of the MAGs (MAG-72) is related

to the immunoglobulin supergene family proteins as well as neural adhesion molecules. CD57 also reacts with a subset of neuroendocrine cells in the anterior pituitary, pancreatic islets, and gastrointestinal tract (100). In addition, CD57 immunoreactivity has been identified in Schwann cells and other nerve-supporting elements. S-100 protein, which was originally isolated from the brain, is present in cells that serve as a supporting structure in many neuroendocrine tissues, such as the adrenal medulla, paraganglia, and anterior pituitary (101).

The neural cell adhesion molecules (NCAMs) represent a family of glycoproteins that play key roles in cell binding, migration, differentiation, and proliferation (101 ,102). The NCAM family includes several major peptides that are generated by alternative

splicing of RNA from a gene that is a member of the immunoglobulin supergene family. The peptide sequences that are external to the plasma membrane contain five regions that are similar to those present in immunoglobulins. The molecules are modified posttranslationally by phosphorylation, sulphation, and glycosylation. The homophilic-binding properties of NCAMs are modulated by differential expression of homopolymers of Î±2, 8-linked N-acetylneuraminic acid (polysialic acid).

CD57 recognizes a 140kDa isoform of NCAM which is expressed on resting and activated NK cells and a subset of CD3+ cells. Although initial studies had suggested that NCAM was restricted in its distribution to the brain, more recent studies indicate that it is also present in a variety of neuroendocrine cells, including the islets of Langerhans, adenohypophysis, and adrenal medulla, as well as in a variety of nonneuroendocrine cells (103). Komminoth et al. have used a monoclonal antibody reactive with a long chain from of Î±-2, 8-linked polysialic acid that is present on NCAMs (104). They reported positive staining in cases of familial medullary thyroid carcinoma, both in the neoplastic cells and in hyperplastic C cells adjacent to the tumorous foci. Cases of primary C-cell hyperplasia unassociated with medullary thyroid carcinoma were also positively stained, whereas most normal C cells and C cells in secondary hyperplasia were nonreactive. These findings indicate that determinations of NCAMs may be helpful in distinguishing reactive proliferations of neuroendocrine cells from neoplastic and preneoplastic proliferations of these cells.

Transcription Factors

Transcription factors are proteins that bind to regulatory elements in the promotor and enhancer regions of DNA and regulate gene expression and protein synthesis. They may be cell/tissue specific or may be present in a variety of different tissue types. CDX2 is a transcription factor that has been used extensively as a marker of

intestinal adenocarcinoma. In addition to its presence in normal enterocytes, CDX2 is present in all serotonin-producing EC cells, 10% of gastrin-producing G cells, 30% of gastric inhibitory peptide cells, and in a small proportion of motilin-producing cells while other gastrointestinal endocrine cells are negative (105). Thyroid transcription factor-1 (TTF-1) is present both in thyroid (follicular cells and C cells) and in the lung (type II epithelial cells, subsets of respiratory nonciliated bronchiolar epithelial cells and pulmonary neuroendocrine cells) (106). The adrenal 4 site/steroidogenic factor (ad4BP/SF-1) is present in steroid-producing cells and in certain anterior pituitary cell types while the pituitary transcription factor, Pit-1, is present in certain cells of the adenohypophysis and the placenta (107).

Somatostatin Receptors

Somatostatin interacts with specific receptors (sst1â€“sst5) expressed on target cells (108). These receptors have attracted considerable attention because of novel clinical applications related to their overexpression in certain tumors, including those of the neuroendocrine system. Because of the metabolic instability of natural somatostatin, a number of synthetic analogs (e.g., octreotide) have been developed. Radionuclide conjugates of these analogs have been used successfully for imaging and treatment of tumors. The ability of tumors to express these receptors can be assessed with antibodies to the specific receptors, particularly the sst-2 receptor. Positive staining of normal gastrin-producing cells for sst-2A has been documented in gastric antrum, duodenum, jejunum, and ileum (109). In addition, occasional sst-2A positive cells have been recognized in the basal cell component of bronchi.

Function of Neuroendocrine Cells

The function of neuroendocrine cells has been established by the use of immunohistochemical techniques for the localization of

specific hormones and other substances. In many instances, the use of region-specific antisera permits the localization of hormone precursors as well as mature hormones. Proinsulin immunoreactivity in the Î² cells of normal pancreatic islets is present in a crescent-shaped perinuclear area that corresponds to the Golgi zone (110). Insulin, on the other hand, is present throughout the cytoplasm with a variably stained perinuclear region.

Although initial studies suggested that single neuroendocrine cells were responsible for the production of a unique hormone (one-cell, one-hormone hypothesis), more recent studies indicate that these cells are multimessenger systems (111). The peptide hormones are synthesized within the granular endoplasmic reticulum and are packaged into secretory granules by way of the Golgi region. Multiple different peptide products may be synthesized via this route in single neuroendocrine cells. Other nonpeptide

hormone constituents such as catecholamines are synthesized within the cytosol and are then taken up into secretory granules (25). Any individual neuroendocrine cell can, therefore, vary the secretion of its products in response to different signals in normal and pathologic states.

Immunohistochemical and molecular biologic studies have led to many interesting insights into the functional interrelationships of the various components of the neuroendocrine system. For example, peptide hormones first isolated from the gastroenteropancreatic axis have been found subsequently in neurons of the central and peripheral nervous systems, where they may function as neurotransmitters or neuromodulators (10). Other peptides initially isolated from the brain have been localized to the endocrine cells of the gut, pancreas, and lung, where they may have a paracrine function (112). Furthermore, such studies have shown that the microarchitecture of endocrine organs, which may appear homogeneous in hematoxylin and eosinâ€“stained

sections, is often organized in a manner that permits paracrine interactions. The somatostatin cells of the pancreatic islets, for example, are located between the insulin and glucagon cells and typically extend short branching processes, which are in apposition to both cell types. Regulation of the secretion of insulin and glucagon may therefore be mediated by the local paracrine effects of somatostatin and by the endocrine effects of somatostatin reaching the islets by the circulation (113 ,114).

Neuroendocrine cells in different tissues may produce identical peptides. Somatostatin, for example, is present in certain hypothalamic neurons, pancreatic D cells, gastrointestinal D cells, bronchopulmonary endocrine cells, thymic endocrine cells, and a subset of thyroid C cells, where it is colocalized with calcitonin (113 ,114 ,115). Calcitonin is present in thyroid C cells, bronchopulmonary and thymic endocrine cells, and certain urogenital endocrine cells. Gastrin-releasing peptide, a 27â€“amino acid peptide that is the mammalian homolog of bombesin, is present in thyroid C cells, small intensely fluorescent cells of sympathetic ganglia, neuronal cells of the gastrointestinal myenteric plexus, and bronchopulmonary endocrine cells (116 ,117).

Neuroendocrine cells may produce multiple distinct peptides from a common precursor molecule. For example, adrenocorticotropin (ACTH) is synthesized from the large precursor molecule pro-opiomelanocortin (POMC) (118). In the adenohypophysis, POMC is processed to yield ACTH, Î²-lipotropin, and a 16KD N-terminal fragment. In the intermediate lobe, ACTH and Î²-lipotropin are processed to yield Î±-MSH and Î²-endorphinâ€“related peptides, respectively. Hormonal diversity in neuroendocrine cells also may result from alternate splicing pathways that produce different messenger RNAs from a single gene. Both calcitonin and the calcitonin geneâ€“related peptide (CGRP) are produced from a primary RNA transcript that is spliced to produce two different forms of mature messenger RNA (119). More than one gene may

also encode closely related peptides. In anglerfish islets, for example, recombinant DNA techniques have shown two different messages for somatostatin, one of which encodes somatostatin I while the other encodes somatostatin II (120).

Distribution of Neuroendocrine Cells

The histology of the adenohypophysis, parathyroid glands, intra- and extra-adrenal paraganglia, and pancreatic islets is discussed in separate chapters in this volume. The remaining sections of this chapter review the distribution of neuroendocrine cells in other tissues and organs.

Bronchopulmonary and Upper Respiratory System

The neuroendocrine components of the lung occur singly as solitary neuroendocrine cells and in small aggregates that have been designated neuroepithelial bodies (NEBs) (121) (Figure 47.12). Solitary neuroepithelial cells may be of the opened or closed type. NEBs are composed of

clusters of clear to faintly eosinophilic cells that extend from the bronchial basement membrane to the lumen. NEBs are extensively innervated. Although the functions of the two neuroendocrine components are not known with certainty, NEBs most likely act as intrapulmonary chemoreceptors. Solitary neuroendocrine cells most likely subserve a paracrine function.

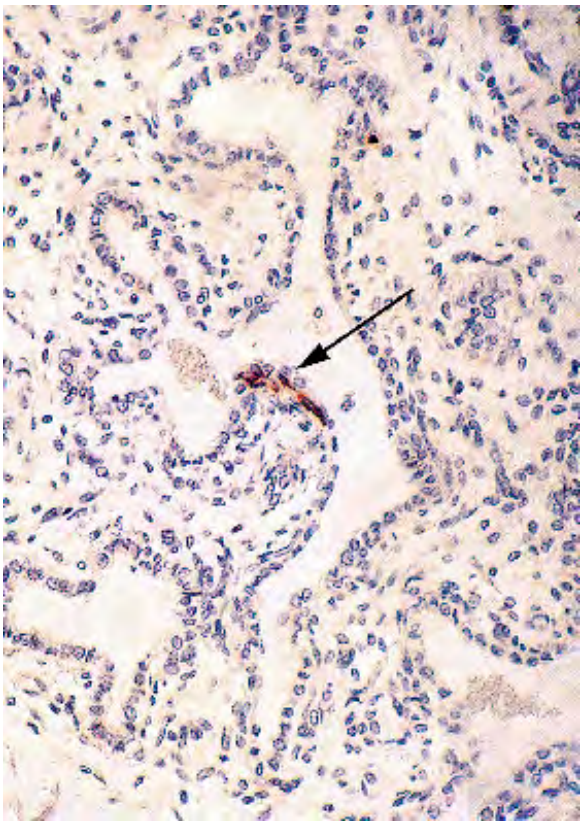

Figure 47.12 Fetal lung stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. A cluster of chromogranin-positive cells (*arrow*) is present just beneath the bronchial epithelium.

The secretory granules of neuroendocrine cells in the lung show considerable variation in size and density (122 ,123). On the basis of granule size, the bronchopulmonary neuroendocrine cells have been divided into three types. The P1 cells have granules that measure 40 to 50 nm in diameter. These cells have been noted in fetal lung. The P2 cells have granules that measure 120 to 130 nm in diameter, whereas the P3 granules measure 180 to 200 nm. The granules of Pa cells, which are found in the adult lung, measure 100 to 120 nm in diameter. Both NEBs and solitary neuroendocrine cells contain serotonin, bombesin/gastrin-releasing

peptide (GRP), and calcitonin, whereas the solitary neuroendocrine cells also contain leu-enkephalin (117 ,121) (Figure 47.13). Severely hyperplastic and dysplastic cells of the NEBs also may produce adrenocorticotropin, vasoactive intestinal peptide, and somatostatin (121). The NEBs are particularly conspicuous in fetal lung tissue but are sparse in the adult (117). The neuroendocrine components of the lung are also prominent in hypoxic conditions, including high-altitude conditions and chronic pulmonary diseases such as bronchiectasis.

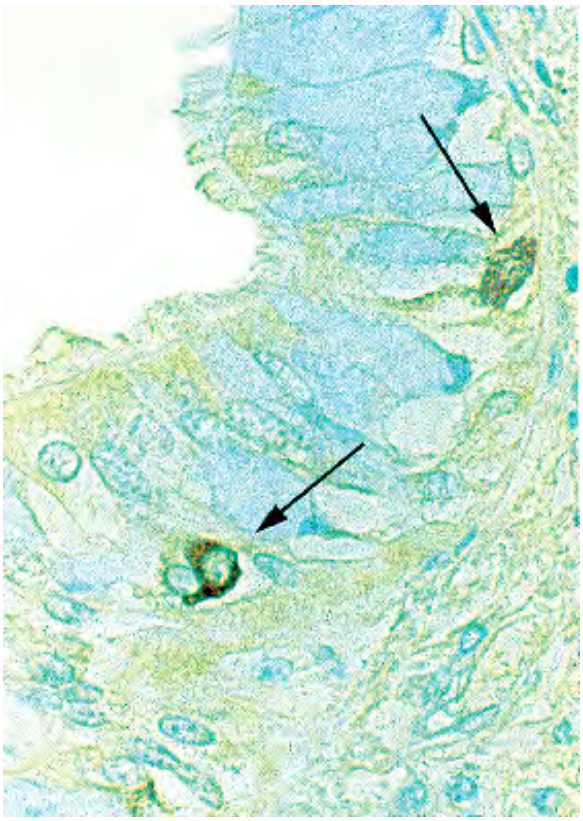

Figure 47.13 Adult lung stained for gastrin-releasing peptide (GRP)/bombesin with an antibody to GRP with the indirect peroxidase-labeled method. Diaminobenzidine was the chromogen with methyl green counterstain. Two GRP-positive cells (*arrows*) are present within the bronchial epithelium. (Courtesy of Dr. Y. Tsutsumi, Tokai University School of Medicine, Japan.)

Both in situ hybridization and immunohistochemical studies have shown GRP and its corresponding messenger RNA (mRNA) as early as 8 weeks of gestation in solitary neuroendocrine cells and NEBs, primarily at branch points of bronchioles. The number of cells reach a peak by 16 to 30 weeks of gestation and decline at about 6 months of age. These findings suggest that GRP may be involved in the growth and development of normal lung. Increased numbers of GRP-containing cells have been found in infants with bronchopulmonary dysplasia and in children with cystic fibrosis or prolonged assisted ventilation (117).

Neuroendocrine cells, as defined by their argentaffinity or argyrophilia, are rare in the larynx. Pesce et al. were able to identify scattered argyrophil cells in only two of 43 specimens of larynx within the respiratory epithelium (124). The studies of Torre-Rendon et al. demonstrated occasional argyrophil cells both within the laryngeal squamous and respiratory epithelium (125). Argyrophil cells are also present within adjacent minor salivary glands and the epithelium of the middle ear.

Thyroid and Thymus

In both adult and neonatal thyroid glands, the calcitonin-containing C cells are concentrated in a zone corresponding to the upper to middle thirds of the lobes along a hypothetical central axis (126). The extreme upper and lower poles, as well as the isthmus, are devoid of C cells. The C cells occupy an exclusively intrafollicular position (Figures 47.9 , 47.14 , and 47.15). In neonates, the C cells are prominent and measure up to 40 Âµm in diameter. Occasional cells may show branching processes that are closely applied to the follicular basement membrane and the plasma membranes of adjacent follicular cells. Groups of up to six C cells may be present in the thyroids of neonates with up to 100 C cells per single low-power microscopic field. C cells are less numerous in adults than in neonates and appear flattened or

spindle shaped. Typically, adult thyroid glands contain fewer than 50 C cells per single low-power field, although occasional normal adult glands may have a higher density of C cells. Rarely, nodules of C cells may be found in normal adult glands, as discussed in the section on aging.

Two types of secretory granule have been observed in normal as well as hyperplastic C cells (127). Type I granules have an average diameter of 280 nm, with moderately dense, finely granular contents that are closely applied to the limiting membranes of the granules. The type II granules, on the other hand, have an average diameter of 130 nm with electron-dense contents that are separated from the limiting membranes of the granules by a small but distinct electron-lucent space. Immunoelectron microscopic

studies have shown that both granule types contain immunoreactive calcitonin. Some of the C cells, both in normal adult and in neonatal glands, also contain somatostatin or bombesin/GRP (117 ,127 ,128). Approximately 70% of fetal and neonatal C cells contain GRP peptide and mRNA, whereas less than 20% of adult C cells are positive for GRP (46). It has been suggested that GRP may play a role as a thyroid growth factor analogous to its presumed role in the developing lung (117).

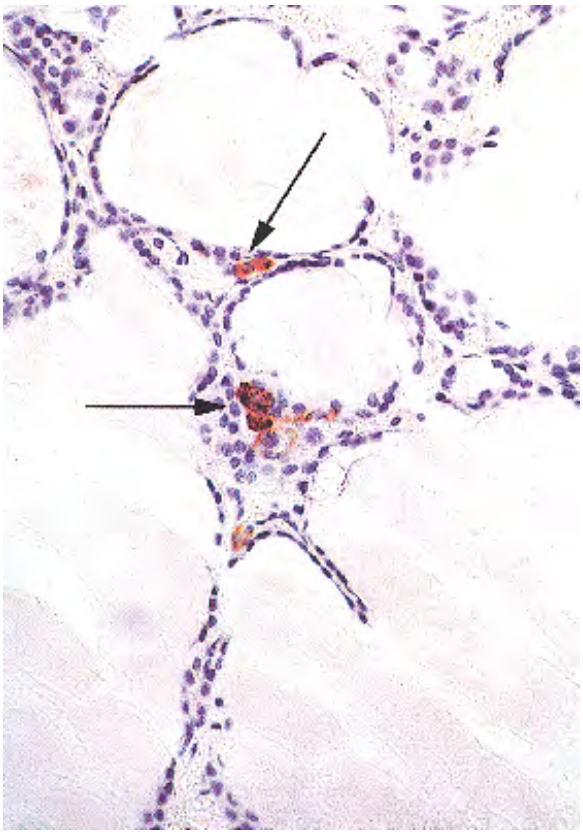

Figure 47.14 Adult thyroid stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. Groups of two to three C cells are present (*arrows*).

Although neuroendocrine cells are found commonly in the thymus glands of many animal species, these cells are sparse in human thymic tissue. In human glands, the neuroendocrine cells may be found within the perivascular connective tissue and in association with Hassall's corpuscles (129).

Skin

The Merkel cells represent the neuroendocrine components of the skin (Figure 47.9). These cells occur singly and in small clusters throughout the epidermis. Merkel cell clusters are particularly

prominent in foci of specialized epithelial differentiation, such as the touch domes (130). The cells have elongate processes that surround neighboring keratinocytes. The Merkel cells are characteristically innervated by long type I myelinated fibers. Secretory granules are abundant and range from 80 to 130 nm in diameter. The granules are particularly prominent in cytoplasmic processes. Aggregates of intermediate filament proteins are predominantly of the cytokeratin type. There is considerable species variation in the content and type of peptide hormone in these cells. The most frequently encountered hormones are met-enkephalin, vasoactive intestinal peptide, and bombesin/GRP (130).

Breast

Although clear cells have been noted in the breast by many observers, the question of whether these cells are neuroendocrine in type has engendered considerable controversy. Bussolati et al. have reported the presence of chromogranin-positive cells in a small number of normal breast samples (131). The cells were present singly or in small clusters in ductules, intralobular ducts of interlobular ducts, and between myoepithelial and epithelial cells. Occasional cell processes extended to the lumen in a manner typical of opened-type neuroendocrine cells. In parallel sections, the chromogranin-positive cells exhibited weak argyrophilia but were negative for a variety of peptide hormones. Chromogranin-positive cells were not identified in cases of fibrocystic disease or in papillomas.

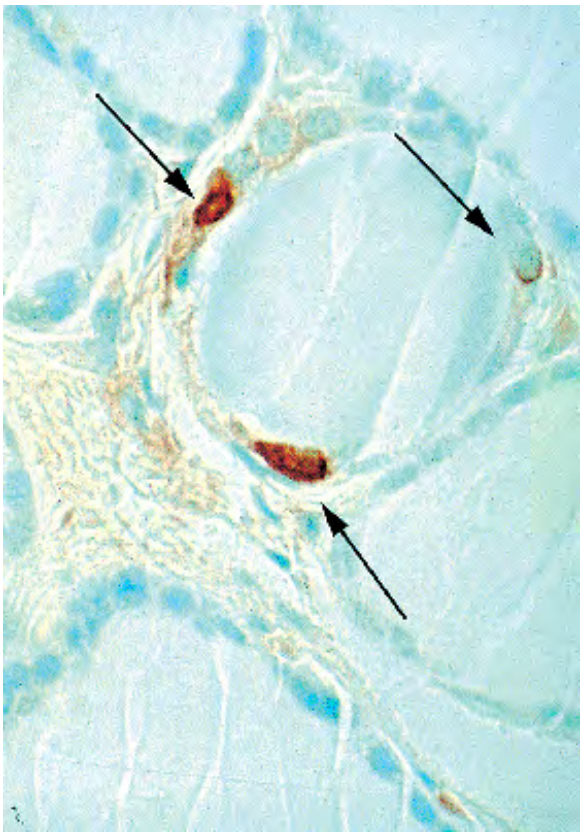

Figure 47.15 Adult thyroid stained for calcitonin via the peroxidaseâ€“antiperoxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. C cells (*arrows*) are present within the follicle as closed-type endocrine cells.

Gastrointestinal System

The gastrointestinal tract, from the esophagus to the anal canal, is extensively populated by a heterogeneous collection of peptide- and amine-producing neurons and neuroendocrine cells (38 ,39 ,40). The gut neuroendocrine cells are responsible for the production of more than 20 different hormones (Figures 47.6 ,47.7 ,47.8 , 47.11 , 47.16 , and 47.17). Cells of similar morphology and function are also present within the intraextrahepatic bile ducts

and the pancreatic ductal system (Figures 47.18 and 47.19). The major products of the gut endocrine cells, together with their morphologic characteristics and distributional patterns, are summarized in Figure 47.16 and in Table 47.2 .

In addition to their presence in mucosal and submucosal endocrine cells, peptide hormones also have been identified within submucosal glands. Brunner's glands, for example, contain neuroendocrine cells storing somatostatin, gastrin-cholecystokinin, and peptide YY. Peptidergic nerve structures containing vasoactive intestinal peptide, peptide histidine methionine, substance P, neuropeptide Y, and gastrin-releasing peptide also have been identified around Brunner's glands. All these peptides, with the exception of gastrin-releasing peptide, have been found in nerve cell bodies of the submucosal ganglia adjacent to the acini of Brunner's glands (40). These findings suggest that multiple peptides may be involved in the control of secretion from these glands.

Figure 47.17 Gastric antrum stained for gastrin using the peroxidaseâ€“antiperoxidase technique with diaminobenzidine as the chromogen and hematoxylin as the counterstain. The G cells are present primarily within the lower thirds of the gastric glands.

Urogenital System

Although argyrophil cells are not present in the adult renal parenchyma, rare argyrophilic cells have been reported in the renal pelvis. These cells may be particularly prominent in areas of glandular metaplasia. Neuroendocrine cells, as defined by their argentaffinity or argyrophilia, were first described in the urinary bladder by Feyrter (5 ,6). Later studies by Fetissof et al. (132) established that the endocrine cells in the urothelium were predominantly of the closed type (Figure 47.20). Immunohistochemical analyses showed that the cells were positive for serotonin but did not contain peptide hormones such as ACTH, gastrin, glucagon, or somatostatin.

The neuroendocrine cells of the prostate include both opened and closed types with a predominance of the latter forms (133 ,134 ,135). As shown in Grimelius-stained preparations,

many of these cells have multiple dendritic processes extending between adjacent epithelial cells and occasionally abutting on other neuroendocrine cells. The neuroendocrine cells are more prominent in normal or atrophic prostate than in hyperplastic foci. Most of these cells contain serotonin, and some also contain somatostatin. Both calcitonin and bombesin/GRP also have been

observed in the normal prostate, but these hormones are present in considerably less than 5% of the neuroendocrine cells. In contrast to the anorectal canal, which is also derived from the cloaca and contains both pancreatic polypeptide and glucagon immunoreactivities, the prostatic neuroendocrine cells are negative for these peptides.

Ultrastructurally, the cells show considerable pleomorphism in granule morphology (133). The opened cells have basally oriented granules, whereas the closed cells have a more uniform distribution of granules. Prominent lamellar bodies are noted in some cells.

Neuroendocrine cells of both opened and closed types have been demonstrated in the endocervical glandular epithelium and in the exocervical squamous epithelium (136). In both sites, however, the argyrophilic cells are extremely uncommon. However, argyrophil cells have not been identified in the normal ovary, fallopian tube, or endometrium.

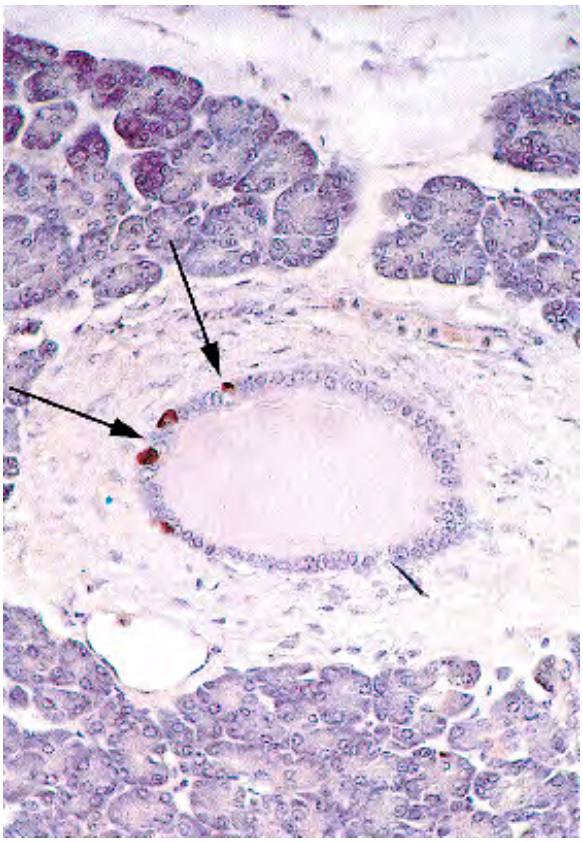

Figure 47.18 Pancreatic duct stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. Occasional closed-type neuroendocrine cells (*arrows*) are present within the ductal epithelium.

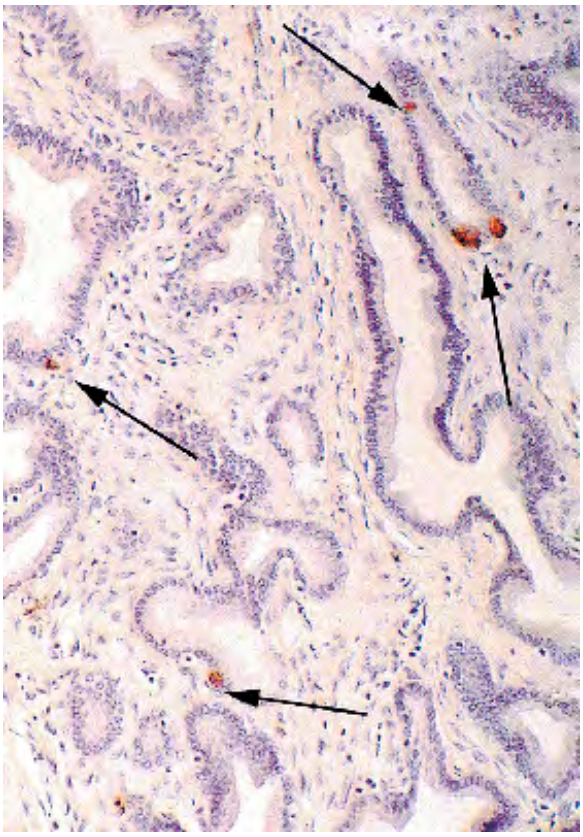

Figure 47.19 Terminal ramifications of bile ducts stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. Both open and closed neuroendocrine cells (*arrows*) are present within the ductal epithelium.

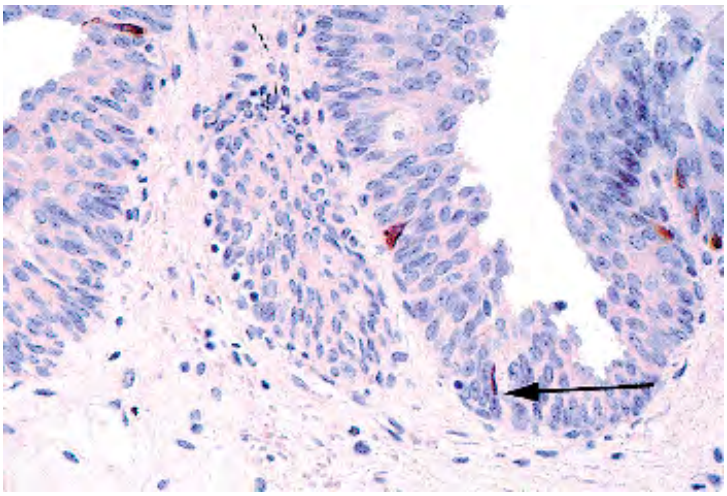

Figure 47.20 Urinary bladder epithelium stained with a monoclonal antibody to chromogranin A (LK2H10) via the avidin-biotin-peroxidase technique using diaminobenzidine as the chromogen and hematoxylin as the counterstain. Neuroendocrine cells are present within the epithelium. A process of another neuroendocrine cell is present at the arrow.

Aging Changes

The endocrine system undoubtedly plays an important role in the aging process; however, there have been relatively few systematic studies of the effects of aging in neuroendocrine cell populations in humans. Sun et al. have demonstrated a significant age-related decline in the number and size of growth hormoneâ€“producing cells that was most marked in the transition from youth to middle age (137). Pituitary parenchymal cells also decreased in number, but there were no changes in pituitary weight. Prolactin cells, on the other hand, did not show age-related changes. Hypertrophy and relative hyperplasia of thyrotroph cells have been demonstrated in pituitaries from older individuals (138).

O'Toole et al. have studied the effects of the aging process on C-cell populations in the thyroid gland (139). Although C cells

appeared to be more numerous in thyroid glands of elderly individuals, as compared with young and middle-aged individuals, the results were not statistically significant because of the large standard deviations. However, C cells more often tended to form clusters or nodules in thyroids from older individuals (140).

Age-related changes in neuroendocrine populations have been characterized in a few other sites, including the prostate. Although the numbers of neuroendocrine cells of the periurethral glands and prostatic ducts remain relatively constant throughout life, those in the peripheral acini are present in highest numbers in the neonatal and postpubertal periods (41). Cohen et al. have suggested that these variations in prostatic neuroendocrine cells may be mediated in part by the levels of androgenic hormones (41).
Bronchopulmonary neuroendocrine cells are considerably more prominent in neonates than in children or adults. In postnatal lungs, there is minimal variation in the numbers of these cells; however, neuroendocrine cells are more likely to be arranged in clusters in younger subjects than in the elderly (141).

Special Procedures

In addition to the histochemical and immunohistochemical approaches that have been discussed throughout this chapter, molecular methodologies including in situ hybridization provide important approaches for analyzing the distribution and function of neuroendocrine cells (142 ,143). In contrast to immunohistochemistry, which is dependent on the peptide content of endocrine cells, in situ hybridization techniques permit the identification of cells on the basis of their content's specific mRNAs. For example, endocrine cells that are acutely stimulated or are secreting their products constitutively often produce a negative immunohistochemical signal for the particular peptide. However, studies using nucleic acid probes for the corresponding mRNAs often provide an intensely positive signal in the same cells

(142). Extensive posttranslational processing and intracellular degradation of peptide products also may lead to positive hybridization signals with negative immunohistochemical reactions for the corresponding peptides. Additionally, in situ hybridization methods are of particular value for demonstrating hormone receptor mRNAs in target cells and for distinguishing de novo synthesis from uptake of hormonal peptides (142 ,143 ,144). The combination of in situ hybridization and immunohistochemistry has the potential for providing the maximal amount of information on the highly dynamic processes of gene transcription and translation (142 ,144).

The in situ hybridization method also has been combined with polymerase chain reaction (PCR) methods for demonstration of low copy number DNAs and RNAs (145 ,146). Detection of intracellular PCR products may be achieved indirectly by in situ hybridization using PCR product-specific probes (indirect in situ PCR) or without in situ hybridization through direct incorporation of labeled nucleotides into the PCR amplificants (direct in situ PCR). Although most protocols are designed for the demonstration of DNA, low copy RNA sequences have been demonstrated by the addition of a reverse transcriptase (RT) step to generate cDNA from RNA templates before in situ PCR. This technique, which has been called in situ RT-PCR, may be of particular value when there are fewer than 20 copies of mRNA per cell (118). This technique is of great potential value for the identification of cells with low levels of mRNA-encoding hormones, hormone receptors, cytokines, growth factors, and growth factor receptors. The technical details and potential pitfalls of these methods are discussed in detail in several recent publications (145 ,147 ,148).

Artifacts

Because neuroendocrine cells often have a clear appearance, they must be distinguished from a variety of other cell types that also

may appear clear in hematoxylin and eosinâ€“stained, formalin-fixed, paraffin-embedded sections. Cytoplasmic clearing may result from intracellular accumulations of lipids or glycogen; alternatively, this change may represent a shrinkage artifact analogous to that seen in the lacunar cells of nodular sclerosing Hodgkin's disease. For example, clear cells in the intestinal epithelium may represent lymphocytes or epithelial cells with retraction of the cytoplasm from the nucleus. In general, this type of artifact is less pronounced in tissues that have been fixed in nonaqueous fixatives. Neuroendocrine cells can be conclusively distinguished from other clear cells by the

presence of neuroendocrine markers, including chromogranin proteins or synaptophysin.

Numerous artefacts may be associated with the use of immunohistochemical procedures for the demonstration of peptide hormones and nonhormonal markers. Appropriate positive and negative controls therefore must be used in conjunction with these procedures, as discussed in standard textbooks of immunohistochemistry (149). Nonspecific binding of immunoglobulins to endocrine secretory granules also may result from ionic interactions that may be suppressed to some extent by the use of buffers containing high concentrations of salt (150), as discussed in the chapter on paraganglia. Endogenous biotin-like activity may also contribute to nonspecific staining in neuroendocrine cells and other cell types, particularly following microwave-induced antigen retrieval (151 ,152). This problem can be circumvented by the use of biotin blocking steps or by the use of biotin free detection systems.

Artifacts also may occur in in situ hybridization procedures. For example, Pagani et al. have demonstrated that oligonucleotides used in in situ hybridization procedures bind to neuroendocrine cells as a result of the presence of endogenous NH_2 groups (153). This type of nonspecific interaction can be blocked effectively by

treating the sections with acetic anhydride. Controls for standard in situ hybridization and PCR-based in situ hybridization are discussed in detail in several recent reviews (145 ,146 ,148).

Differential Diagnosis

The differential diagnosis of various neuroendocrine cell populations is discussed in the chapters dealing with the specific organ systems in this volume.

Specimen Handling

Most histochemical and immunohistochemical procedures for the demonstration of hormones and nonhormonal constituents of neuroendocrine cells can be performed in formalin-fixed and paraffin-embedded tissues. Other fixatives, including carbodiimide, acrolein, and diethyl pyrocarbonate, also have been used in place of formalin, and these fixatives have been reported to achieve optimal fixation of low concentrations of regulatory peptides such as those occurring in peptidergic nerve fibers (154 ,155 ,156 ,157).

The tissue preparative techniques for in situ hybridization studies are discussed in several review articles (142 ,148). In general, these methods may be performed on frozen samples that are postfixed in paraformaldehyde or in formalin-fixed samples that have been embedded in paraffin.

Paraganglia

Arthur S. Tischler

Introduction

Paraganglia are anatomically dispersed neuroendocrine organs associated with the autonomic nervous system and characterized by morphologically and cytochemically similar neurosecretory cells derived from the neural crest. For many physiological and pathophysiological purposes, they may be considered to comprise two groups associated with either sympathetic or parasympathetic nerves. Sympathetic paraganglia are distributed along the prevertebral and paravertebral sympathetic chains and along sympathetic nerve branches that innervate the organs of the pelvis and retroperitoneum. The adrenal medulla is the most extensively studied and best understood example of the sympathetic paraganglia. Parasympathetic paraganglia are predominantly distributed along cervical and thoracic branches of the glossopharyngeal and vagus nerves. The prototypical parasympathetic paraganglion is the carotid body.

History and Nomenclature

The history of the paraganglia is among the more interesting and controversial in the recent annals of medicine. This material is

addressed in detail in several excellent reviews (1,2,3,4). The concept of a unitary paraganglionic system was first proposed by Alfred Kohn at the beginning of the 20th century (5). Several earlier investigators had developed histochemical reactions demonstrating that the adrenal medulla contained substances chemically different from those in the adrenal cortex. The reaction that proved

most significant from a historical perspective, development of brown coloration in the presence of chromate salts, was apparently first discovered by Bertholdus Werner in 1857 (3). Kohn coined the terms â€œchromaffin reactionâ€• for the color change and â€œchromaffin cellsâ€• for the reactive cells, which he described in several extra-adrenal locations in the retroperitoneum. He further noted that some cells in the carotid body exhibited a chromaffin reaction, confirming an earlier report by Stilling (3). Kohn believed that the reactive carotid body cells were derived from precursors of sympathetic ganglia and were innervated by sympathetic axons, and he suggested that they were therefore embryologically, histochemically, and functionally comparable to retroperitoneal chromaffin cells. He proposed a new term to encompass all the tissues composed of cells that were analogous to neurons, but not neuronal: â€œSince the chromaffin tissue complexes form ganglion-like bodies, since their elements are derived from ganglion anlagen, since they are connected to the sympathetic nervous system and still are not genuine ganglia, I have called them paragangliaâ€• (5); translated from German by Dr. Miguel Stadecker).

Obstacles to acceptance of Kohn's concept soon arose from DeCastro's finding that the innervation of the carotid body is primarily derived from the glossopharyngeal nerve (4), and from observations by many investigators that carotid body cells are usually nonchromaffin. Consequently, Watzka (4) divided the paraganglion system into chromaffin and nonchromaffin paraganglia, associated respectively with the sympathetic or parasympathetic nervous systems, and paraganglia of mixed type. Discovery of the

chemoreceptor function of the carotid bodies created further difficulties since it implied that the nonchromaffin paraganglia served physiologically in a sensory role, in contrast to the endocrine function of the adrenal medulla. The suggestion was therefore made by Kjaergaard that the parasympathetic paraganglia be referred to by the term â€œchemodectonâ€• (from the Greek *dechesthai*, to receive). This name was never widely accepted, despite the earlier application by Mulligan of its counterpart, â€œchemodectoma,â€• to paraganglionic tumors (4).

An additional synonym for the parasympathetic paraganglia is â€œglomusâ€• (from the Latin *glomus,* ball). This term is a vestige of a 19th-century hypothesis that the carotid body is of vascular origin (4). Although it aptly describes the microscopic *Zellballen* characteristic of paraganglia, it has caused confusion because it is also applied to thermoregulatory structures in the skin and other locations (e.g., glomera cutanea and the glomus coccygeum) and to their corresponding tumors (glomus tumors or glomangiomas). Those structures are modified arteriovenous anastomoses unrelated to paraganglia developmentally or functionally.

It is now possible to return to a unitary concept of paraganglia with a synthesis of new and old data. Paraganglionic neuroendocrine cells are probably all derived from the neural crest (6,7). All produce catecholamines or, in some cases, indolamines (6,8) detectable by more sensitive methods than the chromaffin reaction, and all express multiple additional neuroendocrine markers (9). Recently, chemosensory properties previously considered specific to parasympathetic paraganglia have been documented in cells derived from sympathetic paraganglia as well (10). It is now apparent that the same basic type of neuroendocrine cell may be used differently in different anatomic locations (9,11,12). The term â€œparaganglionâ€• connotes a constellation of generic characteristics of this type of cell without being dependent on a single histochemical reaction. Since paraganglion was intended by Kohn to imply analogy, rather than merely proximity, to autonomic

ganglia, it continues in this context to be both conceptually helpful and literally correct. The chromaffin reaction as a basis for classification of paraganglia is now obsolete. However, reference to the reaction persists for historical reasons. â€œChromaffin cellâ€• is the name generally accepted for the neuroendocrine cells of the normal adrenal medulla and sometimes still applied to their extra-adrenal counterparts associated with the sympathetic nervous system. Similarly, â€œpheochromocytomaâ€• (from the Greek *phaios*, dusky, + *chroma*, color), the name applied by convention to chromaffin cell tumors, refers to the color change imparted by the chromaffin reaction.

Sympathetic Versus Parasympathetic Paraganglia: A Clinicopathologic Perspective

Sympathetic and parasympathetic paraganglia differ from a clinicopathologic standpoint despite their similarities at the cellular level. This contrast might result from differences in the type, timing, or intensity of physiological signals to which the two classes of paraganglia are exposed during development or in adult life. The only pathologic changes known to be clinically important in paraganglia are hyperplasia and neoplasia. Several generalizations concerning these proliferative lesions underscore the differences between paraganglia of the sympathetic and parasympathetic classes: when multiple lesions occur within families or individuals, they are usually confined to one or the other class. Although both sympathetic and parasympathetic lesions produce catecholamines, clinical signs of excess catecholamine secretion are usually associated with lesions that are sympathetic, and lesions that produce significant amounts of epinephrine are almost invariably sympathetic. Lesions that occur in patients with prolonged hypoxemia or hypercapnia are almost invariably parasympathetic. In addition, sympathetic paraganglia give rise to tumors of both neuronal lineage (i.e., neuroblastomas,

ganglioneuroblastomas, and ganglioneuromas) and neuroendocrine lineage (pheochromocytomas and extra-adrenal paragangliomas),

while neoplasms of parasympathetic paraganglia are almost always of neuroendocrine lineage. Neuronal tumors are most common in children, while neuroendocrine tumors usually occur in adults.

Despite the differences in the contexts in which they arise, sympathetic and parasympathetic paragangliomas strongly resemble each other microscopically and are often indistinguishable. They also exhibit a widely overlapping range of secretory products and other neuroendocrine markers, reflecting the similarities of the neuroendocrine cells that are their normal counterparts. A morphologic foundation for the study of paraganglionic pathology therefore requires familiarity with both systemic differences and cellular similarities.

A need for deeper understanding of the differences and similarities between paraganglia in different locations has become apparent as a result of recent advances in characterizing the genetic abnormalities and gene expression profiles of pheochromocytomas and extra-adrenal paragangliomas. Hereditary syndromes now known to be associated with development of pheochromocytomas are Multiple Endocrine Neoplasia (MEN) 2A and 2B, von Hippel-Lindau disease, neurofibromatosis type 1 and familial paraganglioma/pheochromocytoma syndromes, due respectively to mutations of the *RET* protooncogene, *VHL* and *NF1* tumor suppressor genes, and *SDHD, SDHB,* and *SDHC* succinate dehydrogenase genes (13,14). Extra-adrenal paragangliomas are rare in MEN2 and neurofibromatosis, and those that occasionally do occur often arise in the vicinity of the adrenal. In contrast, VHL tumors, while predominantly intra-adrenal, are not uncommon in extra-adrenal locations and tumors associated with succinate dehydrogenase mutations are predominantly extra-adrenal (13). The combination of sympathetic and parasympathetic paragangliomas may be particularly suggestive of succinate dehydrogenase mutations (13).

Microarray-based gene expression profiling studies complemented by immunohistochemical and/or biochemical analyses have revealed sets of markers that tend to be clustered in tumors with specific genetic backgrounds. For example, genes associated with hypoxia-driven transcription pathways are preferentially expressed in VHL tumors (15). An additional distinctive characteristic of VHL tumors is that they usually produce exclusively norepinephrine, while MEN2 and NF1 tumors produce both epinephrine and norepinephrine (16). Some genotypeâ€“phenotype correlations may be accounted for by characteristics of the predominant anatomic sites of tumor origin; for example, the fact that epinephrine production is normally confined to the adrenal medulla. However, the basis for different gene expression clusters in tumors at any given location is for the most part poorly understood. One possibility is that subtle types of cellular heterogeneity within normal paraganglia might allow for different cells of origin predisposed to respond to distinct genetic abnormalities. Alternatively, distinct genetic abnormalities initiating tumors in a single cell type could produce distinct signatures.

Distribution of Paraganglia

Sympathetic paraganglia are found predominantly in the para-axial regions of the trunk along the prevertebral and paravertebral sympathetic chains and in connective tissue in or near the walls of the pelvic organs. In adult humans, they are especially numerous along the fibers of the inferior hypogastric plexuses leading to and entering the urogenital organs, in the wall of the urinary bladder, and among the nerve fibers of the sacral plexus (17,18,19,20) (Figure 48.1). They are not generally known by individual names, and their precise locations are variable. Exceptions are the adrenal medulla and the organ of Zuckerkandl, located at the origin of the inferior mesenteric artery (21) (Figures 48.1 and 48.2).

The distinctive characteristic of the organ of Zuckerkandl is that it is the only extra-adrenal sympathetic paraganglion that is macroscopic.

Historically, it is said to have been shown initially to Alfred Kohn as an unusual lymph node by his pupil, Emil Zuckerkandl (4,22). In its most frequent anatomic configuration, it is divided into a set of paired organs (Figure 48.2), and it is therefore often referred to by the plural, â€œorgans of Zuckerkandlâ€• (1). Because its fragmentation and its proximity to numerous smaller paraganglia may make it difficult to identify precisely, some investigators have used the plural to encompass all preaortic paraganglia between the inferior mesenteric artery and the aortic bifurcation (23). However, this chapter maintains the traditional, more specific, macroscopic usage.

)

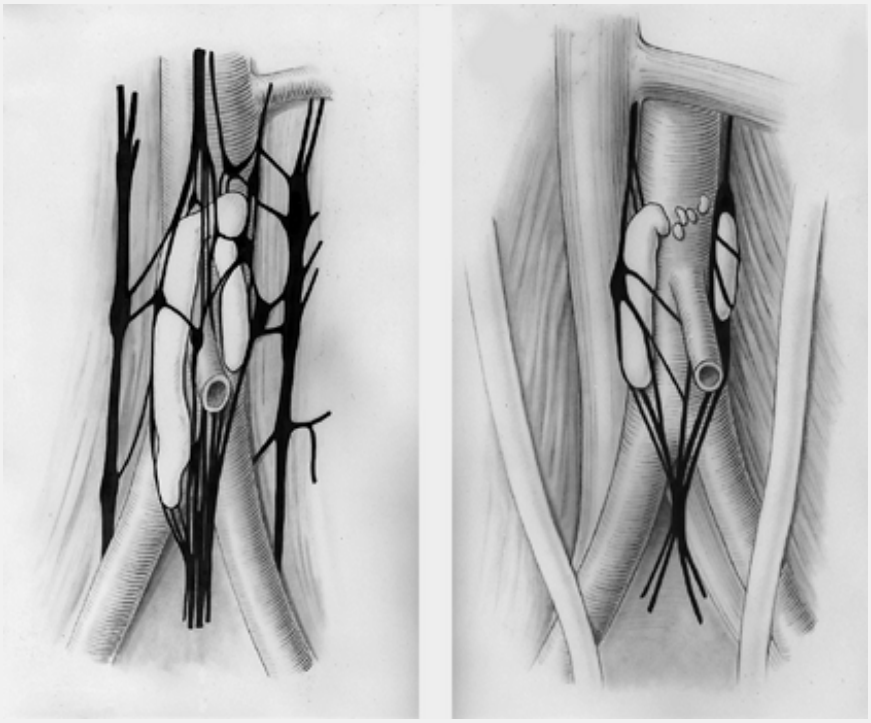

Figure 48.2 Modified renditions of original illustrations by Zuckerkandl (21) representing the anatomic structure that bears his name. The bilobed configuration with a fragmented isthmus (*right*) is the most frequent variation. (Courtesy of Dr. E. E. Lack.)

Neuroendocrine cells are present both within and adjacent to the ganglia of human sympathetic chains. The former have been referred to in neurobiology literature as small intensely fluorescent (SIF) cells (24), intraganglionic chromaffin cells (25), or small granule-containing (SGC) cells (11,12), depending on the particular technique used to detect them. In pathology literature especially, SIF cells are often regarded as intraganglionic paraganglia (26). In anatomy literature, on the other hand, some investigators reserve the term â€œparaganglia â€• for extraganglionic sites (24).

In contrast to sympathetic paraganglia, their parasympathetic counterparts are distributed almost exclusively along the cranial and thoracic branches of the glossopharyngeal and vagus nerves (Figure 48.3). With the exception of the carotid bodies, which are located between the carotid arteries just above the carotid bifurcation (Figure 48.4), parasympathetic paraganglia are highly variable in both number and location (4). Their names refer to general locations, rather than to specific structures. The middle ear, for example, contains 0 to 12 jugular and tympanic paraganglia, with an average of 2.8 (27). The principal paraganglia of the glossopharyngeal nerve are the tympanic paraganglia in the wall of the middle ear and the carotid bodies (4,27). Those of the vagus nerve include the jugular paraganglia in the floor of the middle ear (4,27), the superior and inferior laryngeal paraganglia (4,27,28), and the subclavian and aorticopulmonary or cardioaortic paraganglia near the bases of the great vessels of the heart. They sometimes also may be found in the interatrial septum (4). In addition, â€œintravagalâ€• paraganglia are located within or adjacent to the vagal trunk in or near the nodose and jugular ganglia (4). These two vagal ganglia are thus the only sensory ganglia known to contain neuroendocrine cells comparable to the SIF cells of sympathetic ganglia. These cells have been described as SIF cells in some publications (29).

Some investigators have classified the parasympathetic paraganglia as â€œbranchiomericâ€• (26). This nomenclature is based on the suggestion that the branchial arches during embryogenesis are metameric, or serially homologous, structures, each with its own artery, cranial nerve branches, and associated paraganglia. The carotid body would accordingly develop in association with the glossopharyngeal nerve and the third branchial arch artery, which persists as the internal carotid. Subclavian paraganglia would develop with the vagus nerve and the fourth branchial arch artery, and so on. The evolution of this concept is reviewed elsewhere in detail (4). However, the concept does not contribute to the understanding the pathophysiology of paraganglia and may cause

confusion by distracting attention from the important differences between parasympathetic

and sympathetic paraganglia, which may occur in close proximity to each other (e.g., the carotid bodies and the SIF cells in cervical sympathetic ganglia). It also is plagued by a number of internal inconsistencies, such as its prediction that the temporal paraganglia should be innervated by the facial nerve (4).

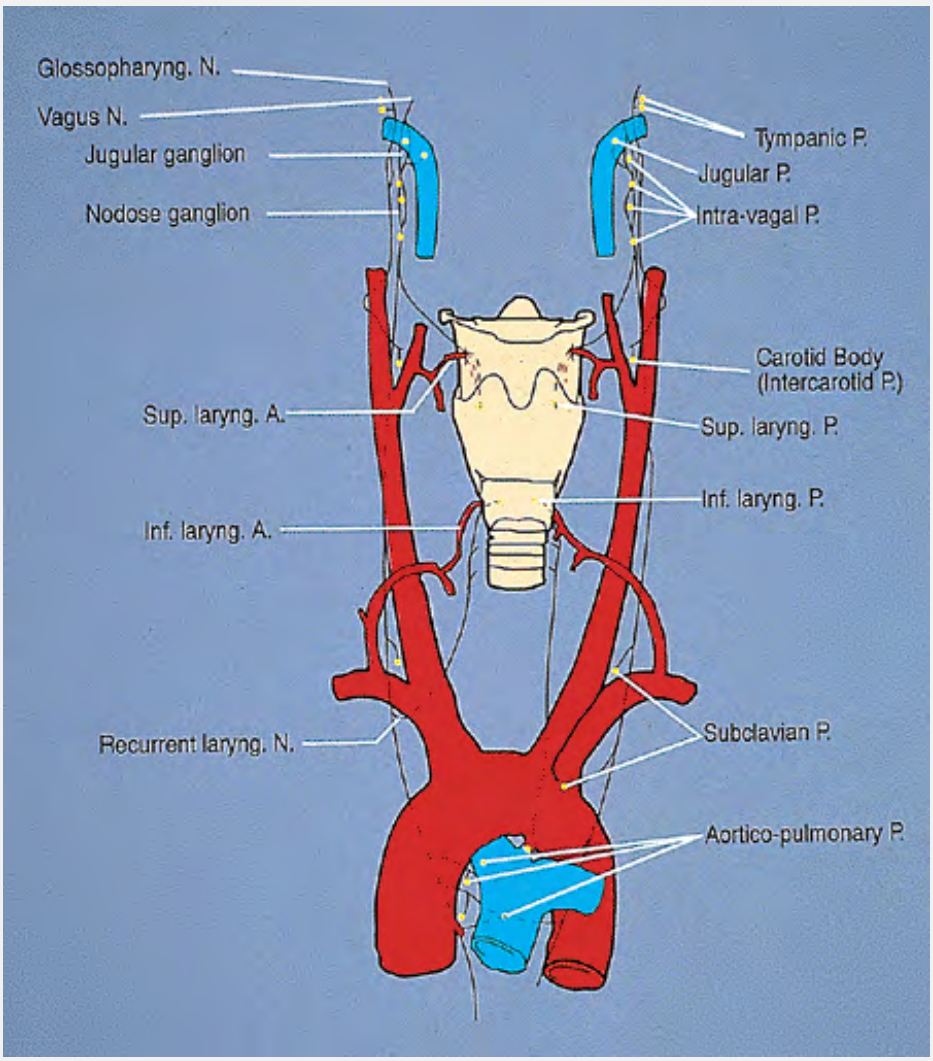

Figure 48.3 The distribution of the principal parasympathetic paraganglia. (Adapted with permission from:

Glenner GG, Grimley PM. Tumors of the extraadrenal paraganglion system (including chemoreceptors). In: Atlas of Tumor Pathology. 2nd series, fascicle 9. Washington, DC: Armed Forces Institute of Pathology; 1974.
)

Figure 48.4 Gross specimens from a 5-year-old girl, illustrating normal carotid bodies and their relationship to the carotid arteries. (Courtesy of Dr. E. E. Lack.)

Knowledge of the distribution of normal paraganglionic tissue is important because of its value in predicting the sites of origin of paragangliomas. These tumors have been reported at virtually all locations where normal paraganglia are found during fetal or adult

life and tend to be most frequent in areas where paraganglionic tissue is most abundant. For example, in early childhood a high percentage of paraganglionic tissue is extra-adrenal (see â€œEmbryologic Changesâ€• and â€œPostnatal and Developmental Changesâ€•). Approximately half of all sympathetic paragangliomas in children are also extra-adrenal, most frequently arising in the vicinity of the organ of Zuckerkandl, while only about 10% are extra-adrenal in adults (30). However, it is also important to note that paraganglia may occur in locations outside the well-established sympathetic and parasympathetic distributions, perhaps explaining the existence of paragangliomas in unusual locations. Although intravagal paraganglia in humans have been identified only in the cervical and thoracic portions of the vagus nerve (31), in

rodents they are also present within the abdominal portions (32). It has not been ruled out that some abdominal paraganglia in humans, for example, in the gallbladder (33) (Figure 48.13), may be associated with small abdominal vagus nerve branches. In scattered reports, paraganglia have been described in various sites including the orbit, mandible, and extremities. The validity of some of these reports is questionable (4).

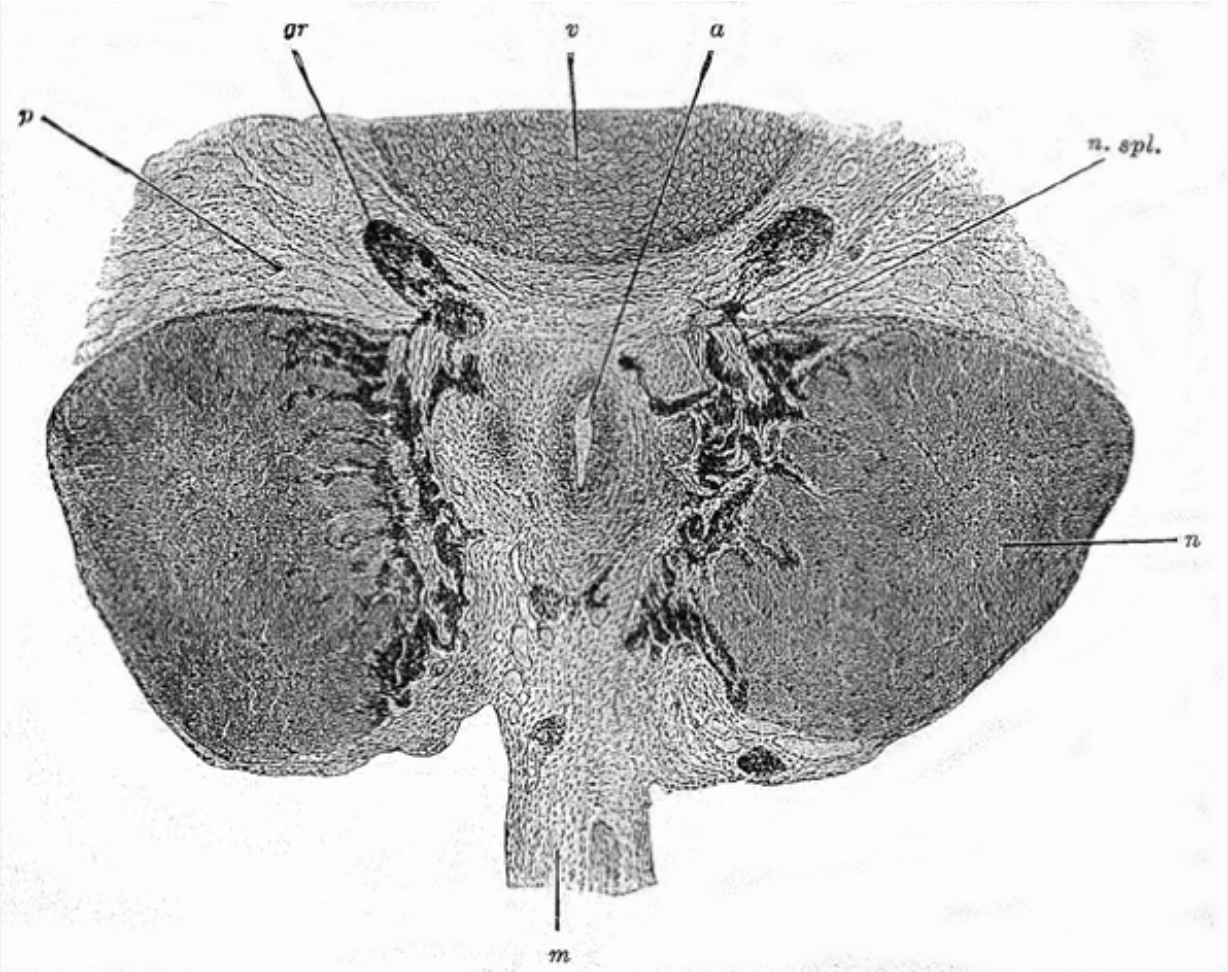

Figure 48.5 Original illustration by Zuckerkandl of a transverse section of a human embryo (17 mm crownâ€“heel length) showing presumed migration of primitive sympathetic cells into the adrenal glands. )

Embryologic Changes

During embryogenesis, the paraganglia are first populated by small, primitive cells similar to those in the anlage of the sympathetic ganglia. These cells include precursors of neuroendocrine, neural, and glial cell lineages in adult paraganglia (34,35) (see â€œLight Microscopyâ€•). They appear to be able to produce some catecholamines at the earliest stages of paraganglionic development (35,36) (see â€œFunctionâ€•), and express cytoskeletal or other markers of immature neurons (35), or glia (35) (see â€œSpecial Proceduresâ€•). They are readily recognized in the paraganglia at about 7 weeks' gestation, although they first arrive somewhat earlier (1), and they are progressively superseded by larger, differentiated, cells. Extra-adrenal sympathetic (1) and parasympathetic (36,37) paraganglia mature cytologically earlier than the adrenal medulla. Primitive cells usually disappear from these locations by week 25 but may persist in small numbers in the adrenal medulla until after birth (1).

Classic, descriptive, embryologic studies (38,39) show primitive sympathetic cells in large numbers around the spinal nerves and branches of the developing sympathetic trunks before the formation of the paraganglia. The cells are also described along the renal and spermatic arteries (39). The adrenal medulla is apparently colonized by invasion of primitive sympathetic cells into the cortex through the medial aspect of the capsule from the contiguous prevertebral and paravertebral sympathetic tissue (Figure 48.5). The invading cells initially form nodular aggregates in the cortex (Figure 48.6) and gradually coalesce around the central vein. They may form rosettes or pseudorosettes early

in gestation (1,40). Chromaffin cells are identifiable among these aggregates from about week 8 on (1,40) and gradually increase in number. The centripetal pattern of migration of primitive sympathetic

cells into the adrenal may result in subcapsular and intracortical chromaffin cell rests (see Figure 48.25). Although some primitive sympathetic cells appear to penetrate the cortex along sympathetic nerve fibers, some are apparently not associated with nerve fibers (1). Innervation of the presumptive medulla by preganglionic nerve fibers does not appear to be necessary for colonization because experimental studies demonstrate that the medulla can form in adrenal primordia from 4- or 5-day chick embryos explanted to chorioallantoic membranes before the onset of innervation (41).

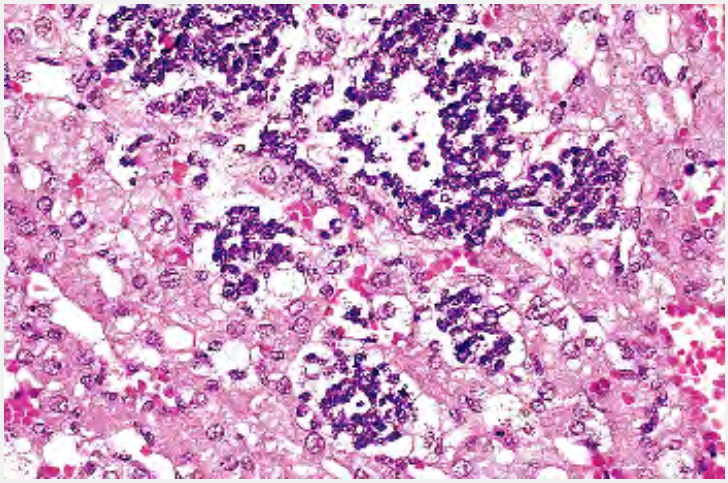

Figure 48.6 Section of adrenal gland from a 16-week human fetus showing typical aggregates of primitive sympathetic cells that are precursors of the medulla. Pyknotic nuclei and nuclei with changes consistent with apoptosis are present within the aggregates. Many of the small cells express immunoreactive tyrosine hydroxylase, the rate-limiting enzyme in catecholamine synthesis, but do not stain for CgA or synaptophysin, which are characteristic of larger, mature, or maturing chromaffin cells (35). Scattered S-100â€“positive cells consistent with the sustentacular cell lineage are observed at about week 20 (34).

Nodular aggregates of primitive sympathetic cells, up to 400 Âµm in greatest dimension, can be demonstrated in the adrenal glands of all human fetuses between the ages of 10 and 30 weeks if the glands are thoroughly sectioned (42). Aggregates with a diameter of over 1 mm may occasionally be observed (40). Nerve fibers may connect intra-adrenal and extra-adrenal aggregates (42). The nodules peak in size and number between the ages of 17 and 20 weeks and then decline. Intranodular cystic degeneration is common from the age of 20 weeks onward (42). Postnatal persistence of the nodules was apparently first described by Wiesel in 1902 (38). These occasional persistent nodules may account for some erroneous diagnoses of â€œin situ neuroblastomaâ€• (42,43) (see â€œDifferential Diagnosisâ€•).

Primitive cells can be observed apparently migrating to developing parasympathetic paraganglia along branches of the glossopharyngeal and vagus nerves as well as from sympathetic nerves (37). The nature, origin, and fate of these cells from different sources and their respective contributions to the mature paraganglia were vigorously debated for more than 70 years (4,37). It is of interest that both the purely morphologic studies of Kohn et al. (38) and later histochemical studies (36) suggest an origin of the neurosecretory cells of the human carotid body, the prototypical parasympathetic paraganglion, from the sympathetic progenitors of the superior cervical ganglion.

Postnatal and Developmental Changes

The amount or distribution of paraganglionic tissue is known to change during development and aging. Sympathetic paraganglionic tissue in fetuses and neonates is primarily extra-adrenal, with the greatest volume in the organ of Zuckerkandl. The organ of Zuckerkandl develops maximally in humans by the age of about 3 years, when its greatest dimension may be more than 20 mm. Thereafter, the organ involutes (1,20), while the adrenal medulla

enlarges until maturity. Similarly, SIF cells are present in all human sympathetic ganglia at birth but are rare in adults (1). Parasympathetic paraganglionic tissue also appears to decrease in some locations and to increase in others. Subclavian and intrapulmonary paraganglia, for example, have been identified in human fetuses but not in adults (4). On the other hand, the number of jugular and tympanic paraganglia apparently increases after birth (27). The carotid bodies, which are the only parasympathetic paraganglia that are macroscopic, increase in size between infancy and adult life, when they are normally about 3 mm in greatest dimension (4) (Figure 48.4).

The mechanisms involved in developmental remodeling of the paraganglionic system may hold a number of clues to the pathobiology of paraganglionic tumors. It is generally accepted that apoptosis plays a critical role in the development of both the central and peripheral nervous systems, where excess neural progenitor cells undergo apoptotic death after failing to establish functional contacts or receive appropriate tropic substances from target tissues (44,45). There have been few studies of apoptosis that are specifically focused on the paraganglia. However, apoptotic bodies can be identified within the aggregates of primitive sympathetic cells in the adrenal medulla (Figures 48.6 and 48.7).

Phenotypic Plasticity

Adult human adrenal chromaffin cells are able to â€œtransdifferentiateâ€• into sympathetic neurons when removed from their in vivo environment and exposed to appropriate neurotrophic signals (46) (Figure 48.8). Capacity to undergo this fascinating metamorphosis is retained to varying degrees by developing or adult chromaffin cells from other species (47). The extent to which it is expressed in various extra-adrenal paraganglia has not been fully explored.

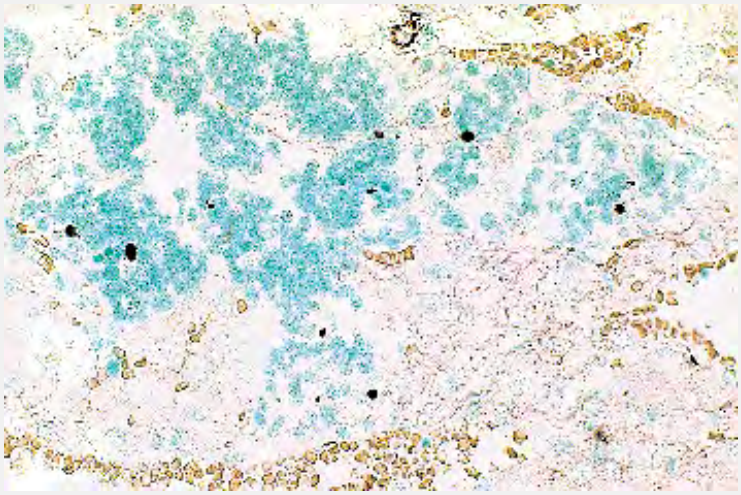

Figure 48.7 Section of the same adrenal as in Figure 48.6 showing terminal deoxynucleotidyl transferaseâ€“mediated end-labeling (48) of nuclei within a neuroblastic aggregate (black nuclei). This method, which detects fragmented DNA, can be helpful in locating apoptotic cells. (Courtesy of Dr. Salvador Diaz-Cano.)

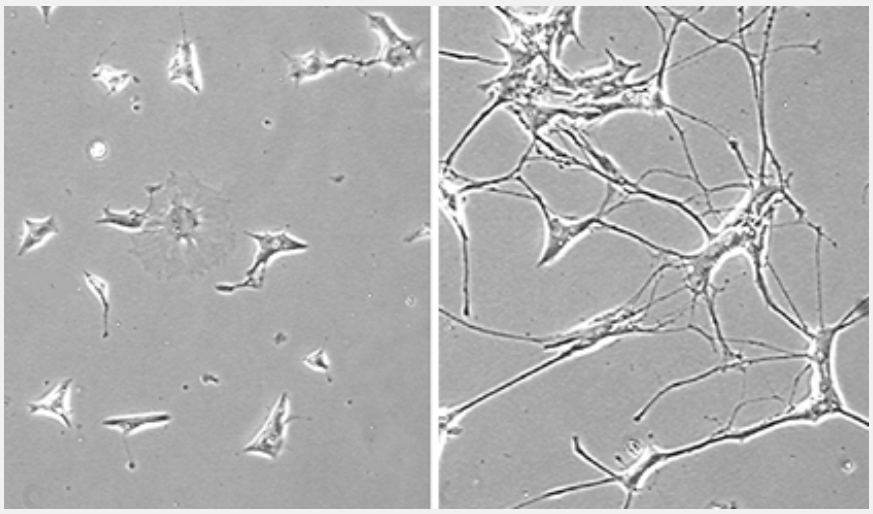

Figure 48.8 Phenotypic plasticity of normal adult human adrenal chromaffin cells demonstrated by acquisition of neuron-like morphology in cell culture. Cells at left were maintained in control medium for 2 weeks and those at right were in medium supplemented with nerve growth factor (46). (Courtesy of Dr. James F. Powers.) Capacity to undergo this â€œtrans-differentiationâ€• is exhibited to varying degrees by chromaffin cells from other species and from other normal or neoplastic paraganglia (47).

Gross Features and Organ Weights

The paraganglionic tissue of the grossly identifiable paraganglia is gray or grayâ€“pink. Recognition of this feature is particularly important in the adrenal gland because the medulla is normally confined to the head and body of the gland but extends into the tail and alae in adrenal medullary hyperplasia (49,50). An accurate gross examination requires that the brown tissue of the cortical zona reticularis not be misidentified as medulla.

Because of the anatomic variability of the microscopic paraganglia and the organ Zuckerkandl, meaningful weights can be ascribed only to the adrenal medulla and carotid bodies. Extensive morphometric studies (51) have shown that the neonatal adrenal medulla accounts for approximately 0.4% of the total volume of the gland and weighs approximately 0.012 g. These values increase to 4.2% and 0.08 g at 2 years of age, 7.0% and 0.28 g between the ages of 10 and 13 years, and 9.9% and 0.46 g in adults up to the age of 40 years. After the age of 40 years, there is a small decline in medullary weight and volume. The weight of the carotid bodies appears to correlate more closely with body weight than with age. Lack (52) has proposed an equation to estimate carotid body weight from body weight for any age group: combined weight of carotid bodies (mg) = 0.29 Ã— body weight (kg) + 3.0. Standard deviations for any age group are large

(53), but in normal adults the combined weight is usually less than 30 mg. The carotid body increases in size and weight in individuals living at high altitudes (54) and in patients with hypoxemia due to a variety of ailments (55,56,57,58).

Anatomy

All paraganglia are highly vascular, a characteristic that permits them to be localized by leakage of systemically injected dye in animal studies (59). However, the details of their blood supply are highly varied according to their location and function. For example, the adrenal medulla receives arterial blood from three arteriesâ€”the inferior phrenic artery, aorta, and renal arteriesâ€”and drains via a single adrenal vein that empties into the renal vein on the left and the aorta on the right. The carotid body receives arterial blood from one or occasionally two small arteries arising from the vicinity of the carotid bifurcation and drains via several small veins into the pharyngeal, superior laryngeal, and lingual veins (4).

The innervation of paraganglia is comparably site specific. In general, sympathetic paraganglia receive preganglionic cholinergic sympathetic innervation and variable amounts of noradrenergic and/or peptidergic innervation from intrinsic neurons, nearby sympathetic ganglia, and other sources. Most of the neuroendocrine cells in the adrenal medulla are innervated (60), in contrast to the sparse innervation of extra-adrenal sympathetic paraganglia (1,61), and it has been suggested that the ability of paraganglia to attract or maintain innervation might determine the extent to which they persist or involute at different sites (11). Parasympathetic paraganglia generally receive their innervation from branches of either the vagus or glossopharyngeal nerves but also may receive some sympathetic input. A small percentage of carotid body cells, for example, reportedly synapse with preganglionic sympathetic fibers (62). Some carotid body cells also may lack innervation (63). In addition to innervation that directly involves neuroendocrine cells,

paraganglia may receive vasomotor innervation from the nearby superior cervical ganglion and from a small number of intrinsic neurons (62,64). Multiple peptide neurotransmitters have been identified in nerve endings innervating the carotid body, and dynamic alterations of innervation have been reported in response to hypoxic stress (65). Multiple neurotransmitters are also present in adrenal medullary nerve endings and play a variety of roles in regulating both the development and function of adrenal chromaffin cells (66).

The neurovascular relationships of individual parasympathetic paraganglia have been described in great detail by several investigators (4,37). Of particular interest to pathologists are the paraganglia that give rise to glomus jugulare and glomus tympanicum paragangliomas in the floor or the wall of the middle ear. The paraganglia in the human temporal bone are distributed along the auricular branch of the vagus nerve (Arnold's nerve), and the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve) (27). About 70% of paraganglia related to Arnold's nerve occur on the jugular bulb. The remainders follow the nerve through the mastoid canaliculus toward the vertical portion of the facial nerve. Paraganglia along Jacobson's nerve occur anywhere from the origin of the nerve at the petrosal ganglion (10%) to the jugular bulb (28%), tympanic canaliculus (40%), promontory of the middle ear (20%), and beyond (2%). Glomus jugulare tumors may therefore be associated with either Arnold's or Jacobson's nerve, although the former is most likely. Glomus tympanicum tumors are almost always associated with Jacobson's nerve (4).

Light Microscopy

Cell Types

Paraganglia contain two major types of cell: neuroendocrine cells and supporting cells. The former have been referred to in many

publications as â€œgranule-containing cells.â€• â€œchromaffin cells,â€• or â€œchromaffin-like cellsâ€• in sympathetic paraganglia and â€œglomus cells,â€• â€œtype I cells,â€• or â€œchief cellsâ€• in parasympathetic paraganglia. The latter also have been called â€œsustentacular cells,â€• â€œsatellite cells,â€• â€œsupporting cells,â€• or â€œtype II cellsâ€• (4,26). In addition, there are variable numbers of connective tissue cells, vascular cells, Schwann cells, myelinated or unmyelinated nerve fibers, and intrinsic neurons. An additional commonly encountered cell type is the mast cell, which may be abundant in both ganglia and paraganglia (4,67). In hematoxylin and eosin (H&E)â€“stained sections, paraganglionic neuroendocrine cells are polygonal cells with amphophilic or basophilic cytoplasm and small, spherical or ovoid, pale-staining nuclei. Immunocytochemical stains for neuroendocrine markers can easily confirm their identity (see â€œSpecial Proceduresâ€•). Electron microscopy or argyrophil-type silver stains to demonstrate secretory granules or fluorescence methods to demonstrate catecholamines are employed in older publications. The neuroendocrine cells in paraganglia tend to form clusters and cords, described as *Zellballen* and *ZellstrÃ¤ngen* by Alfred Kohn (5), and may be partially or completely surrounded by supporting cells. The latter are usually flattened, with less conspicuous cytoplasm and more deeply basophilic nuclei with coarsely clumped chromatin. They appear to be glial cells, possibly related to nonâ€“myelin-forming Schwann cells elsewhere in the peripheral nervous system (68), and can be identified by staining for S-100 protein (69) (see â€œSpecial Proceduresâ€•). Like nonâ€“myelin-forming Schwann cells, they have been reported in some instances to also stain for glial fibrillary acidic protein (70). They are present in both parasympathetic (69,70) and sympathetic (71,72) paraganglia but are more numerous in the former, where they cause the *Zellballen* to appear more pronounced (Figures 48.9,48.10,48.11,48.12).

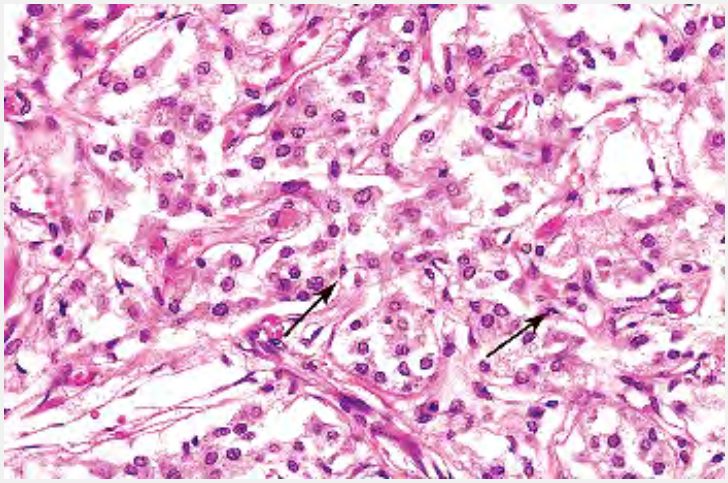

Figure 48.9 Section of organ of Zuckerkandl from a mid-trimester human fetus, demonstrating typical cords and nests of chief cells with rounded or oval nuclei and amphophilic cytoplasm, and occasional interspersed sustentacular cells with flattened nuclei and inconspicuous cytoplasm (*arrows*).

Lobular Architecture of the Carotid Body

The carotid body is architecturally distinctive in that it consists of lobules separated by connective tissue septa (Figure 48.14).

Each lobule is individually reminiscent of the microscopic paraganglia that occur in other sites and is composed of nests of chief cells surrounded by other cell types. This lobular arrangement is important to pathologists because carotid body hyperplasia is generally defined as an increase in mean lobule diameter (52,53,54,55,56). The amount of connective tissue between lobules in the carotid body tends to increase with age. Schwann cell proliferation and axonal sprouting also may occur at the periphery of lobules (Figure 48.15). One group of investigators has reported that the latter change is the pathognomonic feature of lobular hyperplasia in elderly patients with

emphysema or hypertension (56). Other investigators studying specimens predominantly from patients with congenital heart disease have reported proportional proliferation of sustentacular cells and chief cells (52,53,55), whereas still others have reported chief cell hyperplasia in high-altitude dwellers (54). Lobular architecture similar to that of the carotid body is occasionally observed in other parasympathetic paraganglia, particularly if they are enlarged (53).

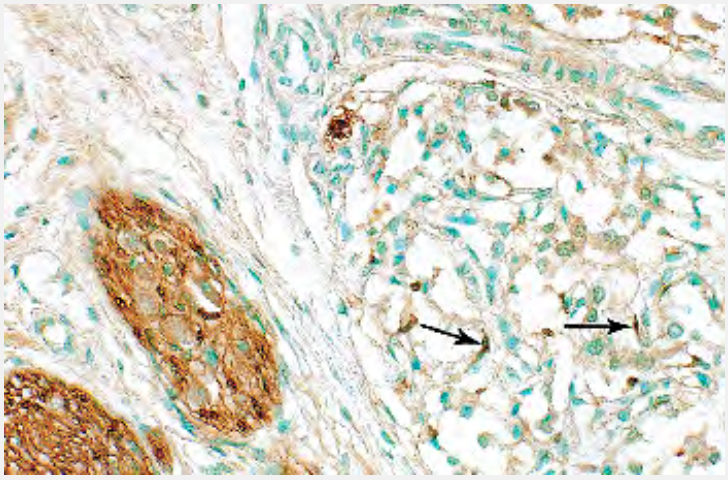

Figure 48.10 Organ of Zuckerkandl and adjacent sympathetic ganglion (same specimen as in Figures 48.20,48.21,48.22,48.23), stained for S-100 protein. Immunoreactivity for this antigen is typically localized in both nuclei and cytoplasm. Scattered sustentacular cells are stained in the organ of Zuckerkandl (*right, arrows*), where they tend to be located at the periphery of cell nests. Schwann cells are stained in the ganglion (*left*).

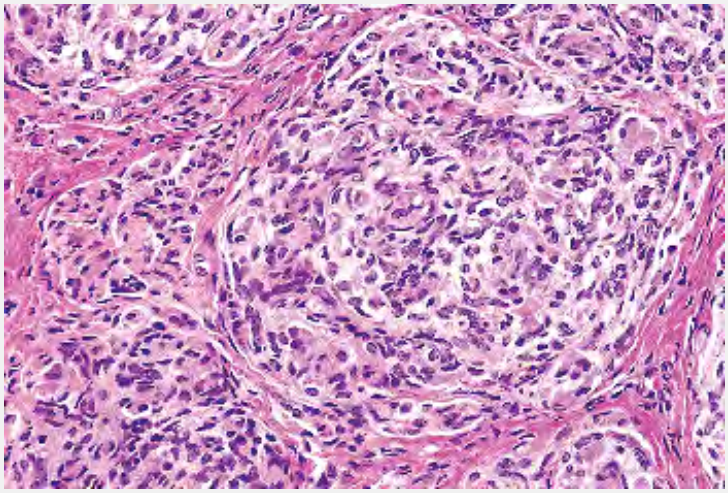

Figure 48.11 Section of carotid body from a 6-day-old infant demonstrating a characteristically more heterogeneous cell population than in Figure 48.9. Small nests of chief cells are highlighted by surrounding sustentacular cells and other cell types.

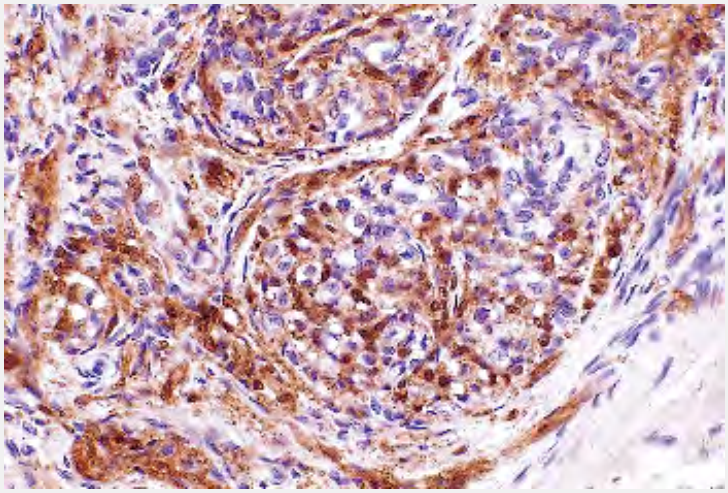

Figure 48.12 Lobule of a carotid body from a 16-day-old infant stained for S-100 protein. In contrast to the relatively sparse S-

100â€“positive cells in the organ of Zuckerkandl (see Figure 48.10), there are numerous stained sustentacular cells within the lobule, accentuating the *Zellballen*, and numerous stained Schwann cells both within and adjacent to the lobule, as diagrammed in Figure 48.17.

Ultrastructure

At the ultrastructural level, paraganglionic neuroendocrine cells are characterized by numerous membrane-bound granules or â€œdense-core vesiclesâ€• approximately 60 to 400 nm in greatest dimension. They sometimes also contain small synaptic-like vesicles that may accumulate in clusters near the plasma membrane (73). Neuroendocrine secretory granules may vary in size, shape, and electron density, reflecting differences in the secretory products stored, the functional state of individual cells, and fixation conditions. In the rodent adrenal medulla, where epinephrine and norepinephrine are mostly stored in separate cells, fixation in glutaraldehyde and postfixation in osmium tetroxide cause granules in norepinephrine cells to appear homogeneously electron dense, whereas those in epinephrine cells are lighter and finely particulate. The mechanism for the differentiation involves formation of an insoluble reaction product between glutaraldehyde and norepinephrine, which is subsequently

darkened by osmium (1,74). Because epinephrine does not similarly react with glutaraldehyde, it diffuses out of the granules, leaving behind other granule constituents that are less osmiophilic. To be successful, this method requires adequate fixation of fresh tissue. Human adrenal medullary cells occasionally exhibit homogeneous populations of epinephrine or norepinephrine-type granules (Figure 48.16), but most cells have mixed granule populations (75) and synthesize both epinephrine and norepinephrine (76). The electron

density of most granules in extra-adrenal paraganglia is comparable to that of norepinephrine-type granules in the adrenal.

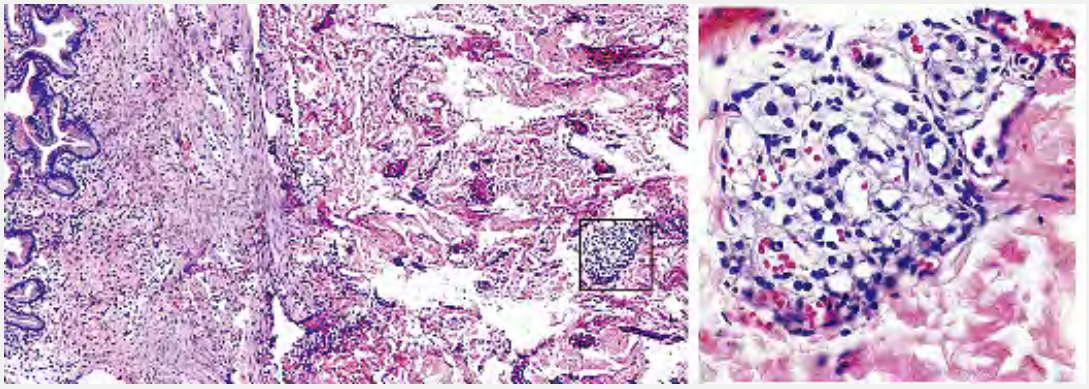

Figure 48.13 A microscopic paraganglion (small, oval, blue structure outlined in box) discovered as an incidental finding in the wall of the gallbladder of a 40-year-old woman. Right panel shows higher magnification of the paraganglion, illustrating prominent capillaries and admixed cell types.

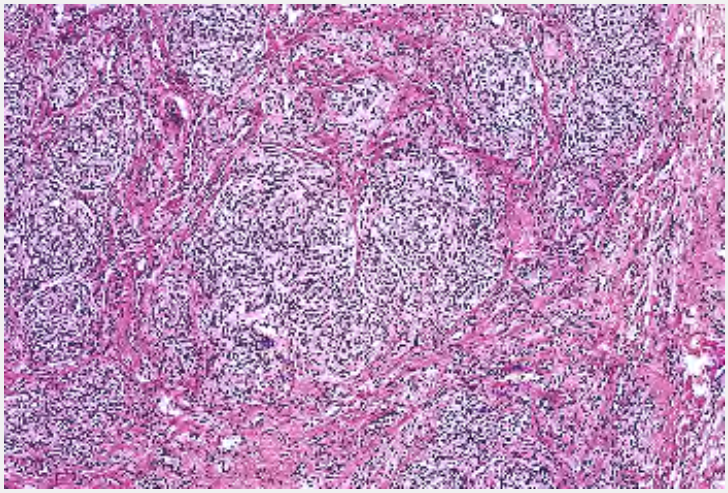

Figure 48.14 Carotid body from a 10-day-old infant, illustrating lobules separated by connective tissue septa.

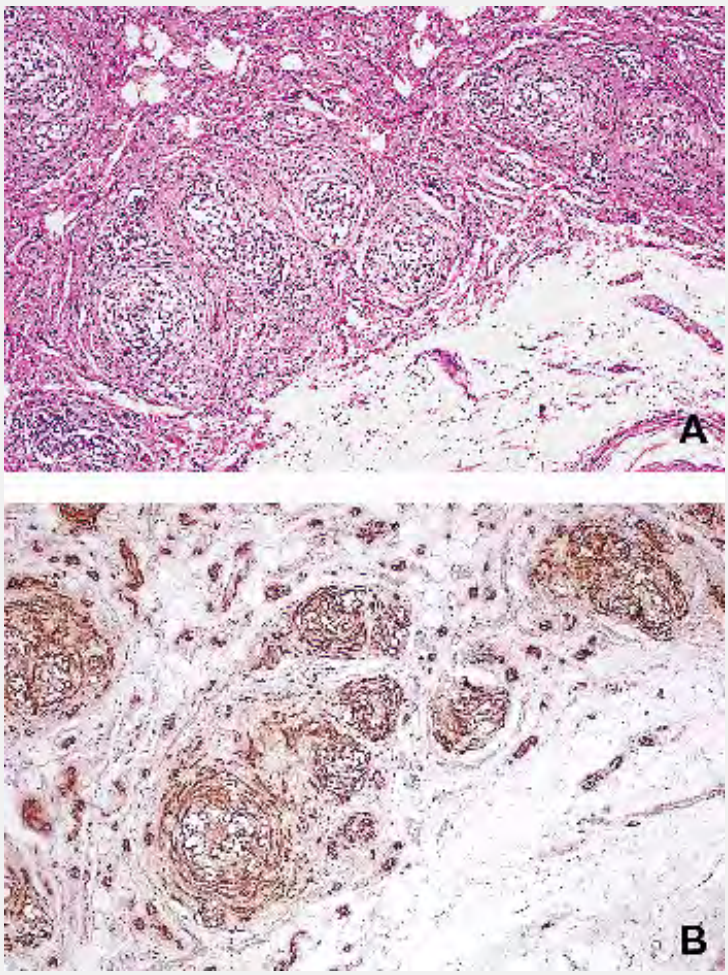

Figure 48.15 A. Carotid body from a 55-year-old woman with hypertension and emphysema. Lobules are separated by greater amounts of connective tissue than in Figure 48.14. In addition, there is a circumlobular proliferation of Schwann cells, demonstrable by staining for S-100 protein (B). The latter change has been reported by some investigators to be characteristic of lobular hyperplasia in patients with hypertension

(56).

The ultrastructural organization of paraganglia and the proportions of their constituent cell types vary in different sites, apparently to suit different physiological needs. Both sympathetic and parasympathetic paraganglia contain numerous small capillaries. In the former, portions of the surfaces of neuroendocrine cells closest to these vessels are usually separated from the capillary endothelium only by basal laminae and occasional collagen fibrils, suggesting that sympathetic paraganglia in most instances function as endocrine glands (61). In some locations, their secretory products appear to be provided for local use (9). In contrast, the neuroendocrine cells in parasympathetic paraganglia tend to be separated from the capillary lumina by sustentacular cells, pericytes, or both (Figures 48.17,48.18,48.19). It therefore appears that a major role of their

secretory products is to act directly on sensory parasympathetic nerve endings rather than to enter circulating blood (62,73,77,78).

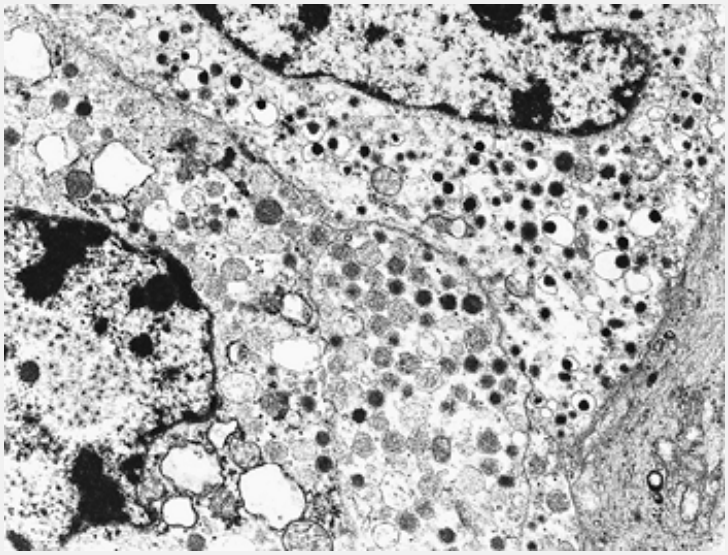

Figure 48.16 Electron micrograph of normal human adrenal

medulla fixed in glutaraldehyde and postfixed in osmium tetroxide. Portions of cells at left contain predominantly light, finely particulate epinephrine-type granules, whereas cells at right contain predominantly dark, homogeneously electron-dense norepinephrine-type granules. The eccentric location of the granule cores within their surrounding membranes is a fixation artefact most commonly observed with granules of the latter type (original magnification Ã—9,677). BÃ¶ck P, Stockinger L, Vyslonzil E. The fine structure of the human carotid body [article in German]. *Z Zellforsch Mikrosk Anat* 1970;105:543â€“568.
)

The relationships between individual neuroendocrine cells and nerve endings in paraganglia can be defined as presynaptic, postsynaptic, or reciprocally synaptic, based on the locations of synaptic membrane densities and vesicle accumulations. In the adrenal medulla the chromaffin cells are postsynaptic, consistent with their principal role of secreting hormones in response to neural stimulation. In contrast, numerous reciprocal synapses involving nerve endings and chief cells of the carotid body are consistent with the carotid body's chemosensory functions.

Despite the above generalizations, there is some overlap in the functional organization of sympathetic and parasympathetic paraganglia. This is especially apparent for SIF cells, at least in rodents, where they have been extensively studied. SIF cells are usually related to blood vessels and nerve endings comparably to other sympathetic paraganglionic cells. In some ganglia, however, they are insulated from the capillary lumina (11,12). Generally, they receive preganglionic sympathetic synapses, but in a few locations some may apparently also provide synapses to sympathetic neurons, suggesting a role as interneurons. Some also may be involved in

reciprocal synapses with their preganglionic axons, suggesting chemoreceptor functions (79). Different SIF cells within a single small cluster can have different synaptic relationships, and a single process from one SIF cell can both synapse on a neuron and be in direct contact with a capillary basal lamina (11).

It is important to note that two morphologically distinct types of SIF cells have been described in rodents, accounting in part for this functional diversity. â€œType I SIF cells,â€• which have ultrastructural features intermediate between neuroendocrine cells and neurons and are possibly interneurons, have not been identified in human ganglia. â€œType II SIF cellsâ€• which are the only identified human SIF cell, resemble chromaffin cells or chief cells in sympathetic paraganglia (2).

This configuration has been described for intravagal paraganglia (53). As in the carotid body (see Figures 48.17 and 48.18), the chief cells are separated from the

lumen of a nearby capillary (original magnification Ã—5,400). C, chief cells; E, endothelial cell; ax, axons. (Courtesy of Professor P. BÃ¶ck.)

Function

Physiological Roles

Paraganglia release secretory products in response to neural or chemical stimuli. Those products may be used for endocrine, paracrine, neurotransmitter, or neuromodulatory functions, depending on their anatomic context. Although their secretory products are similar and there is evidence of some functional overlap, sympathetic and parasympathetic paraganglia generally appear to differ in the major types of stimuli to which they respond. Responses to different types of stimuli also may delineate subsets of paraganglia within the sympathetic and parasympathetic groups.

The adult adrenal medulla responds principally to signals derived from neurons via trans-synaptic stimulation. Various physiological stressors reflexly evoke discharges of splanchnic nerve endings that synapse on chromaffin cells, causing release of secretory granules by Ca^{2+}-mediated exocytosis. This secretory response is accompanied by ancillary effects including activation of protooncogenes (80), activation and induction of enzymes involved in replenishing granule constituents (81), and possibly stimulation of chromaffin cell proliferation (82). Cellular responses to neurally derived signals may be modulated by chemical signals, including corticosteroids and other hormones (81), growth factors (83), and secreted chromogranin fragments (84). Recent studies of the rat adrenal medulla suggest that neurally derived signals may increase the expression of receptors that regulate chromaffin cell function, including the receptor tyrosine kinase RET. The finding that RET expression is not

static may help to resolve the conundrum of how that molecule, which is expressed at very low levels in the adult adrenal, contributes to the development of adrenal medullary hyperplasia and pheochromocytoma in MEN2 syndromes (85).

The sparse innervation of the extra-adrenal sympathetic paraganglia (61) suggests that they respond principally to chemical signals, and one possible signal is hypoxemia. It has been suggested that the organ of Zuckerkandl in rabbits and humans secretes catecholamines in response to hypoxemia during development (86,87). In other species, chemoreceptive functions have also been postulated for certain SIF cells (78,87,88), and for the immature adrenal medulla before the establishment of innervation (90).

Chemoreception is best established as a function of parasympathetic paraganglia. It was first shown in the 1930s that the carotid bodies and aortic paraganglia function as portions of reflex loops involving the central nervous system, whereby low pO_2, low pH, and high pCO_2 stimulate breathing (4). However, it was long debated whether the neuroendocrine cells in the carotid body are the primary receptor elements or whether their function is to modulate chemoreceptor properties intrinsic to the

sensory nerve endings. Electrophysiological studies of the mechanism of chemoreception have shown that the three major chemosensory stimuli depolarize dissociated carotid body chief cells. This leads to influx of calcium through voltage-gated calcium channels and to calcium-dependent release of secretory products to stimulate sensory nerve endings (10,91). Chemoreceptor reflexes have been postulated for other parasympathetic paraganglia on the basis of their similarities to the carotid body (28,92), but the nature and importance of such reflexes in vivo have not been defined. It may be of interest in this regard that patients who have had their carotid bodies removed exhibit impaired ventilatory reflexes (93), and that carotid body hyperplasia occurs in association with life at high altitude (54), chronic obstructive pulmonary disease, restrictive

pulmonary disease, cystic fibrosis, and cyanotic congenital heart disease (52,53,55,56,57,58). In contrast, vagal paraganglia only sometimes increase in number or size (55). A tenfold increase in the prevalence of carotid body paragangliomas is reported at high altitudes (94), but this association has not been made for paragangliomas at other sites.

Secretory Products

Although studies using the chromaffin reaction suggested that catecholamines were produced by sympathetic not parasympathetic paraganglia (4), more sensitive methods now available indicate that they are produced by paraganglia of both classes. Those methods include immunocytochemistry to demonstrate both catecholamines themselves and their biosynthetic enzymes (76,95,96), as well as older fluorescence techniques to demonstrate catecholamine stores (97) (see â€œSpecial Proceduresâ€•). Most of the body's epinephrine production is in the adrenal medulla, where the epinephrine-to-norepinephrine ratio is approximately 4:1 (98). In contrast, over 90% of the catecholamine content of extra-adrenal sympathetic paraganglia is norepinephrine (20). Parasympathetic paraganglia produce almost no epinephrine but may produce significant quantities of dopamine (99). Serotonin has been reported in addition to catecholamines in some human paraganglia (100), but it is not clear in some studies whether the presence of serotonin is due to synthesis or uptake (101).

In addition to producing catecholamines, both sympathetic and parasympathetic paraganglia synthesize regulatory peptides, the most prevalent of which are enkephalins (76,102,103,104,105). Regulatory peptides and amines usually coexist in the same cells and in the same secretory granules (105). The granules also contain granin proteins (103,106,107), adenine nucleotides, peptide-cleaving and amidating enzymes, dopamine beta-hydroxylase, and numerous other constituents of both known and unknown function (108).

Peptide growth factors that might exert autocrine, paracrine, and neurotropic effects also may be present (108,109). Together these granule constituents comprise a â€œsecretory cocktail,â€• the composition of which can be varied in different physiological and pathological states (81,108).

Gender Differences

Significant gender differences in the histology of paraganglia have not been reported. However, there is some evidence for functional differences. For example, women in general appear to have slightly increased susceptibility to carotid body paragangliomas. This difference is accentuated by life at high altitude, where the tumors have a female-to-male ratio of approximately 8:1 (110).

Aging Changes

Aging changes described in human paraganglia are limited to the topographic and involutional changes described in the sections on â€œDistribution of Paraganglia,â€• â€œGross Features and Organ Weights,â€• and â€œLobular Architecture of the Carotid Body.â€• Subtle histochemical changes have been described in the composition of adrenal chromaffin granules of rats (111) and also might occur in other paraganglia. Hypertrophy or hyperplasia of extra-adrenal paraganglia also occurs in aging rats (112).

Special Procedures

Immunohistochemistry

The study of normal and pathologic paraganglia has been greatly facilitated by recent advances in immunohistochemistry. Antibodies that are now commercially available permit identification and functional characterization of specific paraganglionic cell types in sections of formalin-fixed, paraffin-embedded tissue. In addition, the

advent of microwave antigen retrieval (113) has both improved the quality of immunohistochemical staining and eliminated some of the variability previously caused by prolonged fixation. Highly sensitive, polymer-based reporter systems have both increased the sensitivity of immunohistochemical staining and eliminated artefact due to endogenous biotin (114). For most purposes, immunohistochemistry can now replace previously useful but more cumbersome or less specific techniques such as electron microscopy, catecholamine fluorescence, or silver stains.

Paraganglia express a plethora of markers shared to varying degrees with other neural and endocrine tissues. A partial categorization includes amines, regulatory peptides, granins and other constituents of the secretory granule matrix, secretory granule membrane and cell membrane

components, and cytoskeletal proteins. Proteins known as â€œSNAPâ€•s and â€œSNAREâ€•s (SNAP receptors) that are involved in docking of secretory granules at the cell membrane in preparation for exocytosis comprise an important new class of markers. Those proteins include synaptobrevin, synaptotagmin, syntaxin, and SNAP-25 (115).

For pathologists, the major current applications of immunohistochemistry to the paraganglionic system are the diagnosis and functional characterization of paraganglionic tumors. Potential future applications include identification of markers that may be applicable to targeted therapy, such as specific somatostatin receptor subtypes (116), or profiling of tumors for clusters of markers associated with specific tumor syndromes or with malignancy (15) (see â€œClinicopathologic Perspectiveâ€•) (76,103,117).

For diagnostic purposes, care must be taken to select from the large number of available markers those that are the most specific. For example, immunoreactivity for synaptophysin, a secretory vesicle

membrane protein, is characteristically present in paraganglia but also reported in adrenal cortex (118,119). Similarly, certain SNAP and SNARE proteins are present in normal lymphoid cells (120,121). Reagents that have been particularly valuable in histopathology of paraganglia are antibodies against chromogranin A (CgA), catecholamine biosynthetic enzymes, and S-100 protein.

CgA is an acidic protein that constitutes more than half the weight of many types of neuroendocrine secretory granule. It appears to be present in most or all paraganglionic neuroendocrine cells and is therefore a useful generic marker that can, in most instances, serve to establish the neuroendocrine nature of particular cells or tissues in the paraganglionic system (122,123) (Figures 48.20,48.21,48.22,48.23,48.24,48.25,48.26,48.27). Because it is concentrated mostly in secretory granules, it may fail to stain cells that are degranulated due to low rates of synthesis, high rates of turnover, or low storage capacity. In sympathetic ganglia, it can be used to conveniently discriminate SIF cells from principal sympathetic neurons, which produce CgA but have few perikaryal secretory granules (124) (Figures 48.21, 48.22, and 48.24). CgA was the first described member of the granin family of proteins, which now includes seven members (CgA and B, secretogranin II and III, 7B2, NESP55, and VGF) (106,107). These proteins are differentially expressed in neuroendocrine tissues of different species. Although most are present in the adrenal medulla, their distributions in other paraganglia are incompletely mapped (107). Their roles include sorting of proteins to the regulated secretory pathway and directing secretory granule biogenesis. In addition, they serve as multifunctional prohormones, giving rise to cleavage fragments that exert a variety of autocrine, paracrine, and systemic effects.

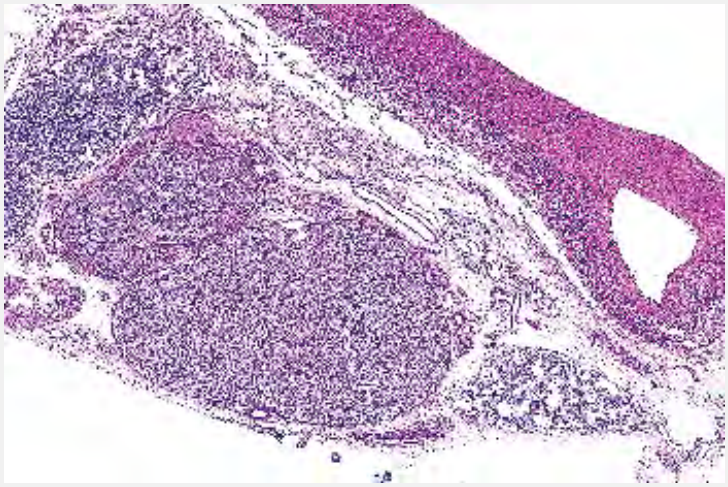

Figure 48.20 Transverse section through the aorta of a mid-trimester human fetus (same fetus as in Figure 48.25) at the level of the inferior mesenteric artery, demonstrating organ of Zuckerkandl and adjacent sympathetic ganglion, related as diagrammed in Figure 48.2.

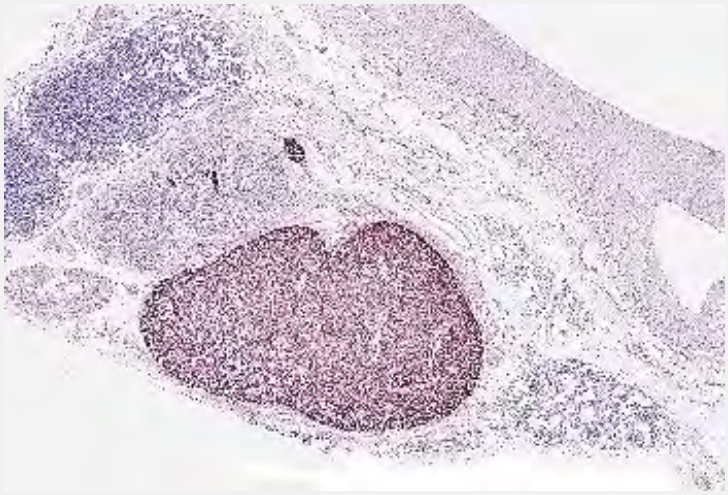

Figure 48.21 Section adjacent to that shown in Figure 48.20, stained for CgA. Staining is intense in the organ of Zuckerkandl

and in small nests of neuroendocrine cells within and adjacent to the ganglion, but not in sympathetic neurons.

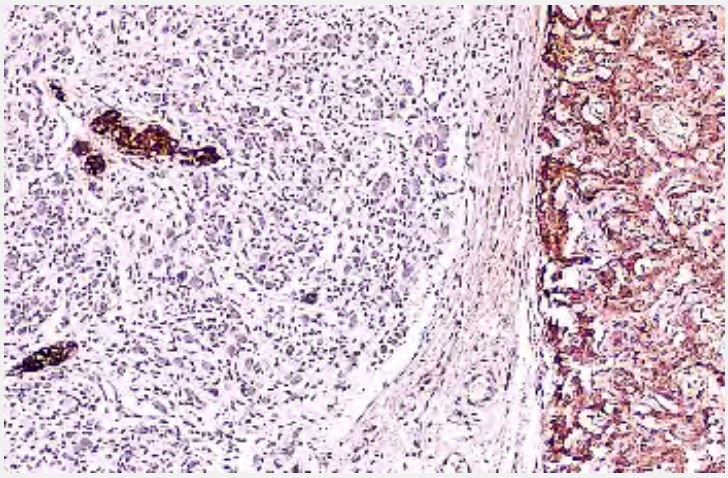

Figure 48.22 Higher magnification of central area of section shown in Figure 48.21. Organ of Zuckerkandl is on right, ganglion on left.

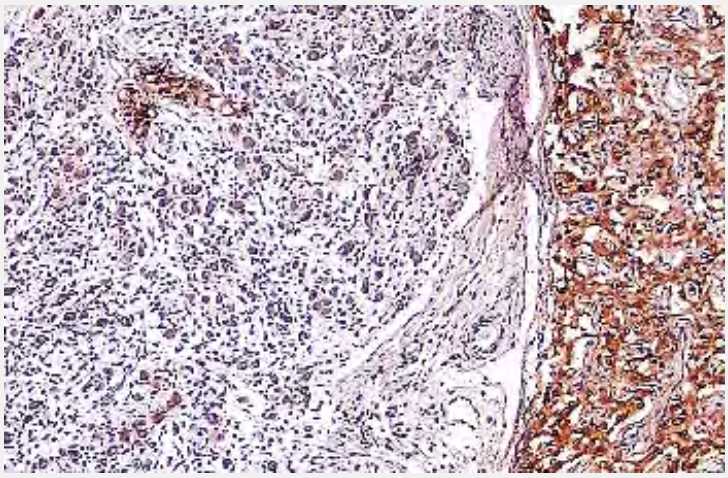

Figure 48.23 Section adjacent to that shown in Figure 48.22, stained for TH. Intense immunoreactivity is present in both sympathetic neurons and paraganglionic neuroendocrine cells.

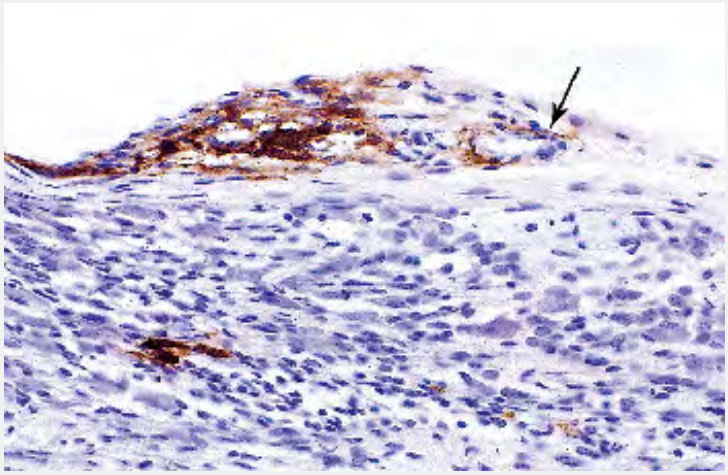

Figure 48.24 Sympathetic ganglion from the paravertebral trunk of a mid-trimester human fetus (same fetus as in Figures 48.20,48.21,48.22,48.23), stained for CgA. Neuroendocrine cells are identified both within and adjacent to the ganglion. CgA-positive processes, which might be derived from either neurons or neuroendocrine cells, surround a small blood vessel (*arrow*).

Figure 48.25 Adrenal gland from a mid-trimester human fetus (same fetus as in Figures 48.20,48.21,48.22,48.23), stained for CgA. The medulla (*bottom*) contains only scattered positive cells, in contrast to the organ of Zuckerkandl (Figure 48.21). Extra-adrenal (*left arrow*) and subcapsular (*right arrow*) paraganglionic cells are also identified by their immunoreactivity.

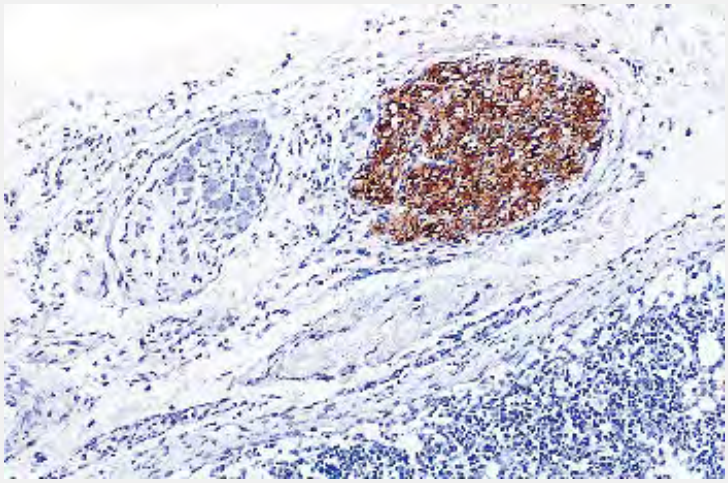

Figure 48.26 A small retroperitoneal paraganglion similar to that in Figure 48.13, incidentally removed along with adjacent ganglion and lymph node from a 5-month-old infant during resection of a Wilms' tumor. Soaking the coverslip off a routine H&Eâ€“stained histologic section and restaining for CgA confirmed the identity of the paraganglion. The stability and abundance of this antigen make it particularly suitable for such procedures.

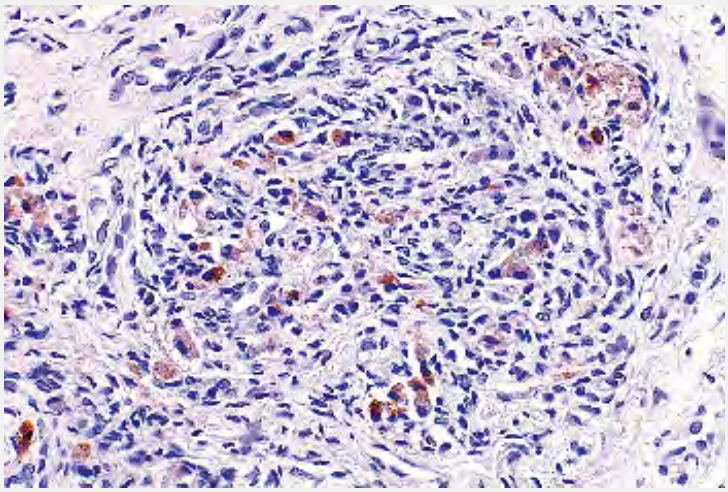

Figure 48.27 Lobule of a carotid body stained for CgA, demonstrating nests of immunoreactive chief cells surrounded by unstained cells of other types.

Perhaps the most important advance in decades from the standpoint of surgical pathology of the paraganglia is the availability of antibodies against the catecholamine-synthesizing enzymes tyrosine hydroxylase (TH), dopamine beta-hydroxylase (DBH), and phenylethanolamine-N-methyltransferase (PNMT). With these reagents, it is now usually possible to infer from a paraffin section not only whether a tumor was catecholamine producing, but also what catecholamines were produced. The need for fluorescence methods that directly detect catecholamine stores but require fresh tissue is therefore, in most instances, eliminated. Tyrosine hydroxylase (TH) is the rate-limiting enzyme in catecholamine synthesis and is therefore found in all catecholamine-producing cells (Figures 48.23 and 48.28), whereas dopamine Î²-hydroxylase (DBH) is found only in cells that produce norepinephrine, and PNMT is found only in cells that can convert norepinephrine to epinephrine. This immunocytochemical approach provides a cellular correlate to biochemical data by demonstrating that only rarely do extra-adrenal paraganglionic cells stain for PNMT (95), in contrast to the adrenal medulla where the great majority of cells are stained (76) (Figures 48.29 and 48.30). It also has been useful in demonstrating catecholamine-synthesizing ability in pheochromocytomas and extra-adrenal paragangliomas (96,125). Because TH and PNMT are cytosolic enzymes (108), staining is not dependent on storage of secretory granules. Sympathetic neurons, for example, stain strongly for TH (Figure 48.23), in contrast to their weak or absent staining for CgA (Figures 48.21, 48.22, 48.24, and 48.26). In contrast to chromogranins, which are present in many types of neuroendocrine cells, catecholamine biosynthetic enzymes in adult humans are

normally present only in paraganglia and neurons (95). In addition to their biosynthetic enzymes, catecholamines themselves may be localized by immunohistochemistry. However, the presence of catecholamines without biosynthetic enzymes under some circumstances (96) suggests that synthesis cannot be distinguished from uptake by this approach.

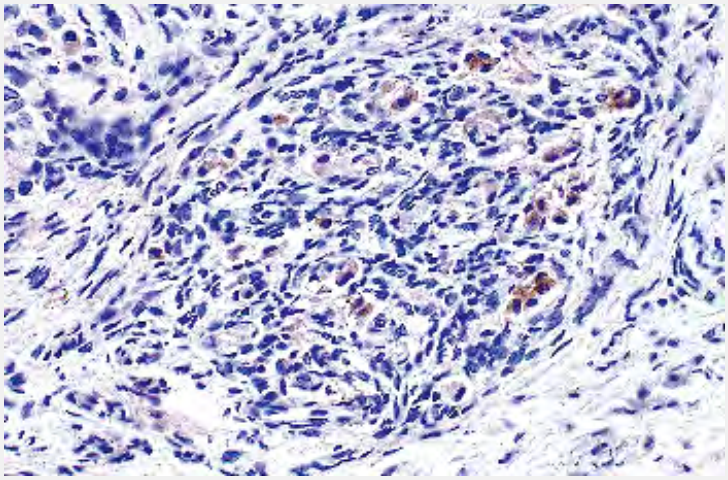

Figure 48.28 Lobule of a carotid body stained for TH. The catecholamine-synthesizing ability of chief cells is inferred by positive staining of chief cell nests, which are surrounded by unstained cells of other types.

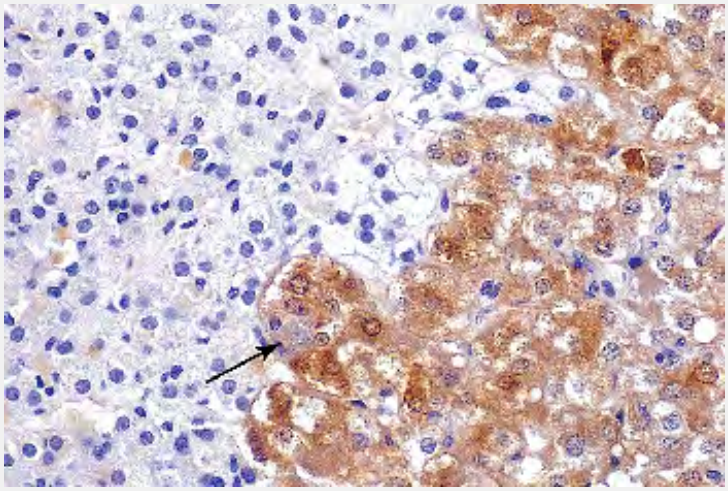

Figure 48.29 Adult adrenal gland stained for PNMT. The ability of almost all neuroendocrine cells in the adrenal medulla to synthesize epinephrine is inferred from their positive staining. Occasional cells are unstained (*arrow*) as previously reported (76) and as suggested by the electron micrograph in Figure 48.16.

S-100 protein was initially described as a calcium-binding dimer consisting of alpha-alpha, alpha-beta, or beta-beta chains and was initially believed to be specific for central and peripheral nervous system glial cells. Subsequent studies showed a wider distribution of immunoreactivity (126). Immunostaining for S-100 nevertheless provides a useful marker in appropriate contexts. Because of their nondescript cytologic characteristics, the sustentacular cells in paraganglia are difficult to identify with certainty in sections stained with hematoxylin and eosin. The intense nuclear

immunoreactivity of these cells for S-100 permits them to be identified in sympathetic and parasympathetic paraganglia (Figures 48.10 and 48.12). Interestingly, they also may be identified in paragangliomas (71,72), a finding that might reflect either ingrowth

from nearby normal tissue or bidirectional differentiation. Sustentacular cells must be distinguished from Langerhans cells and interdigitating reticulum cells of the immune system, which also express S-100. Both sustentacular cells and Schwann cells contain predominantly the beta subunit of S-100 (127). The S-100 protein family has now expanded beyond the original alpha and beta subunits to include at least 17 members postulated to play a variety of roles in different cell types (128).

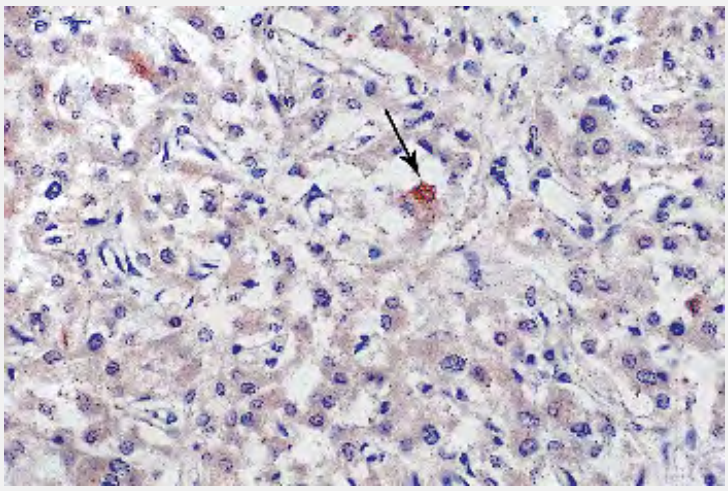

Figure 48.30 Organ of Zuckerkandl (same specimen as in Figures 48.20,48.21,48.22,48.23) stained for PNMT. Although all the neuroendocrine cells stain for TH and can produce catecholamines (Figure 48.23), only rare cells (*arrow*) contain immunoreactive PNMT. This finding is consistent with the limited ability of extra-adrenal paraganglia to synthesize epinephrine, the final step in the catecholamine biosynthetic pathway.

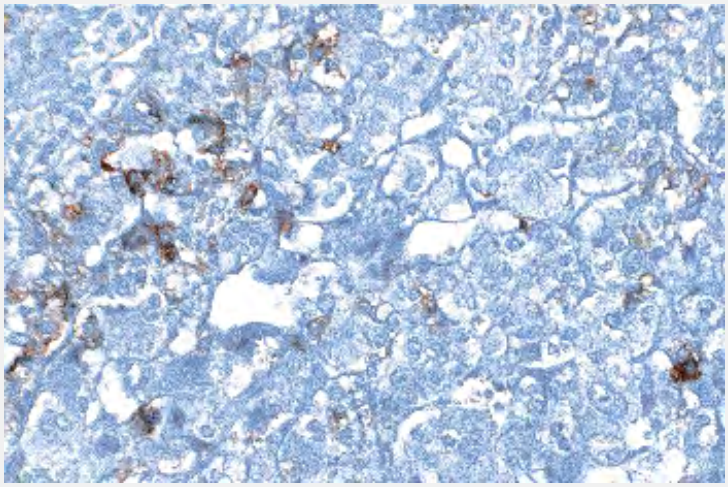

Figure 48.31 Adult adrenal gland stained for somatostatin, illustrating strongly immunoreactive cells scattered among cells with no detectable immunoreactivity. Immunohistochemical staining of paraganglionic neuroendocrine cells for regulatory peptides can suggest functional heterogeneity despite the fact that all of the cells produce catecholamines.

Immunohistochemical studies might help to reveal subtle expressions of functional heterogeneity in normal paraganglia that could contribute to understanding of syndrome-associated phenotypes. Examples might include the absence of epinephrine-synthesizing ability or the expression of particular regulatory peptides in small numbers of human chromaffin cells (76) (Figures 48.29,48.30,48.31). Evidence of differential innervation might also provide clues to differential function (103,117).

Immunohistochemical Artifacts

Important artifacts that must be borne in mind in immunohistochemical studies of paraganglia are the nonspecific interactions of some, but not all, antibodies with the secretory granules of mast cells (129,130) and of certain neuroendocrine cells

(131). These artifacts may be particularly troublesome because, due to their inconstancy, negative controls consisting of irrelevant antibodies or normal sera are not adequate. The mast cell artifact has undoubtedly resulted in erroneous published reports of neuroendocrine secretory products in nonendocrine tissues, and also could produce incorrect results in studies of paraganglia because of their sometimes high mast cell content (67). The mechanism of the mast cell artifact is not known (130), but in some cases the staining may be eliminated by dilution in the presence of normal serum proteins (129). Nonspecific binding of immunoglobulins to neuroendocrine secretory granules appears to result from ionic interactions and may be reduced by high concentrations of salt in the buffer (131). A buffer containing 0.5 mol/L NaCl should not interfere with specific high-affinity antigenâ€“antibody interactions and, in many instances, may be used routinely.

Other artifacts that are not specific to neuroendocrine cells may also be encountered in studies of paraganglia. In immunohistochemical protocols that employ a biotin bridge, such as the widely utilized â€œABCâ€• technique, artefactual staining may result from the presence of endogenous biotin. This problem may be exacerbated by heat-based antigen retrieval, which can unmask endogenous biotin in addition to specific antigens (132). Commercially available biotin blocking kits offer some remedy, but a preferable solution may be to discontinue the use of biotin-based systems and switch to newer methods that employ secondary antibodies conjugated to polymer-bound reporter enzymes (114). Various types of artifactual staining with less clear mechanisms are also sometimes encountered. In the adrenal gland, for example, some antibodies inexplicably produce spurious staining in the adrenal cortex (114). This particularly tends to occur in the inner portion of the cortex, and might therefore result from nonspecific interactions of some antibodies with lipochrome pigments. Cells that are rich in mitochondria occasionally also show weak nonspecific staining. In addition to spurious staining caused by these and other artifacts, the possibility of actual immunological

cross-reactivity of an antibody with different proteins must always be considered.

In general, immunohistochemical studies should be performed with optimally diluted antibodies and verified, when practical, with antibodies from more than one source. Ideally, adsorption controls and immunoblots should also be employed for validation, particularly in research studies or when new markers or antibodies are introduced. Controls consisting solely of primary antibody omission should not be considered adequate even for routine studies. Buffer composition, blocking proteins, and controls are now to some extent becoming standardized in automated staining procedures, but should still be optimized for each new antibody as discussed in many textbooks and reviews (133).

Other Special Procedures

Fluorescence methods for detection of catecholamines or other biogenic amines now have very little use in routine pathology. However, literature searches of PubMed or other databases continue to demonstrate the value of these techniques in occasional research applications.

Catecholamines can be demonstrated in freeze dried or frozen sections or in touch preparations either by formaldehyde vaporâ€“ (97,134) or glyoxylic acidâ€“induced (135) fluorescence. The glyoxylic acid method is usually preferable because it produces nondiffusing fluorophores.

Other research applications of histological techniques include the use of in situ hybridization to detect genetic abnormalities in paragangliomas (136,137,138) or to map the expression of specific mRNAs (139).

Differential Diagnosis

Paraganglia must be discriminated from normal but similar-appearing nonparaganglionic structures and from a variety of malignant tumors. The ampulloglomerular organ (140), glomus coccygeum, and glomera cutanea are thermoregulatory structures respectively located in the suboccipital and coccygeal regions and in the skin, resembling but unrelated to paraganglia. Lobules of fetal fat may at times appear reminiscent of paraganglia. All of these structures can be readily distinguished from paraganglia by their absence of staining for CgA, TH, or other neuroendocrine markers. Reports of paraganglia in anomalous locations (4) are also now amenable to immunohistochemical verification. Prostatic paraganglia may be misinterpreted as prostatic adenocarcinoma (141), bladder paraganglia may be confused with transitional cell carcinoma (142), and retroperitoneal paraganglia may be confused with metastatic clear cell carcinoma (143). The presence of mitoses, cytologic atypia, glandular or squamous differentiation, or stromal reaction point toward a diagnosis of tumor, and questionable cases can be readily resolved by immunohistochemistry.

More problematic are cases in which paraganglia or paragangliomas must be distinguished from other normal or neoplastic neuroendocrine tissues that express many of the same markers. Knowledge of the distribution and morphology of paraganglia is essential in these cases. In addition, the presence of tyrosine hydroxylase in paragangliomas or of other site-suggestive markers in other types of tumors, for example calcitonin in medullary thyroid carcinoma, may be helpful. Tumors showing glandular or squamous differentiation are almost certainly not paraganglionic.

In the adrenal gland, developmental neuroblastic nests (see â€œEmbryologic Changesâ€•) must be distinguished from in situ neuroblastoma (42,43). Cortical invasion, mitoses, and necrosis are all characteristic of normal cells in this instance. Ikeda et al. (40) reported that the nuclei of normal adrenal medullary progenitors are smaller on average than those of neuroblastoma cells, and this might prove to be diagnostically useful. In view of the large potential effect

of fixation on nuclear size, however, the problem is more likely to be resolved using molecular techniques (144).

Specimen Handling

For most purposes, normal and pathologic paraganglionic tissue may be evaluated histologically and immunohistochemically after routine formalin fixation and paraffin embedding (see â€œSpecial Proceduresâ€•). In the age of heat-based antigen retrieval, under-fixation may create as many artefacts as the traditional problem of over-fixation. However, some antigens are still irretrievably damaged by excessive fixation. Fixation of thin tissue slices overnight is usually adequate. Electron microscopy, when necessary, is optimally performed after glutaraldehyde fixation and osmium postfixation (see â€œUltrastructureâ€•). Catecholamines may be demonstrated in touch preparations or frozen sections using glyoxylic acidâ€“induced fluorescence (see â€œSpecial Proceduresâ€•).

For biochemical analysis, catecholamines may be preserved by freezing small minced tissue fragments or tissue homogenates at â€“70Â°C in 0.4 mol/L perchloric acid in 1 mmol/L ethylene diamine tetra-acetic acid (145). Peptide hormones may be preserved by freezing in 1.0 mol/L acetic acid.

With burgeoning interest in molecular studies of paraganglia, it is increasingly necessary to preserve DNA, RNA, and protein samples. Tissue handling is particularly critical for RNA and protein preservation, and the traditional approach is rapid freezing and storage in liquid nitrogen. However, a number of solutions that are now commercially available provide comparable or superior preservation of both nucleic acids and protein for at least several weeks at room temperature for convenient handling and shipping. This approach may facilitate standardization of noncentralized specimen collection (146,147).

Acknowledgments

I thank Drs. Peter BÃ¶ck, Ernest Lack, and James Powers for contributing illustrative material and Dr. Harold Kozakewich for contributing tissue blocks.
